
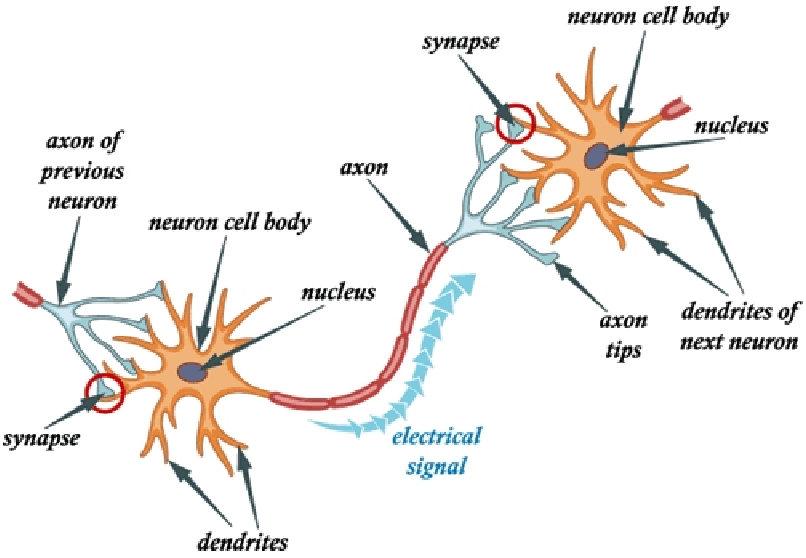

Figure 14.184: Simplified representation of the vocabulary of human neurons

The dendrites form a network of nerve receptors that are used to route to the body of the neuron the electrical signals from other neurons. It acts as like an integrator, accumulating electric charges. When the neuron becomes sufficiently excited (when the accumulated charge exceeds a certain threshold), by an electrochemical process, it generates an electric potential that spreads through its axon to eventually excite other neurons. The point of contact between the axon of one neuron and the dendrite of another neuron is named the "synapse". It seems that this is the spatial arrangement of neurons and their axons and also their quantity ($86,000,000,000$ neurons and $1.5\cdot 10^{14}$ synapses for the average human brain), and the quality of individual synaptic connections that determine the precise function of a biological neural network. This is based on this knowledge that the mathematical model described above has been defined (this is "Biomimicry Engineering" or "Biomimestim Engineering"). The detailed circuitry of neural pathways within it is known as a "connectome".

A weight of an artificial neuron represents somehow the effectiveness of a synaptic connection. A negative weight inhibits in way the entrance, while a positive weight increase its effect. It is important to remember that this is a rough approximation of a real synapse resulting in fact of a quite complex chemical process and dependent on many external factors still unclear. We must understand that our artificial neuron is a pragmatic model which, as we shall see later, will help us to accomplish interesting tasks and more neurons we have more the tasks can be complex. The biological plausibility of this model is not important to us. What counts is the result that this model will allow us to achieve.

Another limiting factor in the model we set ourselves is regarding its discreet nature. Indeed, in order to simulate a neural network, we will make the time discrete in our equations. In other words, we assume that all neurons are synchronous, that is to say that at each time t, they will simultaneously calculate the weighted sum and produce an output $a(t)=f(n(t))$. In biological networks, all neurons are actually asynchronous...

So let us come back to our model as formulated by the previous relation and by doing a change of notation $\vec{w}^T$:

$$\boxed{a=f(n)=f\left(\vec{w}^T\vec{p}-b\right)} \tag{14.1.2056}$$

This equation leads us to introduce a new more formal scheme of our neural network (FNW) or perceptron:

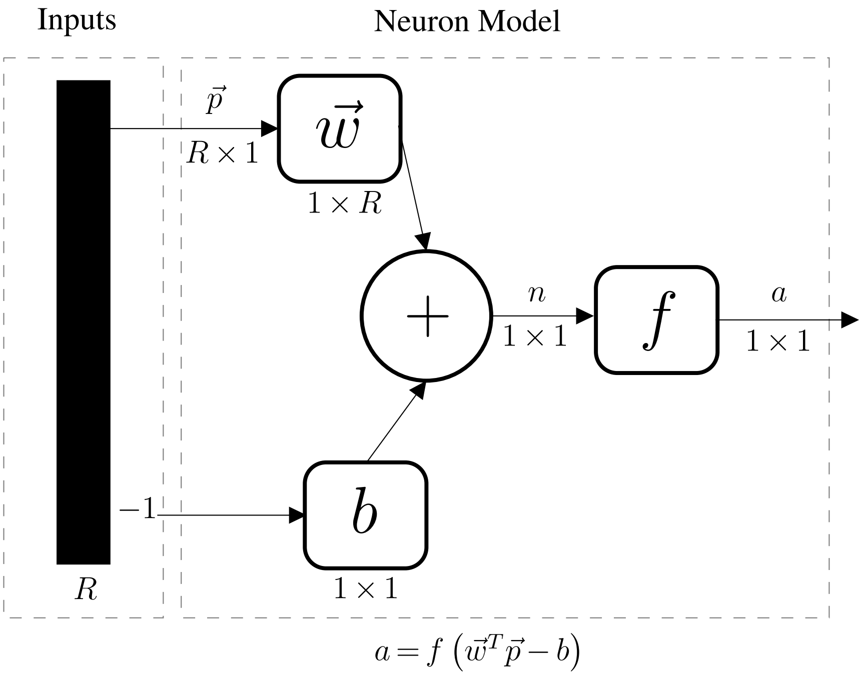

Figure 14.185: **Vector written example of one-layer formal neuron with the input vector and scalar output**

We represent the R inputs as a black rectangle (the number of entries is indicated below the rectangle). From this rectangle result a vector $\vec{p}$ whose dimensions are $R\times 1$. This vector is multiplied by a vector $\vec{w}$ that contains the weights (synaptic) neuron. In the case of a single neuron, this vector has dimension $1\times R$. The result of the multiplication is the "activation level" (scalar) which is then compared to the threshold b (a scalar) by subtraction. Finally, the output of the neuron is calculated by the function f. The output of a single neuron is then always a scalar in this special case.

To find the components of the matrix $\vec{w}$ (neuron input weight), and the bias b we use operational research techniques (simplex method, conjugate gradient method, evolutionary algorithms, etc.) on a sample of data sample of the company of size n in order to "train the model of the neuron". The purpose will then be to find weights $\vec{w}$ that minimize the quadratic cost error function given by:

$$\boxed{\min_{\vec{w},b} \sum_{k=1}^{n}(a_k - y_k)^2} \tag{14.1.2057}$$

where a_k is the model output for the vector $\vec{r}_k$ and y_k is the real value (the expected answer) corresponding to the $\vec{r}_k$.

After we check the results on a sample test before putting the neural network in production for not yet existing data (we will do a detailed example with Microsoft® Excel® just after the presentations of the transfer functions).

14.1.20.8.2 Transfer functions

So far, we have not specified the nature of the activation function $a=f(n)$ of our model. It turns out that several possibilities exist and these are empirical and must adapt to different situations (and the adaptation is sometimes also dynamic). The most common and most cited in the literature are listed in the figure below:

Activation function name f	**Input/Output relation**	**Profile plot**
Threshold	$a=0$ if $n<0$ $a=1$ if $n\geq 0$	Symmetric threshold	$a=-1$ if $n<0$ $a=1$ if $n\geq 0$	Linear	$a=n$	Saturated linear	$a=0$ if $n<0$ $a=n$ if $0\geq n\geq 1$ $a=1$ if $n>1$	Symmetric saturated linear	$a=-1$ if $n<-1$ $a=n$ if $-1\geq n\geq 1$ $a=1$ if $n>1$	Rectified Linear Unit Function (RELU)	$a=0$ if $n<0$ $a=n$ if $n\geq 0$	Sigmoid	$a=\dfrac{1}{1+e^{-n}}$	Hyperbolic tangent (TANH)	$a=\dfrac{e^{n}-e^{-n}}{e^{n}+e^{-n}}$	Competitive	$a=1$ if n is maximum $a=0$ otherwise	**C**
Gompertz	$a=\alpha e^{-\beta e^{\gamma n}}$	...	...	...

Table 14.32: **Types of transfer functions for FNN**

The three most used in the field of engineering are the functions "threshold" (I) , "linear" (II) and "sigmoid" (III) as shown in details below:

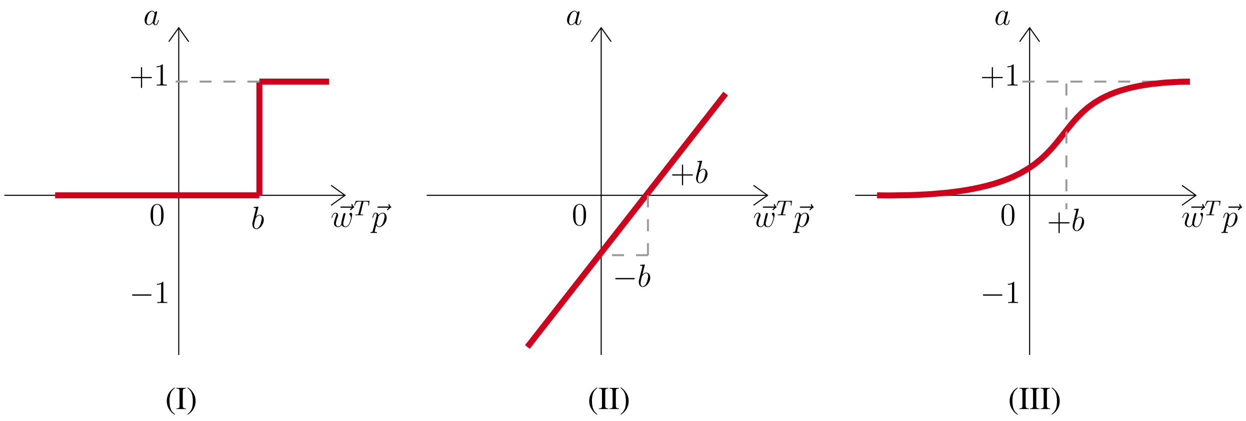

Figure 14.186: **Most used transfer functions for neural networks in the 120th century**

As its name suggests it, the threshold function applies a threshold on its input. Specifically, a negative input does not pass the threshold, the function returns then a 0 (false), while a positive or zero input exceeds the threshold, and the function returns then a 1 (true). It is obvious that this kind of feature is to make binary decisions (this function can also be assimilated to the Heaviside function for those who know it...).

The linear function is itself very simple, it directly associate its input to an output according to the relation $a=f(n)=n$. It is then evident that the output of the neuron corresponds to its activation level for which the zero value (the ordinate at the origin) occurs when $\vec{w}^T\vec{p}=b$.

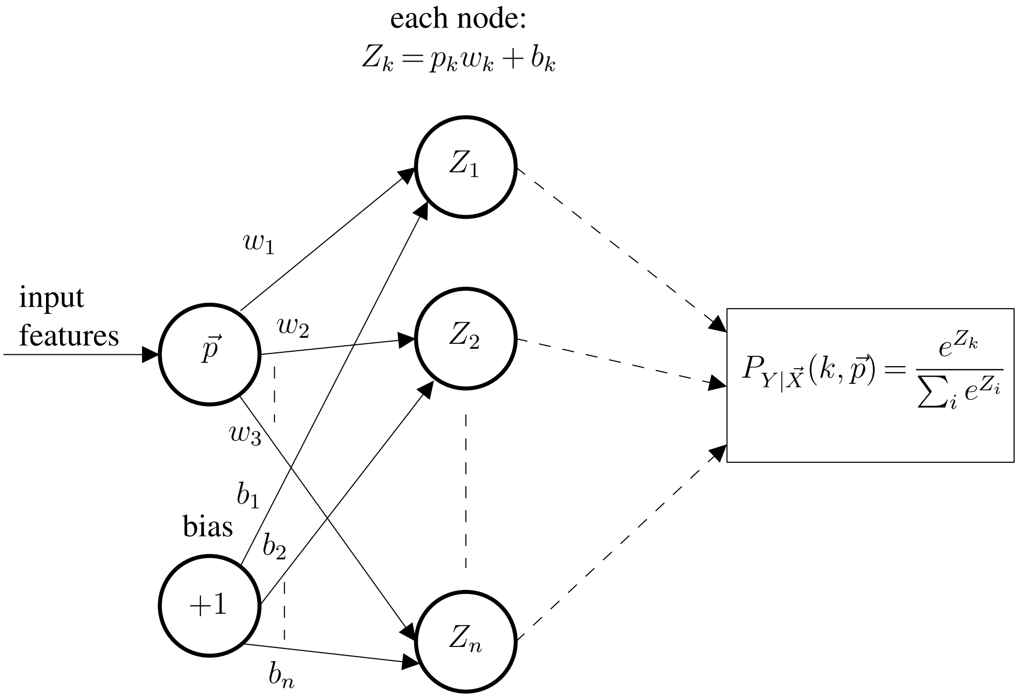
The sigmoid transfer function is itself defined by the mathematical relation:

$$a=\frac{1}{1+e^{-n}} \tag{14.1.2058}$$

It looks like two threshold function, either the linear function, as we are far or near to b respectively. The threshold function is very non-linear because there is a discontinuity when $\vec{w}^T\vec{p}=b$. For its part, the linear function is entirely linear. It has no change in slope. The sigmoid is an interesting compromise between the two. Finally notice that the hyperbolic tangent (TANH) function is a symmetric version of the sigmoid.

It may be quite obvious to the reader that if the activation function is linear, then the neural network is a regression model! If it is a logistic function, then the neural network is a binary classification model!

We have introduced during our study of logistics regressions the softmax function (see above page 6479). The softmax function is a typical activation function for a multi-class neural network classifier. That is a neural network with multiple input but also multiple outputs. If we denote the weights $\vec{v}$ and we index each different output by the letter j, the such a neural network will be represented by:



each node:
$Z_k = p_k w_k + b_k$
input features
$\vec{p}$
w_1
w_2
w_3
bias
$+1$
b_1
b_2
b_n
Z_1
Z_2
Z_n
$P_{Y|\vec{X}}(k,\vec{p}) = \frac{e^{Z_k}}{\sum_i e^{Z_i}}$

Figure 14.187: Multi-class softmax neural network

14.1.20.8.3 Various cost functions

Relatively to Neural Networks, as we already know, a cost function is a measure of how good a neural network did with respect to it's given training sample and the expected output. It also may depend on variables such as weights and biases.

Remember also that a cost function is a single value (scalar), not a vector, because it rates how good the neural network did as a whole.

Specifically, a cost function is of the form:

$$J(W,\vec{b},\vec{y},\vec{\phi}) \tag{14.1.2059}$$

where W is our neural network's weights, $\vec{b}$ is our neural network's biases, $\vec{x}$ is the input of a single training sample, $\vec{y}$ is the desired output (i.e. expected output) of that training sample and ϕ_i is the activation function.

Here are some common empirical cost functions:

- The "Quadratic cost" also known as mean squared error, maximum likelihood, and sum squared error, is defined as:

  $$J_{\text{MST}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\frac{1}{2}\sum_{i=1}^{n}\left(\phi_i(z)-y_i\right)^2 \tag{14.1.2060}$$

  The gradient of this cost function with respect to the output of a neural network is:

  $$\nabla_{\phi}J_{\text{MST}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum_{i=1}^{n}\left(\phi_i(z)-y_i\right) \tag{14.1.2061}$$

- The "Cross-entropy cost" also known as "Bernoulli negative log-likelihood" and "Binary Cross-Entropy", is defined as:

  $$J_{\text{CE}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=-\sum_{i=1}^{n}\left[y_i\ln(\phi(z))+(1-y_i)\ln(1-y_i)\right] \tag{14.1.2062}$$

  The gradient of this cost function with respect to the output of a neural network is:

  $$\nabla_{\phi}J_{\text{CE}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum_{i=1}^{n}\frac{\phi_i(z)-y_i}{(1-\phi_i(z))\phi_i(z)} \tag{14.1.2063}$$

- The "Exponential cost" requires choosing some parameter τ that you think will give you the behaviour you want, typically you'll just need to play with this until things work good, and is it is defined by:

  $$J_{\exp}\left(W,\vec{b},\vec{y},\vec{\phi},\tau\right)=\tau\exp\left(\frac{1}{\tau}\sum_{i=1}^{n}\left(\phi_i(z)-y_i\right)^2\right) \tag{14.1.2064}$$

  The gradient of this cost function with respect to the output of a neural network is:

  $$\nabla_{\phi}J_{\exp}\left(W,\vec{b},\vec{y},\vec{\phi},\tau\right)=\frac{2}{\tau}J_{\exp}\left(W,\vec{b},\vec{y},\vec{\phi},\tau\right)\sum_{i=1}^{n}\phi_i(z)-y_i \tag{14.1.2065}$$

- The "Hellinger distance" is defined as:

$$J_{\text{HD}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\frac{1}{\sqrt{2}}\sum_{i=1}^{n}\left(\sqrt{\phi_i(z)}-\sqrt{y_i}\right)^2 \tag{14.1.2066}$$

  This needs to have positive values, and ideally values between 0 and 1. The same is true for the following divergences.

  The gradient of this cost function with respect to the output of a neural network is:

$$\nabla_{\phi}J_{\text{exp}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\frac{1}{\sqrt{2}}\sum_{i=1}^{n}\frac{\sqrt{\phi_i(z)}-\sqrt{y_i}}{\sqrt{\phi_i(z)}} \tag{14.1.2067}$$

- The "Kullback–Leibler cost" is defined as (see section Statistical Mechanics page 3542):

$$J_{\text{KL}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum_{i=1}^{n}y_i\log\left(\frac{y_i}{\phi_i(z)}\right) \tag{14.1.2068}$$

  The gradient of this cost function with respect to the output of a neural network is:

$$\nabla_{\phi}J_{\text{KL}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=-\sum_{i=1}^{n}\frac{y_i}{\phi_i(z)} \tag{14.1.2069}$$

- The "Generalized Kullback–Leibler cost", a special case of the "Bregman divergence[71]", is defined as:

$$J_{\text{GKL}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum_{i=1}^{n}y_i\log\left(\frac{y_i}{\phi_i(z)}\right)-\sum_{i=1}^{n}y_i+\sum_{i=1}^{n}\phi_i(z) \tag{14.1.2070}$$

  The gradient of this cost function with respect to the output of a neural network is:

$$\nabla_{\phi}J_{\text{GKL}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum_{i=1}^{n}\frac{\phi_i(z)-y_i}{\phi_i(z)} \tag{14.1.2071}$$

- The "Itakura–Saito distance", also a special case of the Bregman divergence, is defined as:

$$J_{\text{IS}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum_{i=1}^{n}\left(\frac{y_i}{\phi_i(z)}-\log\left(\frac{y_i}{\phi_i(z)}\right)-1\right) \tag{14.1.2072}$$

  The gradient of this cost function with respect to the output of a neural network is:

$$\nabla_{\phi}J_{\text{IS}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum_{i=1}^{n}\frac{\phi_i(z)-y_i}{\phi_i^2(z)} \tag{14.1.2073}$$

- And very likely many others...

---

[71] It seems that in machine learning, Bregman divergences are used to calculate the bi-tempered logistic loss, performing better than the softmax function with noisy datasets

To summarize:

Cost function name	**Mathematical expression**	**Gradient**
Quadratic cost	$J_{\text{MST}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\dfrac{1}{2}\sum\limits_{i=1}^{n}(\phi_i(z)-y_i)^2$	$\nabla_{\phi}J_{\text{MST}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum\limits_{i=1}^{n}(\phi_i(z)-y_i)$
Cross-entropy cost	$J_{\text{CE}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=-\sum\limits_{i=1}^{n}\left[y_i\ln(\phi(z))+(1-y_i)\ln(1-y_i)\right]$	$\nabla_{\phi}J_{\text{CE}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum\limits_{i=1}^{n}\dfrac{\phi_i(z)-y_i}{(1-\phi_i(z))\phi_i(z)}$
Exponential cost	$J_{\exp}\left(W,\vec{b},\vec{y},\vec{\phi},\tau\right)=\tau\exp\left(\dfrac{1}{\tau}\sum\limits_{i=1}^{n}(\phi_i(z)-y_i)^2\right)$	$\nabla_{\phi}J_{\exp}\left(W,\vec{b},\vec{y},\vec{\phi},\tau\right)=\dfrac{2}{\tau}J_{\exp}\left(W,\vec{b},\vec{y},\vec{\phi},\tau\right)\sum\limits_{i=1}^{n}\phi_i(z)-y_i$
Hellinger distance	$J_{\text{HD}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\dfrac{1}{\sqrt{2}}\sum\limits_{i=1}^{n}\left(\sqrt{\phi_i(z)}-\sqrt{y_i}\right)^2$	$\nabla_{\phi}J_{\exp}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\dfrac{1}{\sqrt{2}}\sum\limits_{i=1}^{n}\dfrac{\sqrt{\phi_i(z)}-\sqrt{y_i}}{\sqrt{\phi_i(z)}}$
Kullback-Leibler (KL) cost	$J_{\text{KL}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum\limits_{i=1}^{n}y_i\log\left(\dfrac{y_i}{\phi_i(z)}\right)$	$\nabla_{\phi}J_{\text{GKL}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum\limits_{i=1}^{n}\dfrac{\phi_i(z)-y_i}{\phi_i(z)}$
Generalized KL cost	$J_{\text{GKL}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum\limits_{i=1}^{n}y_i\log\left(\dfrac{y_i}{\phi_i(z)}\right)-\sum\limits_{i=1}^{n}y_i+\sum\limits_{i=1}^{n}\phi_i(z)$	$\nabla_{\phi}J_{\text{GKL}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum\limits_{i=1}^{n}\dfrac{\phi_i(z)-y_i}{\phi_i(z)}$
Itakura-Saito distance cost	$J_{\text{IS}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum\limits_{i=1}^{n}\left(\dfrac{y_i}{\phi_i(z)}-\log\left(\dfrac{y_i}{\phi_i(z)}\right)-1\right)$	$\nabla_{\phi}J_{\text{IS}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum\limits_{i=1}^{n}\dfrac{\phi_i(z)-y_i}{\phi_i^2(z)}$
...	...	...

14.1.20.8.4 Network Architecture

By definition, a "neural network" (we will see the formal mathematical definition further below at page 6977) is a network of several neurons, usually organized in layers. To build one layer of neurons S, we simply need to assemble them as in the figure below (R inputs with S hidden neurons and S outputs):

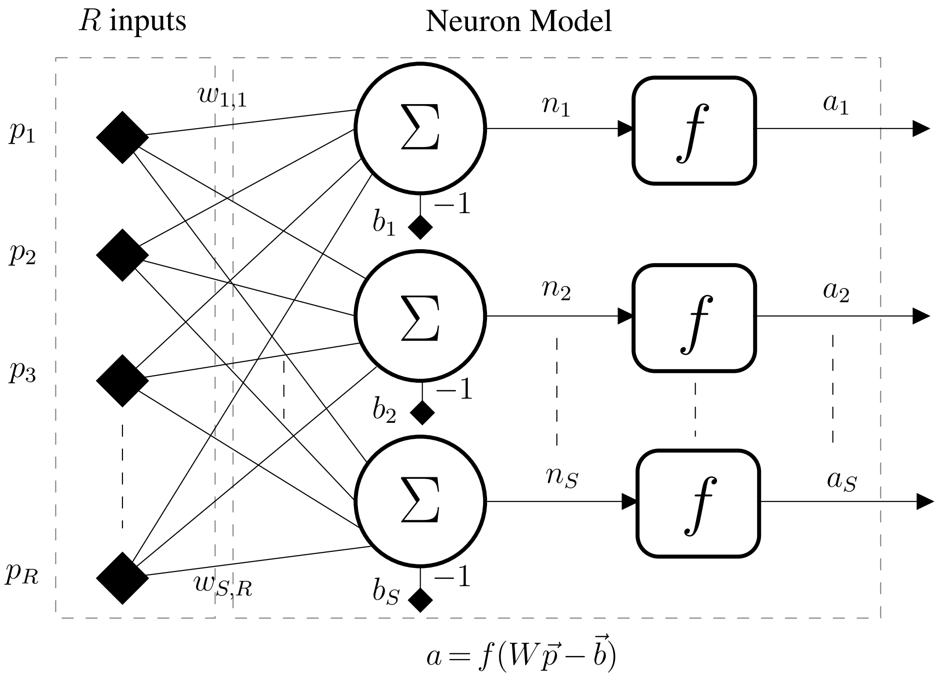


Figure 14.188: Example of one-layer formal neural network with the input vector and output vector

The S neurons of a same layer are all connected to the R inputs in the figure above. We then say that the layer is "fully connected". But this is a special case and not a generality. Often the inputs of a neuron are different from those of another neuron, etc.

Remark

If a neural network that has for purpose to learn that can learn a probability distribution over its set of inputs has only one hidden layer of S neurons not interconnected between them (as is the case in the figure above), that is to say independent, we speak then of "restricted Boltzmann machine RBM ".

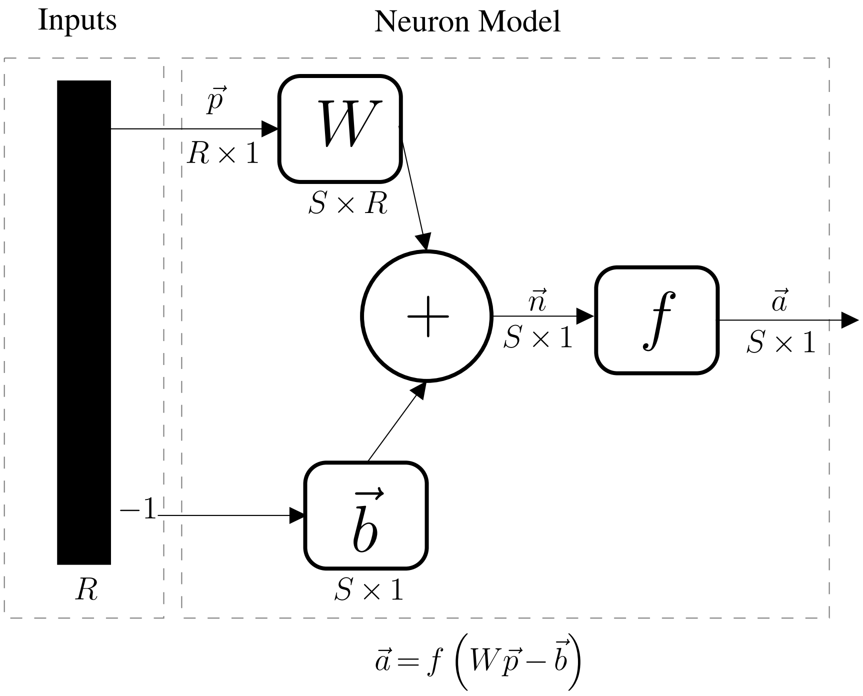
A weight $w_{i,j}$ is associated with each connection. We will always denote the first index by i and the second by j. The first index (row) always means the neuron number on the layer, while the second index (column) specifies the number of the input. Thus, $w_{i,j}$ denotes the weight of the connection that connects the neuron i to its input j. All the weights of a neuron lays thus forms a matrix W of dimension $S \times R$:

$$W=\begin{bmatrix} w_{1,1} & w_{1,2} & \ldots & w_{1,R} \\ w_{2,1} & w_{2,2} & \ldots & w_{1,R} \\ \vdots & \vdots & \ddots & \vdots \\ w_{S,1} & w_{S,2} & \ldots & w_{S,R} \end{bmatrix} \tag{14.1.2074}$$

We must of course take into account that dimensionally we have not necessarily $S=R$ in the general case (the numbers of neurons and inputs are independent). If we consider that the S neurons form a vector, then we can create the vectors:

$$\vec{b}=\begin{pmatrix}b_1\\b_2\\\vdots\\b_S\end{pmatrix}\qquad\vec{n}=\begin{pmatrix}n_1\\n_2\\\vdots\\n_S\end{pmatrix}\qquad\vec{a}=\begin{pmatrix}a_1\\a_2\\\vdots\\a_S\end{pmatrix}\tag{14.1.2075}$$

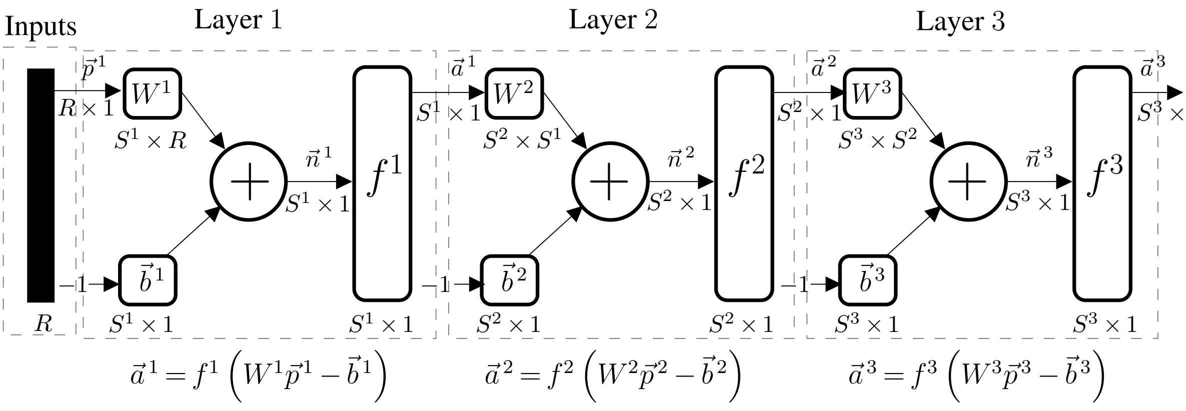
This brings us to the simplified representation illustrated below:



Inputs
Neuron Model
$\vec{p}$
$R\times 1$
W
$S\times R$
$+$
$\vec{n}$
$S\times 1$
f
$\vec{a}$
$S\times 1$
-1
$\vec{b}$
$S\times 1$
R
$\vec{a}=f\left(W\vec{p}-\vec{b}\right)$

Figure 14.189: Vector written example of one-layer formal neural network with the input vector and output vector

Finally, to build a neural network (or MLP for "Multi-Layer Perceptron"), it is just sufficient to combine layers as below:



Inputs
Layer 1
Layer 2
Layer 3
$\vec{p}^1$
$R\times 1$
W^1
$S^1\times R$
$\vec{n}^1$
$S^1\times 1$
f^1
-1
$\vec{b}^1$
$S^1\times 1$
R
$S^1\times 1$
$\vec{a}^1$
$S^1\times 1$
W^2
$S^2\times S^1$
$\vec{n}^2$
$S^2\times 1$
f^2
-1
$\vec{b}^2$
$S^2\times 1$
$S^2\times 1$
$\vec{a}^2$
$S^2\times 1$
W^3
$S^3\times S^2$
$\vec{n}^3$
$S^3\times 1$
f^3
-1
$\vec{b}^3$
$S^3\times 1$
$S^3\times 1$
$\vec{a}^3$
$S^3\times 1$
$\vec{a}^1=f^1\left(W^1\vec{p}^1-\vec{b}^1\right)$
$\vec{a}^2=f^2\left(W^2\vec{p}^2-\vec{b}^2\right)$
$\vec{a}^3=f^3\left(W^3\vec{p}^3-\vec{b}^3\right)$

Figure 14.190: Principle of construction of a Multi-Layer Perceptron

This example includes R inputs and three layers of neurons having respectively S^1, S^2, S^3 neurons. In the general case, again these numbers are not necessarily equal. Each layer also has its own weight matrix W^k, where k is the layer index. In the context of vectors and matrices relatively to one a layer, we always will use an exponent to describe this index. Thus, the vectors $\vec{b}^k$, $\vec{n}^k$, $\vec{a}^k$ are also associated with the layer A.

Remark

Multilayer perceptrons are also named "vanilla feed-forward neural networks[a]". A perceptron is always feedforward, that is, all the arrows are going in the direction of the output. Neural networks in general might have loops, and if so, are often named "recurrent neural networks" (RNN). A superposition of at least three MLP is what seems to be usually named a "deep beliefs net" (DLN).

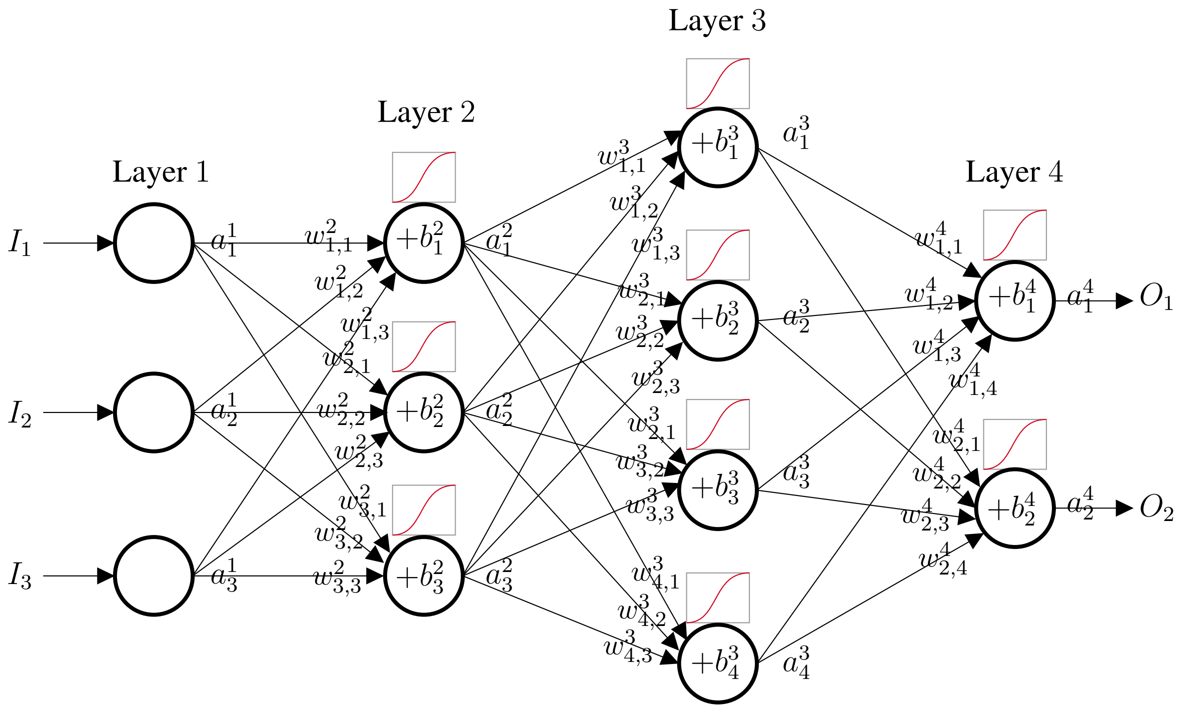
---

[a] "vanilla"= the basic version.

It should be noticed in this example that the layers that follows the first has as input the output of the previous layer. So we can put on as many layers as we want, at least in theory. We can set any number of neurons of each layer. In practice, we will see later however it is not desirable to use too many neurons. Note also that nothing prevents us from changing transfer function from one layer to another. Thus, in the general case we have not necessarily $f^1 = f^2 = f^3$.

The first last layer is obviously named "input layer", and the last layer the "output layer". The layers between the output and input layers are commonly named "hidden layers".

Not all textbooks and softwares count the number of layers in the same way. Here is a typical example where the first layer doesn't have any activation function, but is however counted as one layer (and the notation also differs slightly):



Layer 1
Layer 2
Layer 3
Layer 4
I_1
I_2
I_3
a_1^1
a_2^1
a_3^1

Figure 14.191: **Explicit construction of a Multi-layer Perceptron**

Then we can relate the next layer's input to it's previous via the following relation:

$$a_j^i = f\left(\sum_k (w_{jk}^i \cdot a_k^{i-1}) + b_j^i\right) \tag{14.1.2076}$$

where:

- f is the activation function
- w_{jk}^i is the weight from the k-th neuron in the $(i-1)$-th layer to the j-th neuron in the i-th layer
- b_j^i is the bias of the j-th neuron in the i-th layer
- a_j^i represents the activation value of the j-th neuron in the i-th layer

Remark

Multilayer neural networks are more powerful than simple single layer neural networks of course. Using two layers, provided you use a sigmoid activation function on the hidden layer we can "train" a network to produce an approximation of most functions with arbitrary precision. Except in rare cases, artificial neural networks use two or three layers.

"Train" a neural network means changing the value of its weight matrices and its so that it realizes the desired input/output function (I / O). We will study in detail various algorithms and methods of heuristics approach to achieve it in different contexts.

Figure 14.192: **Neural Information Processing (source: Purdue University image/e-Lab)**

Remark

In the early 121st century (holocene calendar) there seems to no exist any standard nor accepted method for selecting the number of layers, and the number of nodes in each layer, in a feed-forward neural network. It's more trial and error.

Let us now see an easy companion example (originally developed by Joe Breedlove) as always in this textbook first done with a spreadsheet software like Microsoft® Excel®. Afterwards we will show the same output result with R and MATLAB® for which you can find the detailed procedure in the corresponding companion books.

✍**Example:**

A company has measured during 14 weeks its actual sales (Column: *Value to predict*) in function of forecast sales of five of its branches (*Variable1*, *Variable2*, etc.) and has reproduced them in Microsoft® Excel® 14.0.6123:

	A	B	C	D	E	F	G	H
20			Value to predict	Variable1	Variable2	Variable3	Variable4	Variable5
21	Week		y^k	x^1	x^2	x^3	x^4	x^5
22	1997-01-03		32.50	9.25	42.50	52.38	34.63	57.88

Figure 14.193: Training data list for our neural network in Microsoft® Excel® 14.0.6123

Notice that there is absolutely no formula in the list above! The return on experience (especially with Microsoft® Excel®...) tell us it would be better to do a network architecture with two neurons, first with branches $\{1,2,3\}$ based on a sigmoid and a second with branches $\{4.5\}$ also based on a sigmoid. In addition, all should have a single bias and the both neurons should have a specific weight in comparison with the one and the other.

We then prepare the following table:

	B	C	D
6			Values
7	Vector	w_{11}	0.000
8	weights	w_{12}	0.000
9		w_{13}	0.000
10		w_{21}	0.000
11		w_{22}	0.000
12	Bias	θ_0	0.000
13	Ponderation	θ_1	0.000
14		θ_2	0.000

Figure 14.194: Weight bias and weights to determined for our neural network

Once the table of weights, bias and ponderations built, we write our two neurons network with the sigmoid function, for example, right next to the training sample data (which will facilitate the comparison):

	C	D	E	F	G	H	I	J	K	L
20	Value to predict	Variable1	Variable2	Variable3	Variable4	Variable5	Neural Networks			Quadratic Error
21	y^k	x^1	x^2	x^3	x^4	x^5	RNF1	RNF2	Output	
22	32.50	9.25	42.50	52.38	34.63	57.88	0.500	0.500	0.000	1,056.2500
23	33.50	8.88	49.00	54.50	35.75	61.13	0.500	0.500	0.000	1,122.2500

Figure 14.196: List of sample training data with neural network cells

To apply operational research techniques, we need to minimize or maximize something. Therefore, we will seek to minimize the sum of squared errors by creating the following column:

	I	J	K	L
19				
20	Neural Networks			Quadratic Error
21	RNF1	RNF2	Output	
22	0.500	0.500	0.000	1,056.2500
23	0.500	0.500	0.000	1,122.2500
24	0.500	0.500	0.000	1,089.0000
25	0.500	0.500	0.000	1,130.6406
26	0.500	0.500	0.000	1,032.0156
27	0.500	0.500	0.000	1,040.0625
28	0.500	0.500	0.000	1,072.5625
29	0.500	0.500	0.000	1,097.2656
30	0.500	0.500	0.000	1,080.7656
31	0.500	0.500	0.000	1,040.0625
32	0.500	0.500	0.000	1,032.0156
33	0.500	0.500	0.000	1,008.0625
34	0.500	0.500	0.000	953.2656
35	0.500	0.500	0.000	984.3906
36				14,738.6094

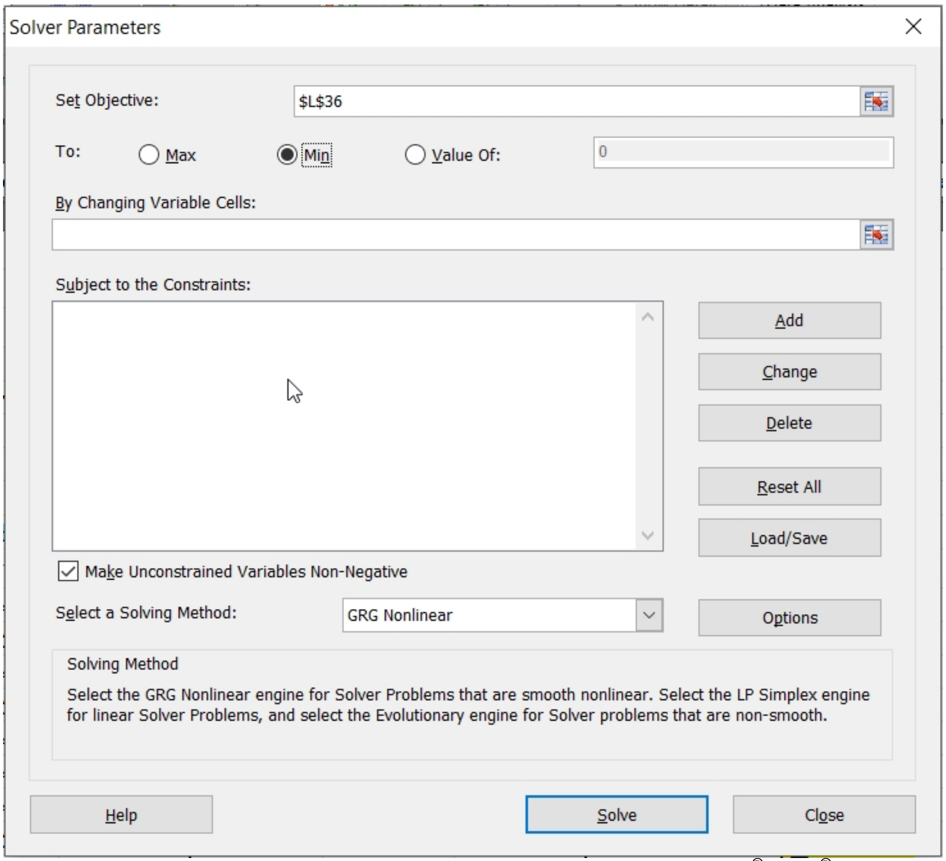
Figure 14.197: **List of sample training data with neural network cells and quadratic error minimization**

Or with the explicit formulas (we see well that this corresponds indeed to the square of the difference between the measurements and model):

	L
19	
20	Quadratic Error
21	
22	=($C22-$K22)^2
23	=($C23-$K23)^2
24	=($C24-$K24)^2
25	=($C25-$K25)^2
26	=($C26-$K26)^2
27	=($C27-$K27)^2
28	=($C28-$K28)^2
29	=($C29-$K29)^2
30	=($C30-$K30)^2
31	=($C31-$K31)^2
32	=($C32-$K32)^2
33	=($C33-$K33)^2
34	=($C34-$K34)^2
35	=($C35-$K35)^2
36	=SUM(L22:L35)

Figure 14.198: **List of sample training data with neural network cells and quadratic error minimization**

Now with the solver of Microsoft® Excel® 14.0.6123 we minimize the content of the cell L36:



Solver Parameters

Set Objective: $L$36

To: ○ Max ● Min ○ Value Of: 0

By Changing Variable Cells:

Subject to the Constraints:

☑ Make Unconstrained Variables Non-Negative

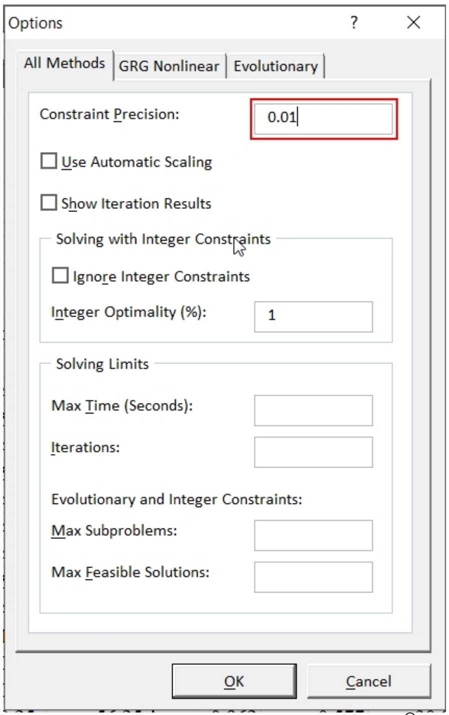
Select a Solving Method: GRG Nonlinear

Solving Method

Select the GRG Nonlinear engine for Solver Problems that are smooth nonlinear. Select the LP Simplex engine for linear Solver Problems, and select the Evolutionary engine for Solver problems that are non-smooth.

Figure 14.199: Neural network solver quadratic error minimization in Microsoft® Excel® 14.0.6123

we should not be too focused about the accuracy of the constraints for this case and therefore we have to play a little with this setting to get a satisfactory result:



Options
?
All Methods
GRG Nonlinear
Evolutionary
OK
Cancel

Constraint Precision: 0.01

☐ Use Automatic Scaling

☐ Show Iteration Results

Solving with Integer Constraints

☐ Ignore Integer Constraints

Integer Optimality (%): 1

Solving Limits

Max Time (Seconds):

Iterations:

Evolutionary and Integer Constraints:

Max Subproblems:

Max Feasible Solutions:

Figure 14.200: Neural network solver settings in Microsoft® Excel® 14.0.6123

To get a satisfactory result, it will be necessary in this case to request an accuracy of 0.001. Which will give after the execution of the search by the solver a total square error of 0.8479 (cell `L36`) and for the parameters of the neural network:

	A	B	C	D
5				
6				Values
7		Vector	w_{11}	-2.629
8		Weights	w_{12}	1.293
9			w_{13}	-0.488
10			w_{21}	0.015
11			w_{22}	0.028
12		Bias	θ_0	-55.833
13		Ponderation	θ_1	20.630
14			θ_2	75.775

Figure 14.201: **Neural network solver solution in Microsoft® Excel® 14.0.6123**

Specialized software will do better with a total square error of 0.8405 (still for cell `L36`) and for the parameters of the neural network:

	A	B	C	D
5				
6				Values
7		Vector	w_{11}	-2.695
8		Weights	w_{12}	1.309
9			w_{13}	-0.486
10			w_{21}	0.002
11			w_{22}	0.004
12		Bias	θ_0	-101.559
13		Ponderation	θ_1	25.337
14			θ_2	187.317

Figure 14.202: **Neural network optimal values with specialized software**

We can graphically compare the measurements used to train the neural network and the result of the neural network model itself. Then we have:

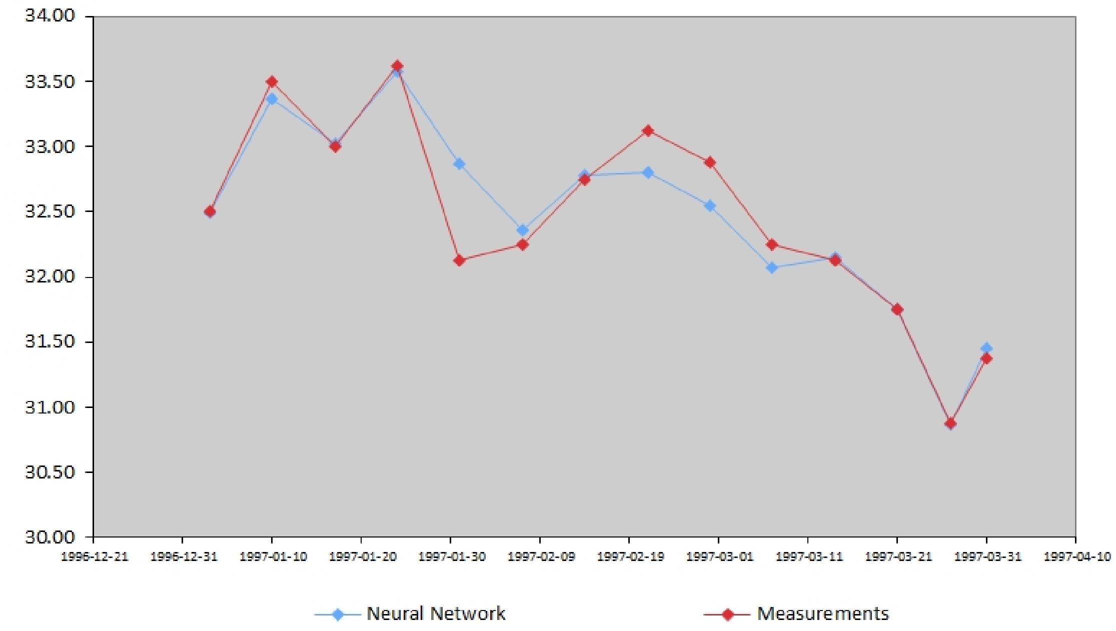


Figure 14.203: **Neural network model vs Measurements**

Which seems not bad for a non-linear model! But once the model trained, we must always see if it applies to other data (test sample). Therefore let us consider:

	C	D	E	F	G	H	I	J	K
37	Measurements						Neural Networks		
38	30.88	8.25	39.13	51.00	30.13	54.00	0.98	0.57	31.00
39	32.25	8.00	37.63	50.25	28.88	53.00	0.96	0.57	30.11
40	34.25	8.13	38.88	52.25	30.38	56.25	0.97	0.58	31.15
41	34.25	8.00	39.13	51.63	29.25	54.88	0.99	0.57	31.19
42	34.75	8.63	41.38	53.38	29.75	57.00	0.99	0.58	31.74
43	36.63	9.25	42.25	53.88	31.25	57.88	0.98	0.58	31.87

Figure 14.204: **Neural network test data sample**

Always with the same formulas:

	I	J	K
37	Neural Networks		
38	=1/(1+EXP(-($D38*$D$7+$E38*$D$8+$F38*$D$9)))	=1/(1+EXP(-($G38*$D$10+$H38*$D$11)))	=$D$12+$D$13*$I38+$D$14*$J38
39	=1/(1+EXP(-($D39*$D$7+$E39*$D$8+$F39*$D$9)))	=1/(1+EXP(-($G39*$D$10+$H39*$D$11)))	=$D$12+$D$13*$I39+$D$14*$J39
40	=1/(1+EXP(-($D40*$D$7+$E40*$D$8+$F40*$D$9)))	=1/(1+EXP(-($G40*$D$10+$H40*$D$11)))	=$D$12+$D$13*$I40+$D$14*$J40
41	=1/(1+EXP(-($D41*$D$7+$E41*$D$8+$F41*$D$9)))	=1/(1+EXP(-($G41*$D$10+$H41*$D$11)))	=$D$12+$D$13*$I41+$D$14*$J41
42	=1/(1+EXP(-($D42*$D$7+$E42*$D$8+$F42*$D$9)))	=1/(1+EXP(-($G42*$D$10+$H42*$D$11)))	=$D$12+$D$13*$I42+$D$14*$J42
43	=1/(1+EXP(-($D43*$D$7+$E43*$D$8+$F43*$D$9)))	=1/(1+EXP(-($G43*$D$10+$H43*$D$11)))	=$D$12+$D$13*$I43+$D$14*$J43

Figure 14.205: **Neural network test data sample neural network formula in Microsoft® Excel® 14.0.6123**

And if we also graphically compare the real data and the modelled data, we get:

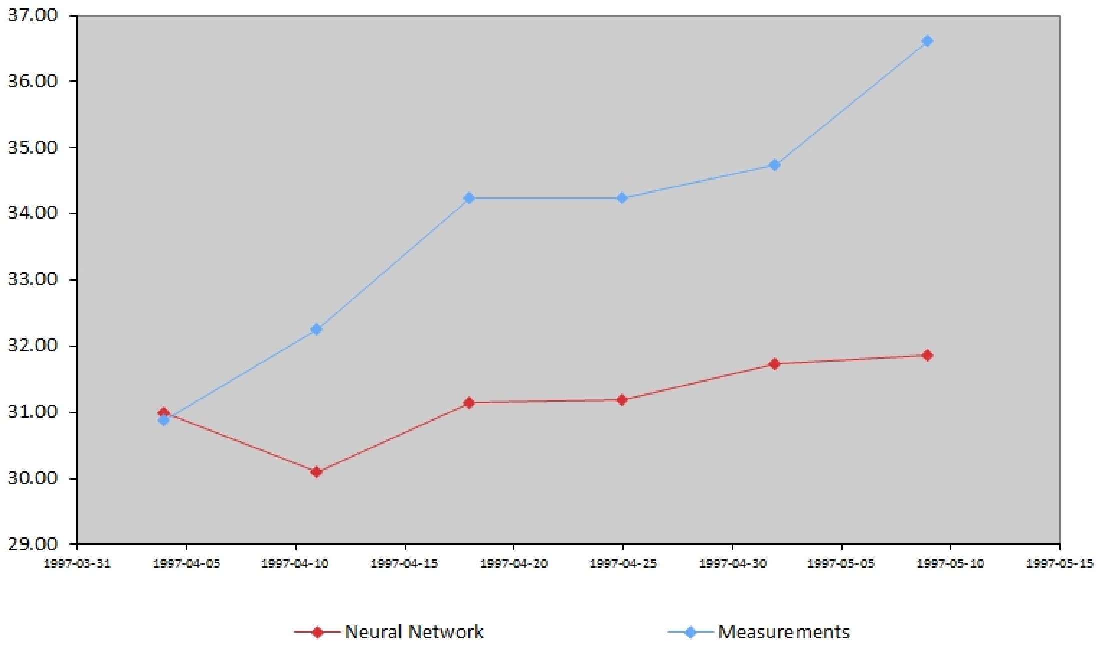

Figure 14.206: **Neural network test data sample neural network formula in Microsoft® Excel® 14.0.6123**

and here we see that the model is significantly worse. But it is so! The predictive science is not an exact science but a heuristic...

In the MATLAB® companion book, working with the same data and building a similar neural network:

we get the following model fitting plot:

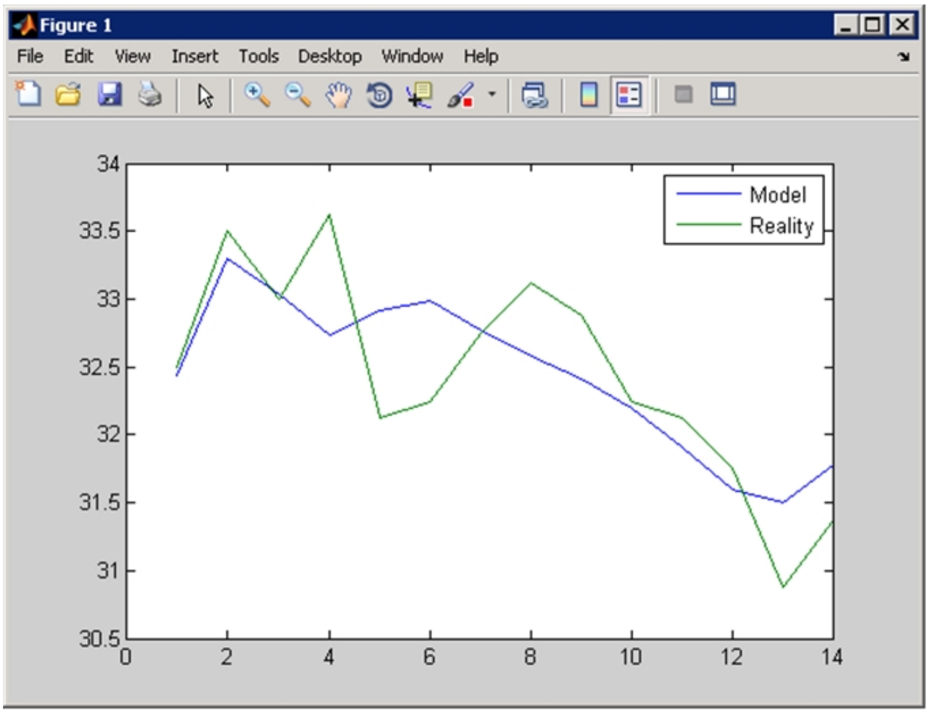

Figure 14.208: **Neural network model vs Measurements in MATLAB® 2013a**

and test sample plot (MATLAB® performs better than Microsoft® Excel® solver in this special case):

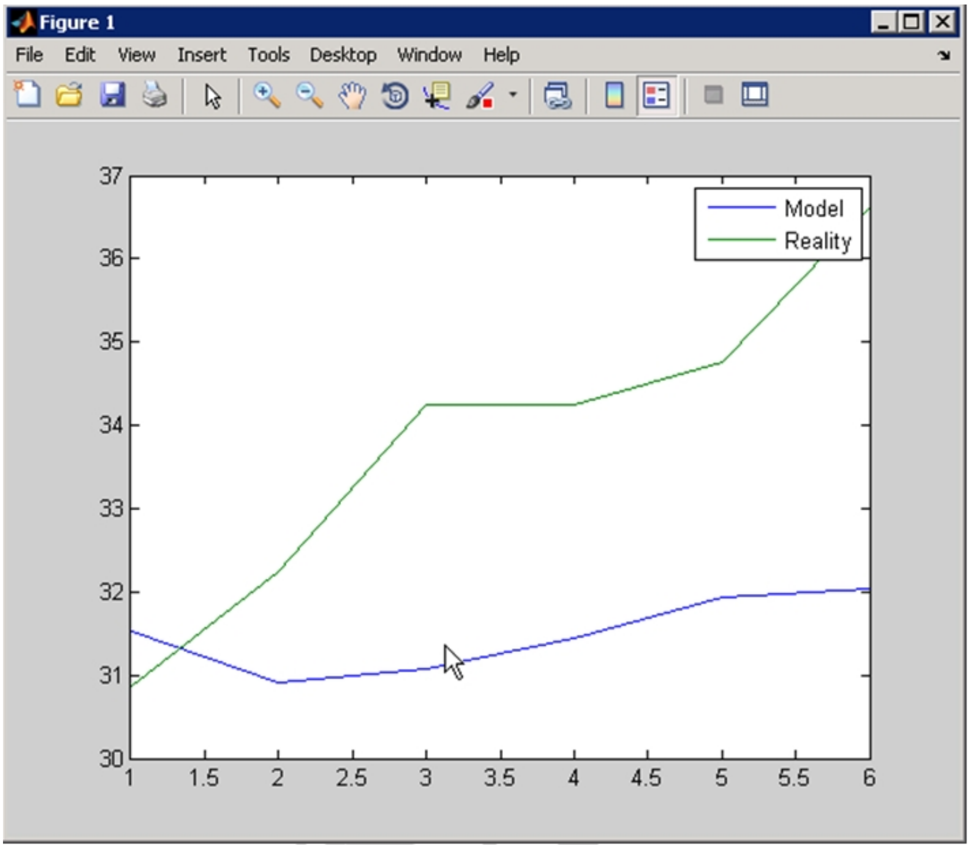

Figure 14.209: **Neural network model test sample plot in MATLAB® 2013a**

Now that we have some basic knowledge of perceptrons and vanilla neural networks we can introduce the mathematical definition of a "neural network" as it should be crystal clear enough for the reader!

Definition (#14.1.573): Let $d, L \in \mathbb{N}$, $N = (N_0, N_\ell, \cdots, N_L) \in \mathbb{N}^{L+1}$ and $\sigma : \mathbb{R} \to \mathbb{R}$. We say that σ is an "activation function", L is the number of layers, and $N_0, N_L, N_\ell, \ell \in [L-1]$ as number of neurons in the input, output, and ℓ-th hidden layer, respectively. Let $\theta = \left(\theta^{(\ell)}\right)_\ell$ be the parameters such that:

$$\theta^{(\ell)} = \left(W^{(\ell)}, \vec{b}^{(\ell)}\right)_\ell \tag{14.1.2077}$$

We denote the number of parameters by $P_N = \sum_{\ell=1}^{L} N_\ell N_{\ell-1} + N_\ell$. Define the corresponding realization function $\vec{\Phi}_\alpha : \mathbb{R}^{N_0} \times \mathbb{R}^{P_N} \to \mathbb{R}^{N_L}$ which satisfies, for any input $\vec{x} \in \mathbb{R}^{N_0}$ and parameters θ, we set $\vec{\Phi}_\alpha = \vec{\Phi}^{(L)}$ where $\alpha = (N, \sigma)$, then:

$$\begin{aligned} \vec{\Phi}^{(1)}(\vec{x}, \theta) &= W^{(1)} \circ \vec{x} + \vec{b}^{(1)} \\ \vec{\bar{\Phi}}^{(\ell)}(\vec{x}, \theta) &= \sigma\left(\vec{\Phi}^{(\ell)}(\vec{x}, \theta)\right), \text{ for } \ell \in [L-1] \\ \vec{\Phi}^{(\ell+1)}(\vec{x}, \theta) &= W^{(\ell+1)} \circ \vec{\bar{\Phi}}^{(\ell)}(\vec{x}, \theta) + \vec{b}^{(\ell+1)} \end{aligned} \tag{14.1.2078}$$

and σ applied component-wise. As we already know, we refer W as the "weight matrix" and $\vec{b}$ as the "bias vector".

Note that $W^{(\ell)} \in \mathbb{R}^{N_\ell} \times \mathbb{R}^{N_{\ell-1}}$ are matrices, so they represent a linear transformation from $\mathbb{R}^{N_\ell}$ to $\mathbb{R}^{N_{\ell-1}}$. Therefore we may see the Neural Networks as successive composition of affine linear transformations, that is:

$$\vec{x} \mapsto W^{(\ell)} \circ \vec{x} + \vec{b}^{(\ell)} \tag{14.1.2079}$$

Now we can also provide the formal definition of a set of set neural networks.

Definition (#14.1.574): Let $\alpha = (N, \sigma)$ be a neural network with input $N_0 = d$ and $N_L = 1$, and activation function σ. The "set of Neural Networks: is defined by:

$$\mathcal{F}_\alpha = \mathcal{F}_{(N,\sigma)} = \left\{\vec{\Phi}_\alpha(\cdot, \theta) : \theta \in \mathbb{R}^{P_N}\right\} \tag{14.1.2080}$$

There is a more simple way to write the two previous definitions, in terms of activation function and affine transformations. Since the realization of a neural network is given by recursively applying σ we may write as:

$$\vec{x} \mapsto F(x) := \vec{T}_L\left(\sigma\left(\vec{T}_{L-1}\left(\cdots\left(\sigma\left(\vec{T}_1(x)\right)\cdots\right)\right)\right)\right) \tag{14.1.2081}$$

where $\vec{T}_L$ is the corresponding affine transformation, i.e. $\vec{T}_\ell = W^{(\ell)} \circ \vec{x} + \vec{b}^{(\ell)}$. Then previous definition of a set of neural network basically becomes the set of all functions $F(x)$ of the form which is described above, that is $F \in \mathcal{F}_{(N,\sigma)}$.

14.1.20.8.5 Backpropagation

Gradient descent (see earlier above page 6678) is a good technique to minimize a cost function. But if we cannot analytically compute the function local derivatives, we will instead have to compute the slope manually by evaluating the function around a neighbourhood. Translated to the example of descending a mountain, it is like either walking with eyes wide open (analytical way), or being blindfolded and having to walk a few steps in each direction, each time we want to assess the slope around us (manual way). This manual option is very time consuming, especially if you have many parameters—which is the case with neural networks.

Hopefully, a technique was found to analytically compute the local derivatives in a neural network: back-propagation. The idea is that a neural network can be used in two directions:

1. Forward propagation where the neurons propagate information through the network by applying their activation functions to their weighted inputs and biases.
2. Backpropagation where the neurons propagate their local derivatives (that is the impact of changing weights, input values, and biases). In other words, each neuron will propagate how much a change in one of its inputs (weights, input values, bias) will impact its own output.

During the training phase of a neural network, forward propagation and back-propagation will be performed in turns. Forward propagation will be used to generate predictions (as data flow through the network). Backpropagation will be used to tune the weights based on the latest errors.

Therefore in the field of neural networks "back-propagation" is a method to calculate the gradient of the loss function with respect to the weights in an artificial neural network. It is commonly used as a part of algorithms that optimize the performance of the network by adjusting the weights, for example in the gradient descent algorithm (see page 6678). It is also named "backward propagation of errors". It seems that there is no shortage of papers online that attempt to explain how back-propagation works, but few that include an example with actual numbers. The text and example below is an attempt of Matt Mazur[72] to explain how it works with a concrete example that everybody can compare their own calculations to in order to ensure they understand backpropagation correctly.

To explain backpropagation, we're going to use a neural network with two inputs, two hidden neurons, two output neurons. Additionally, the hidden and output neurons will include a bias.

Here's the basic structure:

w_8 0.55
b_1 0.35
b_2 0.60

The goal of backpropagation is to optimize the weights so that the neural network can learn how to correctly map arbitrary inputs to outputs.

For the rest of this tutorial we're going to work with a single training set: given inputs 0.05 and 0.10 and $b_1 = 1$ and $b_2 = 2$, we want the neural network to output 0.01 and 0.99.

Let us decompose the method:

1. The Forward Pass:

   To begin, lets see what the neural network currently predicts given the weights and biases above and inputs of 0.05 and 0.10. To do this we will feed those inputs forward though the network.

We figure out the total net input[73] to each hidden layer neuron, squash the total net input using an activation function (here we use the logistic function), then repeat the process with the output layer neurons.

Here is how we calculate the total net input for h_1:

$$\text{net}_{h_1}=w_1 i_1+w_2 i_2+b_1\cdot 1=0.15\cdot 0.05+0.2\cdot 0.1+0.35\cdot 1=0.3375 \tag{14.1.2082}$$

We then squash it using (arbitrarily) using the logistic function to get the output of h_1:

$$\text{out}_{h_1}=\frac{1}{1+e^{\text{net}_{h_1}}}=\frac{1}{1+e^{-0.3775}}=0.593269992 \tag{14.1.2083}$$

Carrying out the same process for h_2 we get:

$$\text{out}_{h_2}=0.596884378 \tag{14.1.2084}$$

We repeat this process for the output layer neurons, using the output from the hidden layer neurons as inputs.

Here's the output for o_1:

$$\begin{aligned}\text{net}_{o_1}&=w_5\text{out}_{h_1}+w_6\text{out}_{h_2}+b_2\cdot 1\\&=0.4\cdot 0.593269992+0.45\cdot 0.596884378+0.6\cdot 1\\&=1.105905967\end{aligned} \tag{14.1.2085}$$

Hence:

$$\text{out}_{o_1}=\frac{1}{1+e^{-\text{net}_{o_1}}}=\frac{1}{1+e^{-1.105905967}}=0.75136507 \tag{14.1.2086}$$

And carrying out the same process for o_2 we get:

$$\text{out}_{o_2}=0.772928465 \tag{14.1.2087}$$

We can now calculate the error for each output neuron using the squared error function (a loss function) and sum them to get the total error (using the traditional notations in the field...), i.e. a cost function:

$$E_{\text{tot}}=\sum\frac{1}{2}(\text{target}-\text{output})^2 \tag{14.1.2088}$$

Or if written in another common way:

$$J(\vec{w},\vec{b})=\frac{1}{2}\sum_i(y_i-\phi_i(z))^2=\frac{1}{2}\sum_i\left(y_i-\phi_i(\vec{w}^T\vec{x}+\vec{b})\right)^2 \tag{14.1.2089}$$

Since backpropagation uses the gradient descent method (see page 6678), the factor of $\frac{1}{2}$ is included to cancel the exponent when differentiating. Later, the expression will be multiplied with an arbitrary learning rate, so that it doesn't matter if a constant coefficient is introduced now.

---

[73] The "Total net input" is also referred to as just "net input" by some sources.

Remark

Some textbooks refer to the "target" as the "ideal" and the "output" as the "actual".

For example, the target output for o_1 is 0.01 but the neural network output 0.75136507, therefore its error is:

$$E_{o_1}=\frac{1}{2}(\text{target}_{o_1}-\text{out}_{o_1})^2=\frac{1}{2}(0.01-0.75136507)^2=0.274811083 \qquad (14.1.2090)$$

Repeating this process for o_2 (remembering that the target is 0.99) we get:

$$E_{o_2}=\frac{1}{2}(\text{target}_{o_2}-\text{out}_{o_2})^2=0.023560026 \qquad (14.1.2091)$$

The total error for the neural network is the sum of these errors:

$$E_{\text{tot}}=E_{o_1}+E_{o_2}=0.274811083+0.023560026=0.298371109 \qquad (14.1.2092)$$

2. The Backwards Pass: Our goal with backpropagation is to update each of the weights in the network so that they cause the actual output to be closer the target output, thereby minimizing the error for each output neuron and the network as a whole.

   Consider w_5. We want to know how much a change in w_5 affects the total error, aka $\frac{\partial E_{\text{tot}}}{\partial w_5}$.

   By applying the chain rule twice (see section Differential and Integral Calculus page 1483) we know that:

$$\frac{\partial E_{\text{tot}}}{\partial w_5}=\frac{\partial E_{\text{tot}}}{\partial \text{out}_{o_1}}\frac{\partial \text{out}_{o_1}}{\partial \text{net}_{o_1}}\frac{\partial \text{net}_{o_1}}{\partial w_5} \qquad (14.1.2093)$$

   We need to figure out each piece in this equation.

   - First, how much does the total error change with respect to the output? As:

$$E_{\text{tot}}=\frac{1}{2}(\text{target}_{o_1}-\text{out}_{o_1})^2+\frac{1}{2}(\text{target}_{o_2}-\text{out}_{o_2})^2 \qquad (14.1.2094)$$

     Therefore:

$$\begin{aligned}\frac{\partial E_{\text{tot}}}{\partial \text{out}_{o_1}}&=2\cdot\frac{1}{2}(\text{target}_{o_1}-\text{out}_{o_1})^{2-1}\cdot(-1)+0=-(\text{target}_{o_1}-\text{out}_{o_1})\\&=-(0.01-0.75136507)=0.74136507\end{aligned} \qquad (14.1.2095)$$

   - Next, how much does the output of o_1 change with respect to its total net input? As:

$$\text{out}_{o_1}=\frac{1}{1+e^{-\text{net}_{o_1}}} \qquad (14.1.2096)$$

     Therefore:

$$\begin{aligned}\frac{\partial \text{out}_{o_1}}{\partial \text{net}_{o_1}}&=-\frac{e^{-\text{out}_{o_1}}\ln(e)}{(1-e^{-\text{out}_{o_1}})^2}=-\frac{e^{-\text{out}_{o_1}}}{(1-e^{-\text{out}_{o_1}})^2}=\text{out}_{o_1}(1-\text{out}_{o_1})\\&=0.75136507(1-0.75136507)=0.186815602\end{aligned} \qquad (14.1.2097)$$

- Finally, how much does the total net input of o_1 change with respect to w_5?

  As:

$$\text{net}_{o_1} = w_5 \text{out}_{h_1} + w_6 \text{out}_{h2} + b_2 \cdot 1 \tag{14.1.2098}$$

  Therefore:

$$\frac{\partial \text{net}_{o_1}}{\partial w_5} = 1 \cdot \text{out}_{h_1} \cdot w_5^{(1-1)} + 0 + 0 = \text{out}_{h_1} = 0.593269992 \tag{14.1.2099}$$

Putting it all together:

$$\begin{aligned}\frac{\partial E_{\text{tot}}}{\partial w_5} &= \frac{\partial E_{\text{tot}}}{\partial \text{out}_{o_1}} \frac{\partial \text{out}_{o_1}}{\partial \text{net}_{o_1}} \frac{\partial \text{net}_{o_1}}{\partial w_5} = \frac{\partial E_{\text{tot}}}{\partial w_5} = -(\text{target}_{o_1} - \text{out}_{o_1})\text{out}_{o_1}(1-\text{out}_{o_1})\text{out}_{h_1} \\ &= 0.74136507 \cdot 0.186815602 \cdot 0.593269992 = 0.082167041\end{aligned} \tag{14.1.2100}$$

To decrease the error, we then subtract this value from the current weight, by applying the relation derived earlier above (see page 6678):

$$\vec{\omega}^+ = \vec{\omega} + \Delta\omega = \vec{\omega} - \eta \vec{\nabla} E_{\text{tot}}(\vec{\omega}) \tag{14.1.2101}$$

optionally multiplied by some learning rate, η, which we will set to 0.5:

$$w_5^+ = w_5 - \eta \frac{\partial E_{\text{tot}}}{\partial w_5} = 0.4 - 0.5 \cdot 0.082167041 = 0.35891648 \tag{14.1.2102}$$

Remark

Some textbooks use the notation α to represent the learning rate, others use η, and others even use ε...

We can repeat this process to get the new weights w_6, w_7, and w_8:

$$w_6^+ = 0.408666186 \qquad w_7^+ = 0.511301270 \qquad w_8^+ = 0.561370121 \tag{14.1.2103}$$

We perform the actual updates in the neural network after we have the new weights leading into the hidden layer neurons (i.e., we use the original weights, not the updated weights, when we continue the backpropagation algorithm below)!

Next, we will continue the backwards pass by calculating new values for w_1, w_2, w_3, and w_4 of the hidden layer.

Here is what we need to figure out:

$$\frac{\partial E_{\text{tot}}}{\partial w_1} = \frac{\partial E_{\text{tot}}}{\partial \text{out}_{h_1}} \frac{\partial \text{out}_{h_1}}{\partial \text{net}_{h_1}} \frac{\partial \text{net}_{h_1}}{\partial w_1} \tag{14.1.2104}$$

We are going to use a similar process as we did for the output layer, but slightly different to account for the fact that the output of each hidden layer neuron contributes to the output (and therefore error) of multiple output neurons.

We know that out_{h_1} affects both out_{o_1} and out_{o_2} therefore the $\frac{\partial E_{\text{tot}}}{\partial \text{out}_{h_1}}$ needs to take into consideration its effect on the both output neurons:

$$\frac{\partial E_{\text{tot}}}{\partial \text{out}_{h_1}} = \frac{\partial E_{o_1}}{\partial \text{out}_{h_1}} + \frac{\partial E_{o_2}}{\partial \text{out}_{h_1}} \tag{14.1.2105}$$

Starting with $\frac{\partial E_{o_1}}{\partial \text{out}_{h_1}}$:

$$\frac{\partial E_{o_1}}{\partial \text{out}_{h_1}} = \frac{\partial E_{o_1}}{\partial \text{net}_{o_1}} \frac{\partial \text{net}_{o_1}}{\partial \text{out}_{h_1}} \tag{14.1.2106}$$

We can calculate $\frac{\partial E_{o_1}}{\partial \text{net}_{o_1}}$ using values we calculated earlier:

$$\frac{\partial E_{o_1}}{\partial \text{net}_{o_1}} = \frac{\partial E_{o_1}}{\partial \text{out}_{o_1}} \frac{\partial \text{out}_{o_1}}{\partial \text{net}_{o_1}} = 0.74136507 \cdot 0.186815602 = 0.138498562 \tag{14.1.2107}$$

And $\frac{\partial \text{net}_{o_1}}{\partial \text{out}_{h_1}}$ is equal to w_5. Indeed:

$$\text{net}_{o_1} = w_5 \text{out}_{h_1} + w_6 \text{out}_{h_2} + b_2 \cdot 1 \tag{14.1.2108}$$

Therefore:

$$\frac{\partial \text{net}_{o_1}}{\partial \text{out}_{h_1}} = w_5 = 0.40 \tag{14.1.2109}$$

Plugging them in:

$$\frac{\partial E_{o_1}}{\partial \text{out}_{h_1}} = \frac{\partial E_{o_1}}{\partial \text{net}_{o_1}} \frac{\partial \text{net}_{o_1}}{\partial \text{out}_{h_1}} = 0.138498562 \cdot 0.40 = 0.055399425 \tag{14.1.2110}$$

Following the same process for $\frac{\partial E_{o_2}}{\partial \text{out}_{h_1}}$, we get:

$$\frac{\partial E_{o_2}}{\partial \text{out}_{h_1}} = -0.019049119 \tag{14.1.2111}$$

Therefore:

$$\begin{aligned}\frac{\partial E_{\text{tot}}}{\partial \text{out}_{h_1}} &= \frac{\partial E_{o_1}}{\partial \text{out}_{h_1}} + \frac{\partial E_{o_2}}{\partial \text{out}_{h_1}} = \frac{\partial E_{o_1}}{\partial \text{net}_{o_1}} \frac{\partial \text{net}_{o_1}}{\partial \text{out}_{h_1}} + \frac{\partial E_{o_2}}{\partial \text{net}_{o_2}} \frac{\partial \text{net}_{o_2}}{\partial \text{out}_{h_1}} \\ &= 0.055399425 + (-0.019049119) = 0.036350306\end{aligned} \tag{14.1.2112}$$

Now that we have $\frac{\partial E_{\text{tot}}}{\partial \text{out}_{h1}}$, we need to figure out $\frac{\partial \text{out}_{h_1}}{\partial \text{net}_{h1}}$ and then $\frac{\partial \text{net}_{h_1}}{\partial w_1}$.

As:

$$\text{out}_{h_1} = \frac{1}{1 + e^{-\text{net}_{h_1}}} \tag{14.1.2113}$$

Therefore identically as earlier above:

$$\frac{\partial \text{out}_{h_1}}{\partial \text{net}_{h_1}} = \text{out}_{h_1}(1 - \text{out}_{h_1}) = 0.59326999(1 - 0.59326999) = 0.241300709 \tag{14.1.2114}$$

And as:

$$\text{net}_{h_1} = w_1 i_1 + w_2 i_2 + b_1 \cdot 1 \tag{14.1.2115}$$

Therefore:

$$\frac{\partial \text{net}_{h_1}}{\partial w_1} = i_1 = 0.05 \tag{14.1.2116}$$

Putting it all together (and writing all the steps explicitly):

$$\begin{aligned}\frac{\partial E_{\text{tot}}}{\partial w_1}&=\frac{\partial E_{\text{tot}}}{\partial \text{out}_{h_1}}\frac{\partial \text{out}_{h_1}}{\partial \text{net}_{h_1}}\frac{\partial \text{net}_{h_1}}{\partial w_1}=\left(\frac{\partial E_{o_1}}{\partial \text{out}_{h_1}}+\frac{\partial E_{o_2}}{\partial \text{out}_{h_1}}\right)\frac{\partial \text{out}_{h_1}}{\partial \text{net}_{h_1}}\frac{\partial \text{net}_{h_1}}{\partial w_1}\\&=\left(\frac{\partial E_{o_1}}{\partial \text{net}_{o_1}}\frac{\partial \text{net}_{o_1}}{\partial \text{out}_{h_1}}+\frac{\partial E_{o_2}}{\partial \text{net}_{o_2}}\frac{\partial \text{net}_{o_2}}{\partial \text{out}_{h_1}}\right)\frac{\partial \text{out}_{h_1}}{\partial \text{net}_{h_1}}\frac{\partial \text{net}_{h_1}}{\partial w_1}\\&=0.036350306\cdot 0.241300709\cdot 0.05=0.000438568\end{aligned}\tag{14.1.2117}$$

We can now update w_1:

$$w_1^+=w_1-\eta\frac{\partial E_{\text{tot}}}{\partial w_1}=0.15-0.5\cdot 0.000438568=0.149780716\tag{14.1.2118}$$

Repeating this for w_2, w_3, and w_4:

$$w_2^+=0.19956143\qquad w_3^+=0.24975114\qquad w_4^+=0.29950229\tag{14.1.2119}$$

Finally, we have updated all of our weights! When we fed forward the 0.05 and 0.1 inputs originally, the error on the network was 0.298371109. After this first round of backpropagation, the total error is now down to 0.291027924. It might not seem like much, but after repeating this process $10,000$ times, for example, the error plummets to 0.000035085. At this point, when we feed forward 0.05 and 0.1, the two outputs neurons generate 0.015912196 (vs 0.01 target) and 0.984065734 (vs 0.99 target).

Therefore we have seen that this optimization algorithm repeats a two phase cycle, propagation and weight update. When an input vector is presented to the network, it is propagated forward through the network, layer by layer, until it reaches the output layer. The output of the network is then compared to the desired output, using a loss function, and an error value is calculated for each of the neurons in the output layer. The error values are then propagated backwards, starting from the output, until each neuron has an associated error value which roughly represents its contribution to the original output. Backpropagation uses these error values to calculate the gradient of the loss function. In the second phase, this gradient is fed to the optimization method, which in turn uses it to update the weights, in an attempt to minimize the loss function.

We have also seen that the backpropagation requires that the activation function used by the artificial neurons (or "nodes") to be differentiable.

Remarks

R1. Backpropagation requires a known, desired output for each input value in order to calculate the loss function gradient – it is therefore usually considered to be a supervised learning method.

R2. The choice of learning rate η is important for the method, since a high value can cause too strong a change, causing the minimum to be missed, while a too low learning rate slows the training unnecessarily. In order to avoid oscillation inside the network, such as alternating connection weights, and to improve the rate of convergence, there are refinements of this algorithm that use an adaptive learning rate.

R3. Backpropagation learning does not require normalization of input vectors; however, normalization could improve performance.

R4. Over-fitting is a major-concern in deep learning (and to humans also...) since large networks can have hundreds of millions of weights. In image recognition, the number of training images can be significantly increased by random jittering of the images. Another technique named dropout randomly deletes a fraction of the weights at each training iteration. Regularization (see page 6435) is used to assign a cost to the size of weights and many other ideas are being explored.

For information... when the net is passed to the activation (transfer) function and the function's output is used for adjusting the weights we then speak of "McCulloch–Pitts perceptron" or just simply of a "(feed-forward) perceptron". If the weights are adjusted only according to the weighted sum of the inputs (that is without passing through the activation function!), we then speak of "adaptive linear neuron" (ADALINE) or of "feed-forward adaptive linear neuron[74]".

Finally, don't forget (as we have seen earlier) that gradient descent with backpropagation is not guaranteed to find the global minimum of the error function, but only a local minimum!

As the number of layers grew, we encounter mainly two calculatory difficulties (aside computer memory issues): "exploding gradient" and "vanishing gradient".

While the problem of exploding gradient can be treated quite well by applying simple techniques like gradient clipping and L_1 or L_2 regularization (see earlier above page 6441), the problem of vanishing gradient remained intractable for decades.

What is vanishing gradient and why does it arise? To update the values of the parameters in neural networks, we have seen that the back-propagation algorithm was typically used and is based on the chain rule to calculated partial derivatives of some more or less complex functions. During gradient descent, the neural network's parameters receive an update proportional to the derivative of the cost function with respect to the current parameter in each iteration of training. The problem is that in some cases, the gradient will be vanishingly small, effectively preventing some parameters from chaining their value. In the worst case, this may completely stop the neural network from further training.

Traditional activation functions, such as the hyperbolic tangent function i mentioned above, have gradients in the range $[0, 1]$, and back-propagation computes gradients by the chain rule. That has the effect of multiplying n of these small numbers to compute gradients of the earlier (leftmost) layers in an n-layer network, meaning that the gradient decreases exponentially with n. That results in the effect that the earlier layers train very slowly, if at all.

Remark

At this point the reader may have noticed that technically, logistic regression is equivalent to a single layer neural network with a sigmoid transfer function (and vice-versa).

---

[74] A multilayer network of ADALINE units is known as a MADALINE.

14.1.20.8.6 Recursive Neural Networks (RNN)

Sometimes we want to remember an input for later use. There are many examples of such a situation, such as the stock market. To make a good investment judgement, we have to at least look at the stock data from a time window.

The naive way to let neural network accept a time series data is connecting several neural networks together. Each of the neural networks handles one time step. Instead of feeding the data at each individual time step, you provide data at all time steps within a window, or a context, to the neural network.

A "recurrent neural network" (RNN) is a class of artificial neural networks where connections between nodes form a directed graph along a temporal sequence. This allows it to exhibit temporal dynamic behaviour. Derived from feed-forward neural networks, RNNs can use their internal state (memory) to process variable length sequences of inputs.

There are three common type of recursive neural network[75] (recurrent neural network, long short term memory unit and gated recurrent unit):

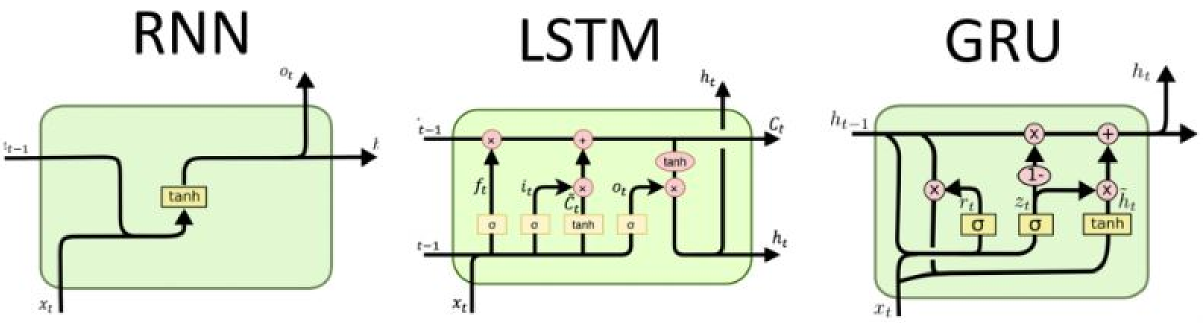

Figure 14.211: **Three common type of recursive neural networks**

As we will provide further below the equations of LSTM (Long-Short Term Memory) and GRU (Gated Recurrent Unit), the reader will be able to notice that GRU (introduced in year 12014 according to holocene calendar) are a special case of LSTM (introduced in year 11997 according to holocene calendar)!

Remark

The GRU is an alternative to the LSTM which is similarly difficult to justify. It seems that comparison of the GRU to the LSTM and its variants provides evidence that the GRU outperforms the LSTM on nearly all tasks except language modelling.

A lot of times, you need to process data that has periodic patterns (LSTM at the day we write these lines seems to be efficient only for such patterns!). As a silly example, suppose you want to predict Christmas tree sales. This is a very seasonal thing and likely to peak only once a year. So a good strategy to predict Christmas tree sale is looking at the data from exactly a year back. For this kind of problems, you either need to have a big context to include ancient data points, or you have a good memory. You know what data is valuable to remember for later use and what needs to be forgotten when it is useless.

---

[75] Huge thanks to Shi Yan, senior software engineer at NVIDIA, for having authorized us to use and slightly modify his LSTM illustrations!

Theoretically the naively connected neural network, so named "recurrent neural network":

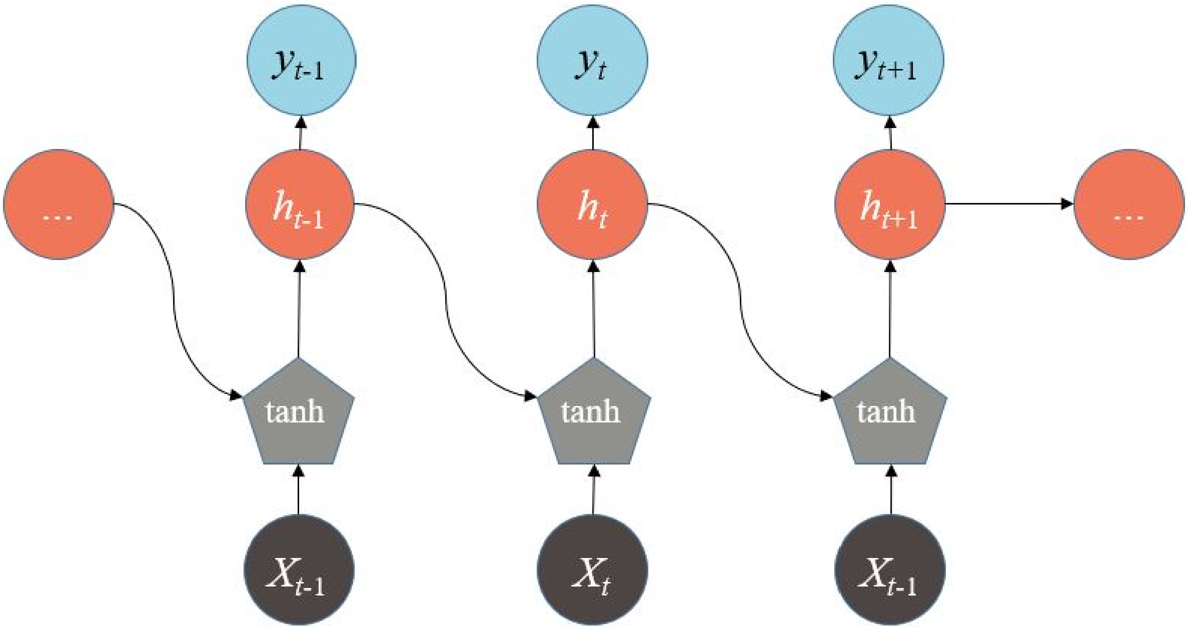

Figure 14.212: **Recurrent neural network**

can work. But in practice, it suffers from two problems: vanishing gradient and exploding gradient, which make it unusable.

Then later,"Long-Short Term memory Neural Networks" (LSTM) were introduced by Hochreiter & Schmidhuber (11997 according to holocene calendar) [255] to solve this issue by explicitly introducing a memory unit, named the "cell" into the network. This is the diagram of a LSTM building block:

Figure 14.213: LSTM (long short term memory) building block

Obviously in the general case most variables are vectors. But in most typical univariate forecasting techniques, most vectors (excepted $\vec{X}_t$) are one-dimensional vectors: i.e. scalars!

Remark

LSTM networks are a type of RNN that uses special units in addition to standard units. Again (!), standard RNNs (Recurrent Neural Networks) suffer from vanishing and exploding gradient problems. LSTMs (Long Short Term Memory) deal with these problems by introducing new gates, such as input and forget gates, which allow for a better control over the gradient flow and enable better preservation of long-range dependencies.

At a first sight, this looks intimidating. Let's ignore the internals, but only look at the inputs and outputs of the unit. The network takes three inputs. X_t is the input of the current time step. h_{t-1} is the output from the previous LSTM unit and C_{t-1} is the "memory" of the previous unit, which may be seen as the most important input. As for outputs, h_t is the output of the current network. C_t is the memory of the current unit.

Therefore, this single unit makes decision by considering the current input, previous output and previous memory. And it generates a new output and alters its memory.

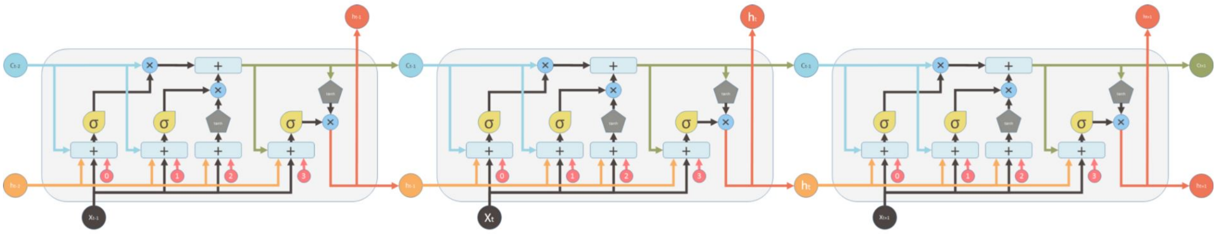

Figure 14.214: **Typical LSTM overall structure**

The way its internal memory C_t changes is pretty similar to piping water through a pipe. Assuming the memory is water, it flows into a pipe. You want to change this memory flow along the way and this change is controlled by two valves:

1. The first valve is named the "forget valve". If you shut it, no old memory will be kept. If you fully open this valve, all old memory will pass through.

2. The second valve is the new "memory valve". New memory will come in through a T shaped joint like below and merge with the old memory. Exactly how much new memory should come in is controlled by the second valve.

On the LSTM diagram below the red area is the memory pipe (do not confuse it with the "memory valve"!). The input is the old memory (a vector). The first cross × it passes through is the forget valve. It is actually an element-wise multiplication operation (i.e. "Hadamard product"). So if you multiply the old memory C_{t-1} with a vector that is close to 0, that means you want to forget most of the old memory. You let the old memory goes through, if you forget valve equals 1.

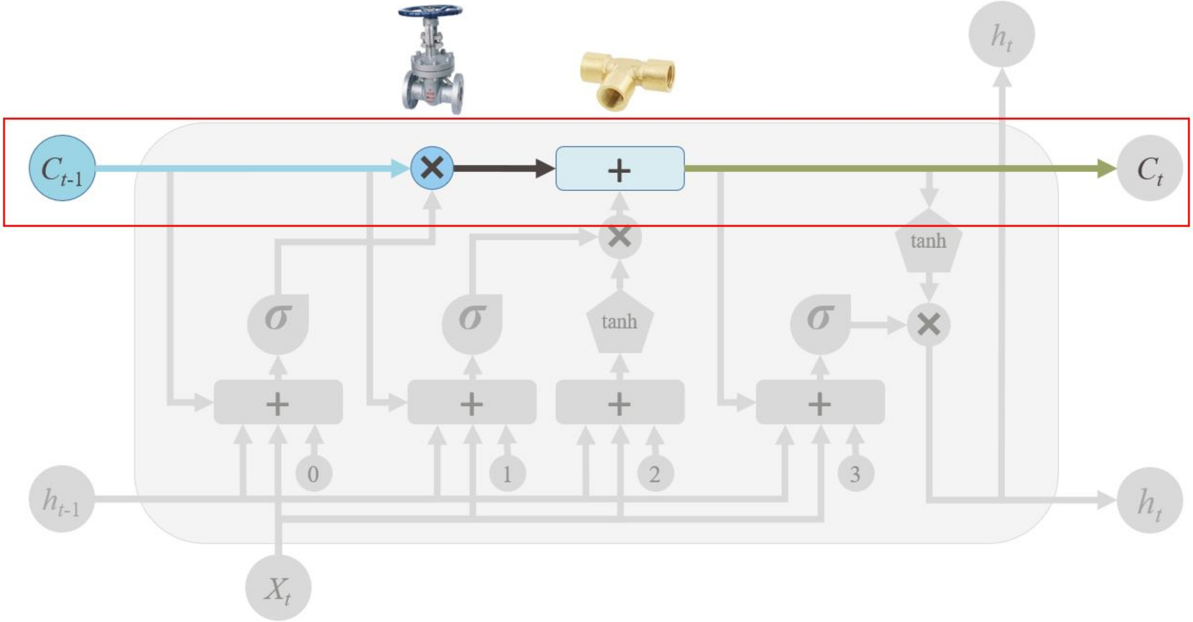

Figure 14.215: **Memory pipe with memory valve and forget valve of a LSTM**

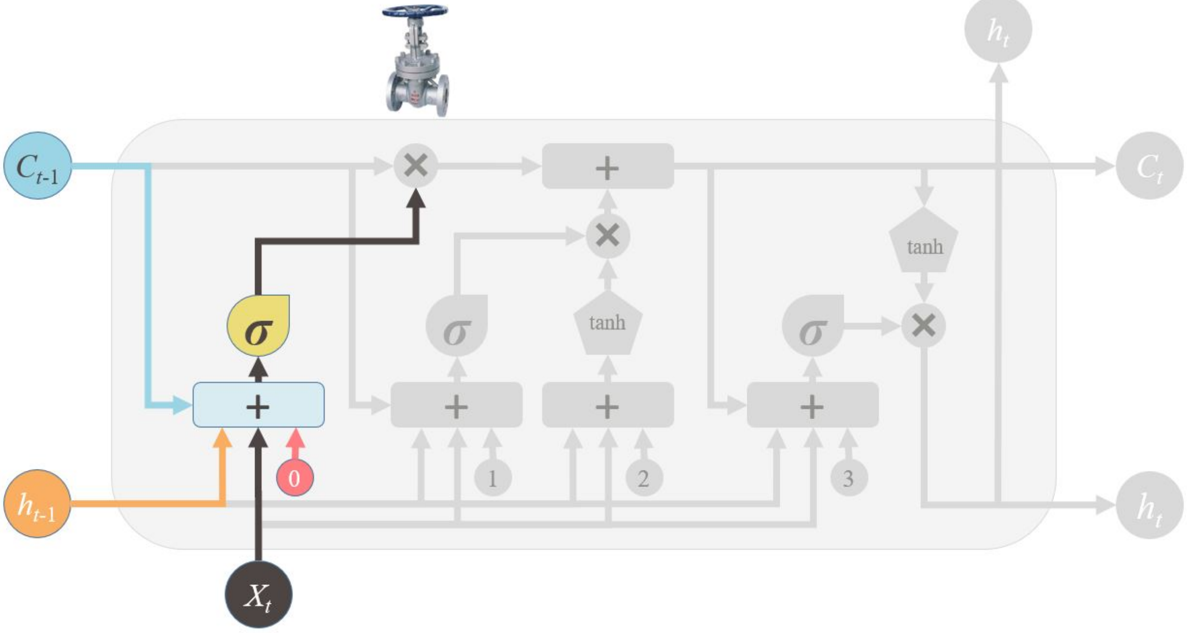
Then the second operation the memory flow will go through is this $+$ operator. This operator means piece-wise summation. It resembles the T shape joint pipe. New memory and the old memory will merge by this operation.

After these two operations, you have the old memory C_{t-1} changed to the new memory C_t.

Now let us look at the input of both valves more in details.

We begin with the "forget valve"! It is controlled by a simple feed-forward one layer neural network. The inputs of the neural network is h_{t-1}, the output of the previous LSTM block, X_t, the input for the current LSTM block, C_{t-1}, the memory of the previous block and finally a bias vector b_0. This neural network has a sigmoid function as activation, and it's output vector is the forget valve, which will applied to the old memory C_{t-1} by element-wise multiplication.



h_t
X_t

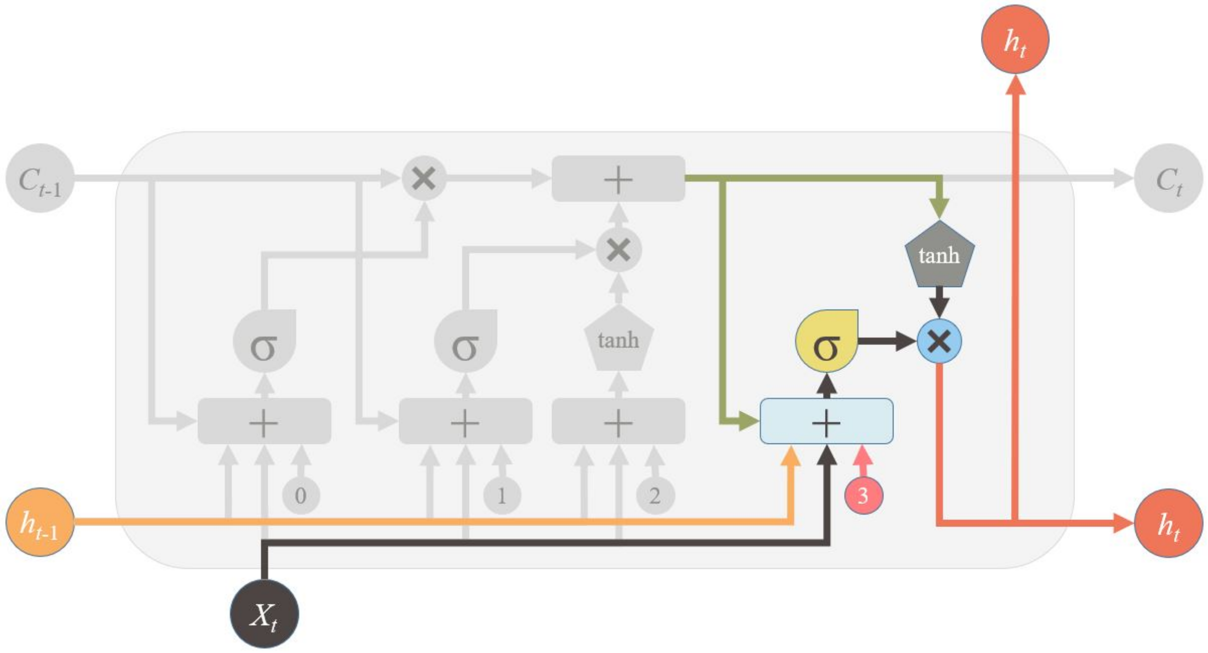
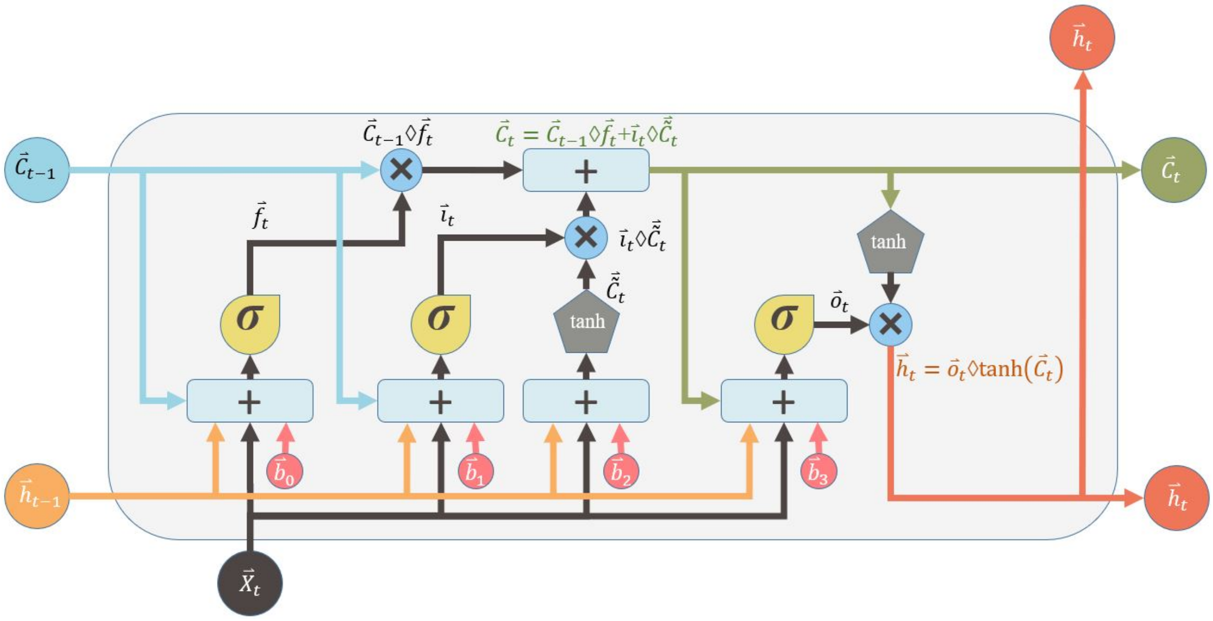
And finally, we need to generate the output for this LSTM unit. This step has an output valve that is controlled by the new memory, the previous output h_{t-1}, the input X_t and a bias vector. This valve controls how much new memory should output to the next LSTM unit:



h_t
C_{t-1}
C_t
tanh
σ
σ
tanh
σ
+
+
+
+
+
0
1
2
3
h_{t-1}
h_t
X_t

Let us see now the mathematical point of view. For this consider again the LSTM block but with more explicit notations (for recall, $\diamond$ is the vector element-wise multiplication):



$\vec{h}_t$
$\vec{C}_{t-1}$
$\vec{C}_{t-1}\Diamond\vec{f}_t$
$\vec{C}_t = \vec{C}_{t-1}\Diamond\vec{f}_t+\vec{\imath}_t\Diamond\vec{\vec{C}}_t$
$\vec{C}_t$
$\vec{f}_t$
$\vec{\imath}_t$
$\vec{\imath}_t\Diamond\vec{\vec{C}}_t$
tanh
$\vec{\vec{C}}_t$
σ
σ
tanh
σ
$\vec{o}_t$
$\vec{h}_t = \vec{o}_t\Diamond\tanh(\vec{C}_t)$
$\vec{h}_{t-1}$
$\vec{b}_0$
$\vec{b}_1$
$\vec{b}_2$
$\vec{b}_3$
$\vec{h}_t$
$\vec{X}_t$

And here are the corresponding relations:

- Gating variables (respectively $\vec{f}_t$ forget gate, $\vec{\imath}_t$ update gate, $\vec{o}_t$ output gate):

$$\begin{aligned}\vec{f}_t&=\sigma\left(W_f\circ[\vec{C}_{t-1},\vec{h}_{t-1},\vec{X}_t]+\vec{b}_0\right)\\ \vec{\imath}_t&=\sigma\left(W_i\circ[\vec{C}_{t-1},\vec{h}_{t-1},\vec{X}_t]+\vec{b}_1\right)\\ \vec{o}_t&=\sigma\left(W_o\circ[\vec{C}_t,\vec{h}_{t-1},\vec{X}_t]+\vec{b}_3\right)\end{aligned}\tag{14.1.2120}$$

- Candidate (memory) cell state:

$$\vec{\vec{C}}_t=\tanh\left(W_c\circ[\vec{h}_{t-1},\vec{X}_t]+\vec{b}_2\right)\tag{14.1.2121}$$

- Cell and hidden state:

$$\begin{aligned}\vec{C}_t&=\vec{C}_{t-1}\diamond\vec{f}_t+\vec{\imath}_t\diamond\vec{\vec{C}}_t\\ &=\vec{C}_{t-1}\diamond\left[\sigma\left(W_f\circ[\vec{C}_{t-1},\vec{h}_{t-1},\vec{X}_t]+\vec{b}_0\right)\right]\\ &+\left[\sigma\left(W_i\circ[\vec{C}_{t-1},\vec{h}_{t-1},\vec{X}_t]+\vec{b}_1\right)\right]\diamond\tanh\left(W_c\circ[\vec{h}_{t-1},\vec{X}_t]+\vec{b}_2\right)\\ \vec{h}_t&=\vec{o}_t\diamond\tanh\left(\vec{C}_t\right)=\vec{o}_t\diamond\tanh\left(\vec{C}_{t-1}\diamond\vec{f}_t+\vec{\imath}_t\diamond\vec{\vec{C}}_t\right)\end{aligned}\tag{14.1.2122}$$

Remark

For a "Gated Recurrent Unit Neural Network" (GRU), only two relations change:

$$\begin{aligned}\vec{C}_t&=\vec{C}_{t-1}\diamond(1-\vec{\imath}_t)+\vec{\imath}_t\diamond\vec{\vec{C}}_t\\ \vec{h}_t&=\vec{C}_t\end{aligned}\tag{14.1.2123}$$

hence the fact that GRU is a special case of LSTM!

The core reason that recurrent nets are more exciting is that they allow us to operate over sequences of vectors: Sequences in the input, the output, or in the most general case both. A few examples may make this more concrete:

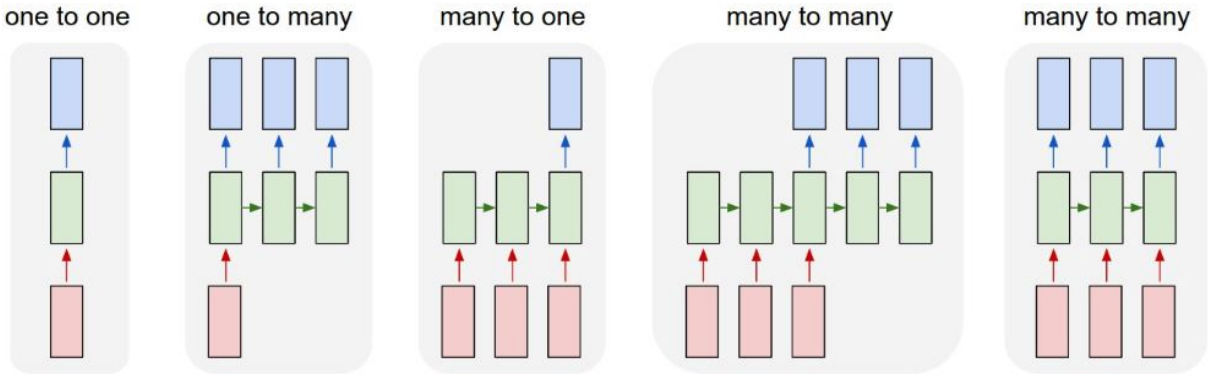


Figure 14.218: **Each rectangle is a vector and arrows represent functions (e.g. matrix multiply). Input vectors are in red, output vectors are in blue and green vectors hold the RNN's state (more on this soon). From left to right: (1) Vanilla mode of processing without RNN, from fixed-sized input to fixed-sized output (e.g. image classification). (2) Sequence output (e.g. image captioning takes an image and outputs a sentence of words). (3) Sequence input (e.g. sentiment analysis where a given sentence is classified as expressing positive or negative sentiment). (4) Sequence input and sequence output (e.g. Machine Translation: a RNN reads a sentence in English and then outputs a sentence in French). (5) Synced sequence input and output (e.g. video classification where we wish to label each frame of the video). Notice that in every case are no pre-specified constraints on the lengths sequences because the recurrent transformation (green) is fixed and can be applied as many times as we like.**

RNNs are often used in text processing because sentences and texts are naturally sequences of either words/punctuation marks or sequences of characters. For the same reason, recurrent neural networks are also used in speech processing.

In the case of a recurrent neural network, the loss function L of all time:

$$L_{\text{RNN}}(\hat{y},y)=\sum_{t=1}^{T}L(\hat{y}_t,y_t) \tag{14.1.2124}$$

And as always we do first a forward pass (first estimation based on initial chosen values) and afterwards we correct the weights with a backward pass done at each point in time (BPTT: Back-propagation Through Time). At time-step T the derivative of the loss L_{RNN} with respect to the different weight matrices W and biases is expressed as follows:

$$\frac{\partial L^{(T)}}{\partial W}=\sum_{t=1}^{T}\left.\frac{\partial L^{(T)}}{\partial W}\right|_{(t)} \qquad \frac{\partial L^{(T)}}{\partial b}=\sum_{t=1}^{T}\left.\frac{\partial L^{(T)}}{\partial b}\right|_{(t)} \tag{14.1.2125}$$

Remember that during our example introducing back-propagation earlier above, we used the chain rule twice. The ideal here would be to write something similar:

$$\frac{\partial L_t^T}{\partial W}=\frac{\partial L_t^T}{\partial W}\frac{\partial \widetilde{C}_T}{\partial h_t}\frac{\partial h_t}{\partial W} \tag{14.1.2126}$$

However this is incomplete as h_t depends on previous $h_{t-\ldots}$. Therefore we should write instead:

$$\begin{aligned}\frac{\partial L_t^T}{\partial W}&=\frac{\partial L_t^T}{\partial W}\frac{\partial \widetilde{C}_T}{\partial h_t}\left(\frac{\partial h_t}{\partial W}+\frac{\partial h_t}{\partial h_{t-1}}\frac{\partial h_{t-1}}{\partial W}+\frac{\partial h_t}{\partial h_{t-1}}\frac{\partial h_{t-2}}{\partial h_{t-2}}\frac{\partial h_{t-2}}{\partial W}+\ldots\right)\\&=\frac{\partial L_t^T}{\partial W}\frac{\partial \widetilde{C}_T}{\partial h_t}\left[\sum_{k=0}^{t}\left(\prod_{i=k+1}^{t}\frac{\partial h_i}{\partial h_{i-1}}\right)\frac{\partial h_k}{\partial W}\right]\end{aligned} \tag{14.1.2127}$$

Remark

A recursive network is just a generalization of a recurrent network. In a recurrent network the weights are shared (and dimensionality remains constant) along the length of the sequence because how would you deal with position-dependent weights when you encounter a sequence at test-time of different length to any you saw at train-time. In a recursive network the weights are shared (and dimensionality remains constant) at every node for the same reason.

There are lots of others variant of the LSTM presented above, like "Depth Gated RNNs" by Yao, et al. (12015 according to holocene calendar). There's also some completely different approach to tackling long-term dependencies, like "Clockwork RNNs" by Koutnik, et al. (12014).

Which of these variants is best? Do the differences matter? Greff, et al. (12015) do a nice comparison of popular variants, finding that they're all about the same. Jozefowicz, et al. (12015) tested more than ten thousand RNN architectures, finding some that worked better than LSTMs on certain tasks [297].

Remark

For people interested in practical application, see our `R` companion book where there is an example with a vanilla RNN, GRU and LSTM neural network on the same meteorological dateset.

14.1.20.8.7 Convolutional Neural Networks (CNN)

A "Convolutional Neural Network" (ConvNet/CNN) is a class of Deep Learning feed-forward artificial neural networks algorithm which can take in an input image, assign importance (learnable weights and biases) to various aspects/objects in the image and be able to differentiate one from the other[76].

The whole idea of Convolutional Neural Networks is inspired by the biology of the eye. While we as humans perceive a visual image as a detailed, coloured image of the world around us, there is actually quiet a lot of processing done in our brain to get to this point. The higher we go into the brain, the more concrete features are detected by the cells. With combination of cells that can perceive more and more complex contrast patterns, the brain is able to form cells that react to very specific visual stimulation, like cells that respond when we see cats or dogs.

Remark

CNNs are inspired by the layered structure of mammalian visual cortex based on studies of Hubel and Wiesel (11968 according to holocen calendar) in which the understanding of a scenery occurs through a hierarchical construction of images at different levels of abstraction from simple primitive feature extraction in earlier layers to more complex and expressive high-level contextual features in the later layers (Aggarwal, 12018).

What researchers did with Convolutional Neural Networks is exactly the same: CNN try to use this concept of combining low-level features in the image to higher and higher-level features, until we have cells that react to very specific things: Fur, eyes, cat ears etc. Then, we use a classic Neural Network to combine these features to a meaningful context: Two ears, fur and two eyes will with a high probability be a cat. You get the idea.

The objective of the Convolution Operation is to extract the high-level features such as edges, from the input image. ConvNets need not be limited to only one Convolutional Layer. Conventionally, the first ConvLayer is responsible for capturing the Low-Level features such as edges, color, gradient orientation, etc. With added layers, the architecture adapts to the High-Level features as well, giving us a network which has the wholesome understanding of images in the dataset, similar to how we would.

Caution! The fields of CNN is in its nascent age in this early 121st century (holocene calendar). At the time we write these lines there are, as far as we know, no textbooks for "pure mathematical" lovers detailing in a purely mathematical way each step of a CNN.

The reader may have noticed that in images, pixels that are close to one another usually represent the same type of information: sky water, leaver, fur bricks, and so on. The exception from the rule are the edges: the parts of an image where two different objects "touch" one another.

If we can train the neural network to recognize regions of the same information as well as the edges, this knowledge would allow the neural network to predict the object represented in the image. For example, if the neural network detected multiple skin regions and edges that look like parts of an oval with skin-like tone on the inside and bluish tone on the outside, then it is likely that it's a face on the sky background. If our goal is to detect people on pictures, the neural network will most likely succeed in predicting a person in this picture.

---

[76] A common misconception is to think that CNN are dedicated only to pure Computer Vision applications. However they are also used in Time Series analysis in Finance or Supply chain to detect anomalies thanks to Spectral Residual CNN (SR-CNN). Softwares like Microsoft Power BI have such tools natively available.

In the figure below, we have a RGB image which has been separated by its three color planes: Red, Green, and Blue. There are a number of such color spaces in which images exist — Grayscale, RGB, HSV, CMYK, etc.

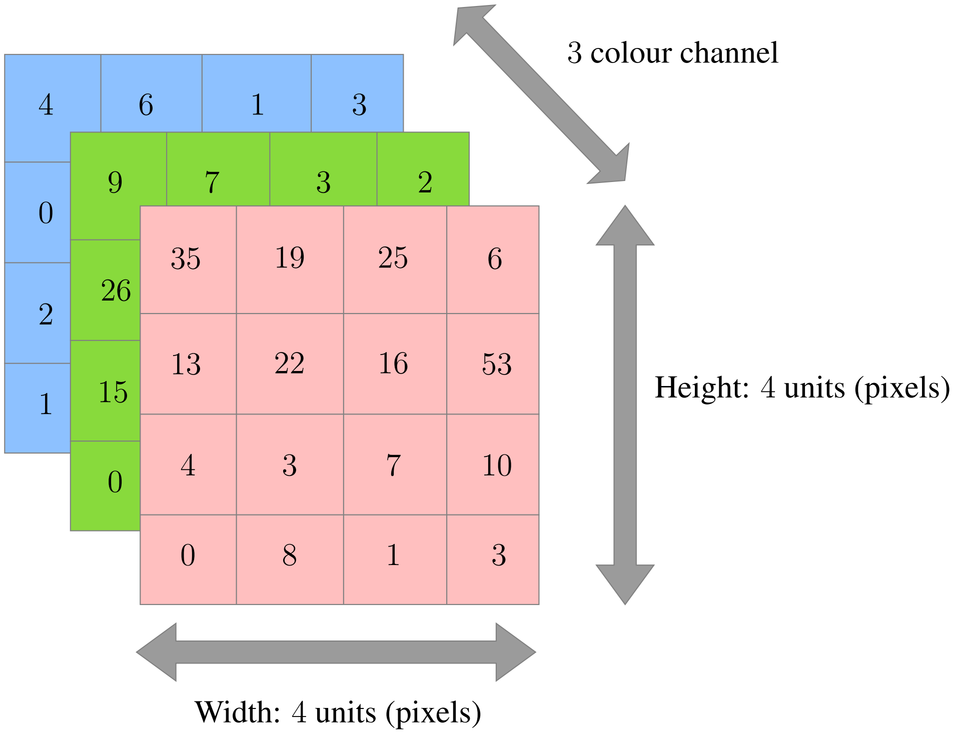

Figure 14.220: $4 \times 4 \times 3$ **RGB Image**

The reader can imagine how computationally intensive things would get once the images reach dimensions, say 8K (7680×4320). The role of the ConvNet is to reduce the images into a form which is easier to process, without losing features which are critical for getting a good prediction. This is important when we are to design an architecture which is not only good at learning features but also is scalable to massive datasets.

Having in mind that the most important information in the image is local, we can split the image into square patches using a moving window approach[77]. We can then train multiple smaller regression models at once, each small regression model receiving a square patch as input. The goal of each small regression model is to learn to detect a specific kind of pattern in the input patch. For example, one small regression model will learn to detect the sky; another one will detect the grass, the third one will detect edges of a building, and so on.

In the below demonstration, the image is a $5 \times 5 \times 1$ input image, The element involved in carrying out the convolution operation in the first part of a convolutional layer is named the "Kernel" or "filter" and is denoted K, represented in the figure below by the black border square. Below we have selected K as a $2 \times 2 \times 1$ matrix (see section Functional Analysis page 2299):

---

[77] Consider this as if we looked at a dollar bill in a microscope. To see the whole bill we have to gradually move our bill from left to right and from top to bottom. At each moment in time, we see only a part of the bill of fixed dimensions. This approach is named "moving window"

Figure 14.221: **A filter convolving across an image**

As we can see above see above, the kernel, filter shifts 9 times because of stride length $=1$ (non-strided), every time performing a matrix multiplication operation between K and the portion P of the image over which the kernel is hovering.

Also notice that if we denote by $H\times W$ the dimension on the input image (Height $\times$ Width), then the output dimension after the convolution by a kernel of dimension $k_1\times k_2$ will be:

$$(H-k_1+1)\times(W-k_2+1) \tag{14.1.2128}$$

And if we denote by S the stride value we then have:

$$\left(\frac{H-k_1}{s}+1\right)\times\left(\frac{W-k_2}{s}+1\right) \tag{14.1.2129}$$

The filter moves to the right with a certain stride value till it parses the complete width. Moving on, it hops down to the beginning (left) of the image with the same Stride Value and repeats the process until the entire image is traversed.

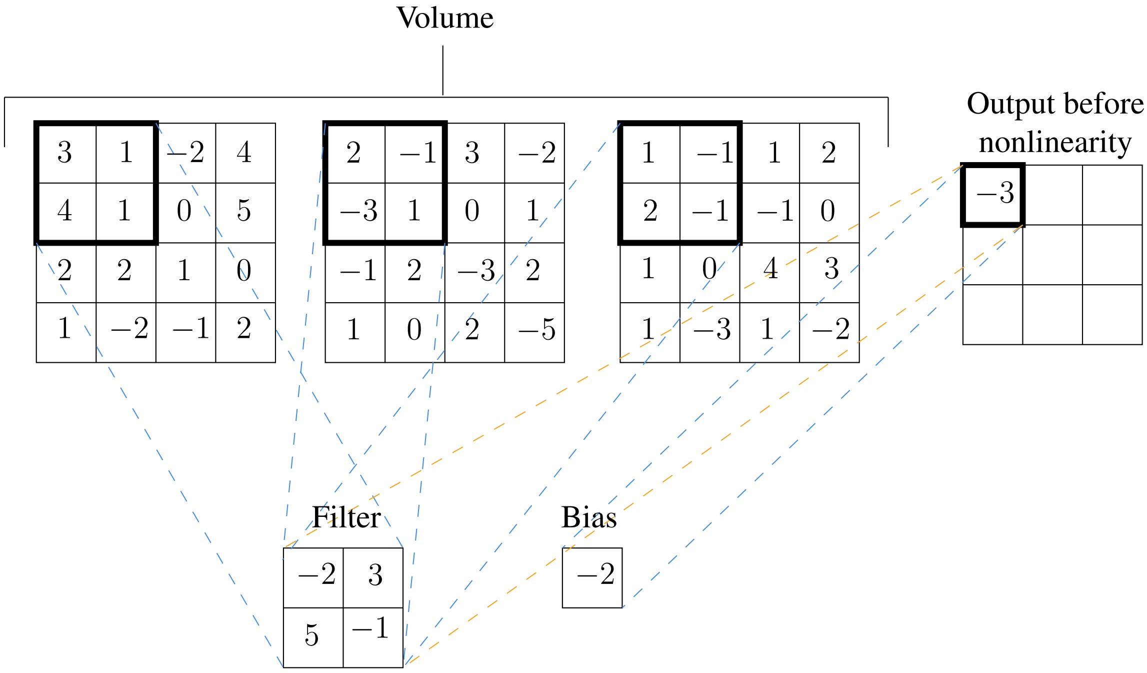

Figure 14.222: **Convolution of a volume consisting of three matrices**

An example of a convolution of a patch of a volume consisting of depth $L=3$ is shown above. The value of the convolution, -3, was obtained as:

$$\begin{aligned} C(1,1) = &(-2\cdot 3+3\cdot 1+5\cdot 4+-1\cdot 1)+(-2\cdot 2+3\cdot(-1)+5\cdot(-3)+-1\cdot 1)\\ &+(-2\cdot 1+3\cdot(-1)+5\cdot 2+-1\cdot(-1))+(-2)=-3 \end{aligned} \tag{14.1.2130}$$

Or in the most general case this will be written (the expression is slightly different from what we saw during our study of matrix convolution):

$$\boxed{\begin{aligned} C[m,n] &= \text{Image} * \text{Kernel} + \text{Bias} = f*h[m,n]+\text{Bias}\\ &= \sum_{L=1}^{n}\sum_{i=-\lceil\frac{k-1}{2}\rceil}^{+\lceil\frac{k-1}{2}\rceil}\sum_{j=-\lceil\frac{k-1}{2}\rceil}^{+\lceil\frac{k-1}{2}\rceil} h\left(i+\left\lfloor\frac{k+1}{2}\right\rfloor, j+\left\lfloor\frac{k+1}{2}\right\rfloor\right) f(m+i,n+j)+\text{Bias} \end{aligned}} \tag{14.1.2131}$$

What some engineer also write sometimes (...) assuming the Kernel is zero centered:

$$C[m,n]=f*h[m,n]+\text{Bias}=\sum_{k=-\infty}^{+\infty}\sum_{j=-\infty}^{+\infty}\sum_{i=-\infty}^{+\infty}h[m-i,n-j,p-k]f[i,j,k]+\text{Bias} \tag{14.1.2132}$$

or :

$$C_{ij}=(I*K)_{ij}=\sum_{m=0}^{k_1-1}\sum_{n=0}^{k_2-1}I_{i-m,j-n}\cdot K_{m,n}+b \tag{14.1.2133}$$

where C denotes the number of layers, I the input, K the kernel.

✍**Example:**

Let us consider the following notation:

$$C[x,y]=(I*K)(x,y)=\sum_{\alpha=-\infty}^{+\infty}\sum_{\beta=-\infty}^{+\infty}I(x-\alpha,y-\beta)K(\alpha,\beta)$$

Let's not zero-center I and compute $C[2,2]$ with a 3×3 kernel:

$$\begin{aligned}
C_{22}=&\sum_{\alpha=-1}^{+1}\sum_{\beta=-1}^{+1}I(x-\alpha,y-\beta)K(\alpha,\beta)\\
=&I_{2+1,2+1}K_{-1,-1}+I_{2+1,2-0}K_{-1,0}+I_{2+1,2-1}K_{-1,1}\\
&\quad+I_{2-0,2+1}K_{0,-1}+I_{2-0,2-0}K_{0,0}+I_{2-0,2-1}K_{0,1}\\
&\quad+I_{2-1,2+1}K_{1,-1}+I_{2-1,2-0}K_{1,0}+I_{2-1,2-1}K_{1,1}\\
=&I_{3,3}K_{-1,-1}+I_{3,2}K_{-1,0}+I_{3,1}K_{-1,1}\\
&\quad+I_{2,3}K_{0,-1}+I_{2,2}K_{0,0}+I_{2,1}K_{0,1}\\
&\quad+I_{1,3}K_{1,-1}+I_{1,2}K_{1,0}+I_{1,1}K_{1,1}
\end{aligned}$$

We notice that a 3×3 kernel that is zero-centered (i.e., its origin is in the middle of the filter) has indices running from -1 to $+1$. To reiterate, -1 is a valid index for K (not padded) because we are zero-centered, but anything lower than that will just return zero.

Remark

Given an input image I and a filter (kernel) K of dimensions $k_1\times k_2$, the cross-correlation operation is given by:

$$(I\otimes K)_{ij}=\sum_{m=0}^{k_1-1}\sum_{n=0}^{k_2-1}I(i+m,j+n)K(m,n)\tag{14.1.2134}$$

Given an input image I and a filter (kernel) K of dimensions $k_1\times k_2$, the convolution operation is given by:

$$\begin{aligned}
(I*K)_{ij}&=\sum_{m=0}^{k_1-1}\sum_{n=0}^{k_2-1}I(i-m,j-n)K(m,n)\\
&=\sum_{m=0}^{k_1-1}\sum_{n=0}^{k_2-1}I(i+m,j+n)K(-m,-n)
\end{aligned}\tag{14.1.2135}$$

It is easy to see that convolution is the same as cross-correlation with a flipped kernel i.e: for a kernel K where $K(-m,-n)=K(m,n)$.

In computer vision, CNNs often get volumes as input, since an image is usually represented by three channels: R, G, and B, each channel being a monochrome picture.

Two important properties of convolution are "stride" and "padding". Stride is the step size of the moving window. In the first example above, the stride is 1, that is the filter slides to the right and to the bottom by one cell at a time. In the figure below we can see a partial example of convolution with stride 2. We can see that the output matrix is smaller when the stride is bigger:

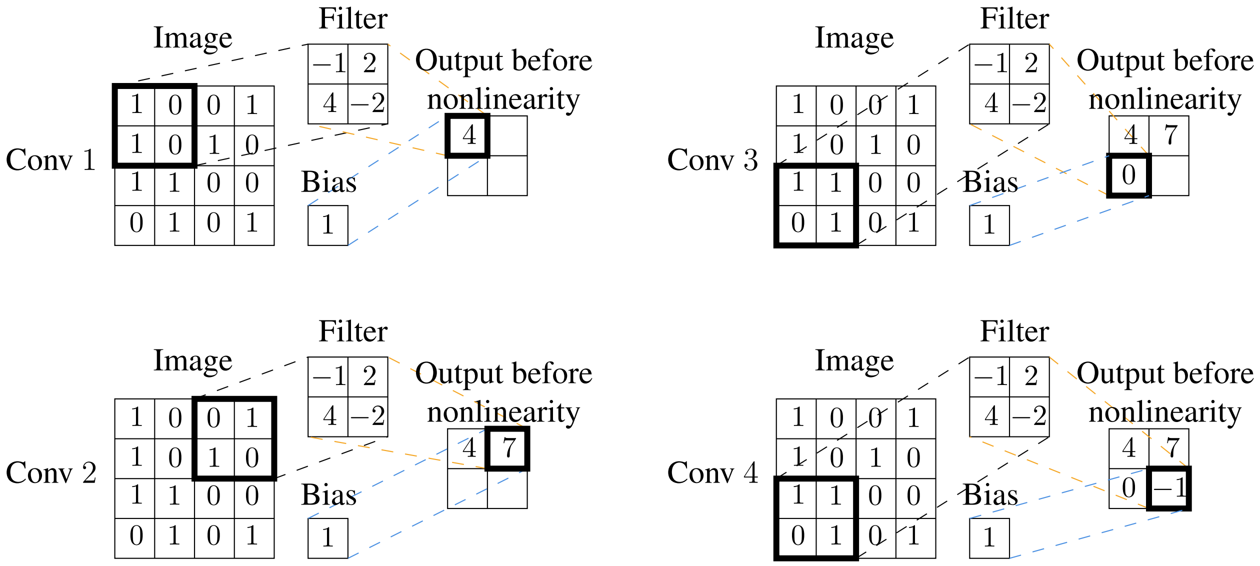

Figure 14.223: Convolution with stride 2

The convolutional formula above with a spride s becomes:

$$C[m,n]=\text{Image}*\text{Kernel}+\text{Bias}=f*h[m,n]+\text{Bias}$$
$$=\sum_{L=1}^{n}\sum_{i=-\lceil\frac{k-1}{2}\rceil}^{+\lceil\frac{k-1}{2}\rceil}\sum_{j=-\lceil\frac{k-1}{2}\rceil}^{+\lceil\frac{k-1}{2}\rceil} h\left(si+\left\lfloor\frac{k+1}{2}\right\rfloor,sj+\left\lfloor\frac{k+1}{2}\right\rfloor\right)f(m+si,n+sj)+\text{Bias} \tag{14.1.2136}$$

Padding allows getting a larger output matrix (often, we want the output of a convolution to have the same size as the input[78]); it's the width of the square of additional cells with which we surround the image (or volume) before we convolve it with the filter. The cells added by padding usually contain zeroes. In the first example, the padding is 0, so no additional cells are added to the image. In the figure below, on the other hand, the stride is 2 and padding is 1, so a square of width 1 of additional cells are added to the image. We can see that the output matrix is bigger when padding is bigger (to save space only the first two of the nine convolutions are shown).

---

[78] It's quite common to see convolution layers with stride of 1, filters of size k, and zero padding of size $(k-1)/2$ to preserve size!

0	0	0	1	0	1	0	0
0	0	0	0	0	0	0	0
0	0	0	0	0	0	0	0

Figure 14.225: **Image with padding** 2

Remark

There are two types of results to the operation — one in which the convolved feature is reduced in dimensionality as compared to the input, and the other in which the dimensionality is either increased or remains the same. This is done by applying "Valid Padding" in case of the former, or "Same Padding" in the case of the latter.

This section would not be complete without presenting "pooling", a technique very often used in CNNs. Pooling works in a way very similar to convolution, as a filter applied using a moving window approach. However, instead of applying a trainable filter to an input matrix or a volume, pooling layer applies a fixed operator, usually either max ("Max pooling") or average ("Average pooling"). Similarly to convolution, pooling has hyperparameters: the size of the filter, the stride and the type of pooling.

Mainly the purpose of pooling is to decrease the computational power required to process the data through dimensionality reduction. Furthermore, it is useful for extracting dominant features which are rotational and positional invariant, thus maintaining the process of effectively training of the model.

An example of max pooling with filter of size 2 and stride 2 is shown below:

Usually, a pooling layer follows a convolution layer, and it gets the output of convolution as input. When pooling is applied to a volume, each matrix in the volume is processed independently of others. Therefore, the output of the pooling layer applied to a volume of the same depth as the input.

Depending on the complexities in the images, the number of such layers may be increased for capturing low-levels details even further, but at the cost of more computational power.

We may have noticed that we create quite a lot of images by running our input image through many different filters. Even though the images size will slightly decrease with each filter in each layer, we generally generate exponentially more and more data with each convolutional layer we add. To combat this issue, we use a process named MaxPooling: After filtering an image, we will reduce its size drastically by unifying a pixel neighbourhood to one single value. Most prominently, we use MaxPooling, meaning we take the maximum pixel value of a pixel neighbourhood, but we could also use other methods like MinPolling, AvgPolling or MedianPolling.

After going through the above process, we have successfully enabled the model to understand the features. Moving on, we are going to flatten the final output and feed it to a regular Neural Network for classification purposes.

In the example below depicting a complete forward pass:

1. We start with an input image of size 5×5.
2. We then apply convolution using 2×2 kernel and stride $= 1$, that produces feature map of size 4×4.

3. We then apply a 2×2 max-pooling with stride 2, that reduces feature map to size 2×2.
4. We then apply a logistic sigmoid.
5. Then one fully connected layer with two neurons.
6. And an output layer

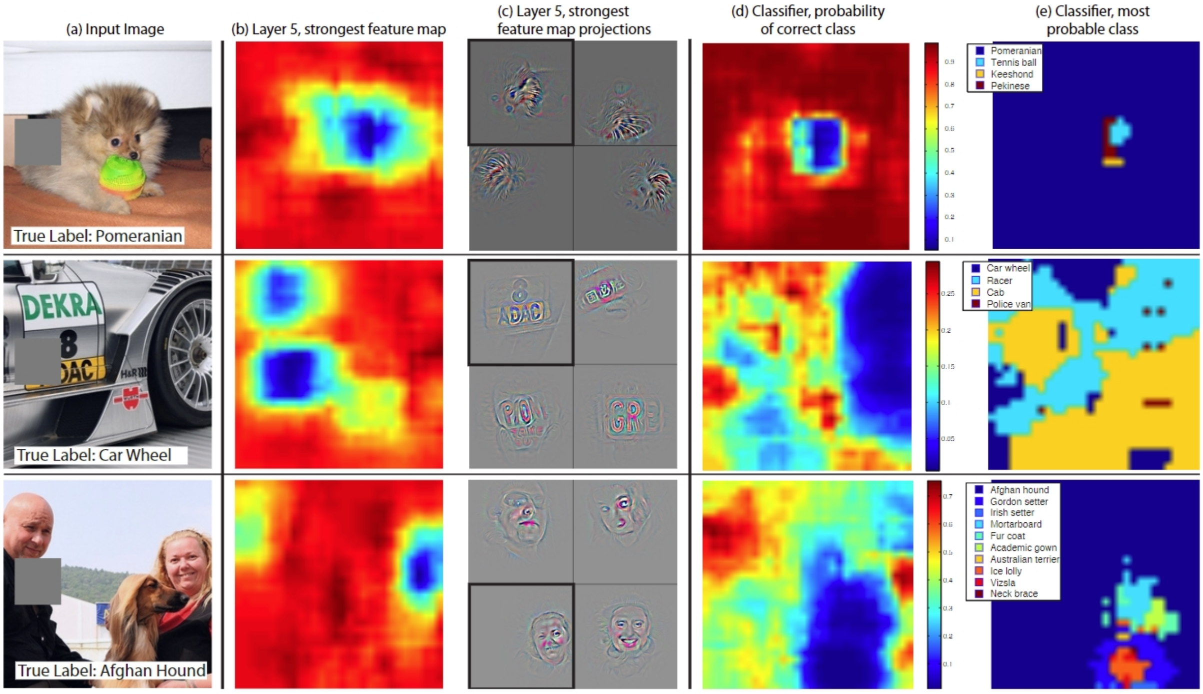
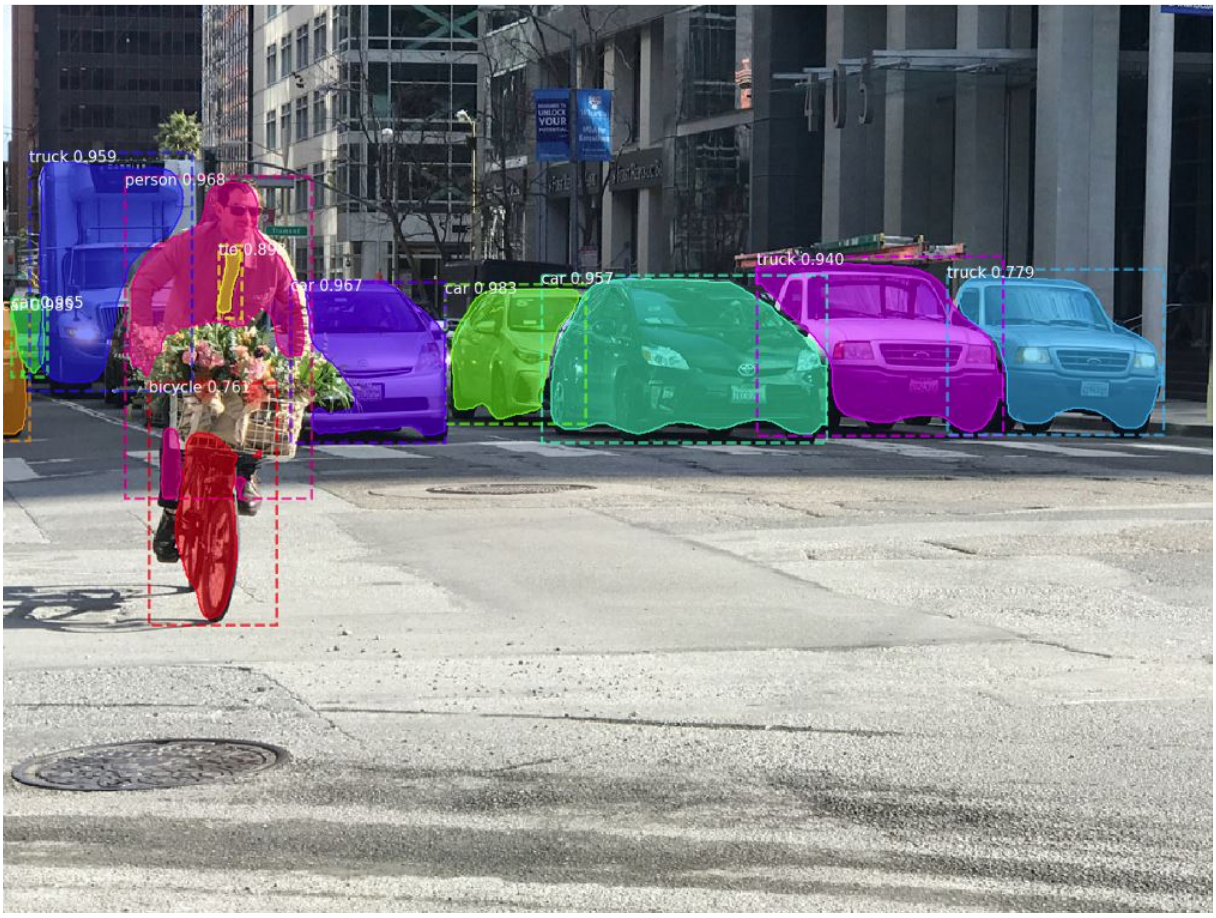
In the figure below we can see how CNN are influenced by the presence of a perfect gray square on a photo:



The last level of a CNN, the most popular known one in massmedia, is sometimes named a "segmentation mask" because the input image is reduced to its simple geometrical elements:



truck 0.959
person 0.968
tie 0.89
car 0.965
car 0.967
car 0.983
car 0.957
truck 0.940
truck 0.779
bicycle 0.761

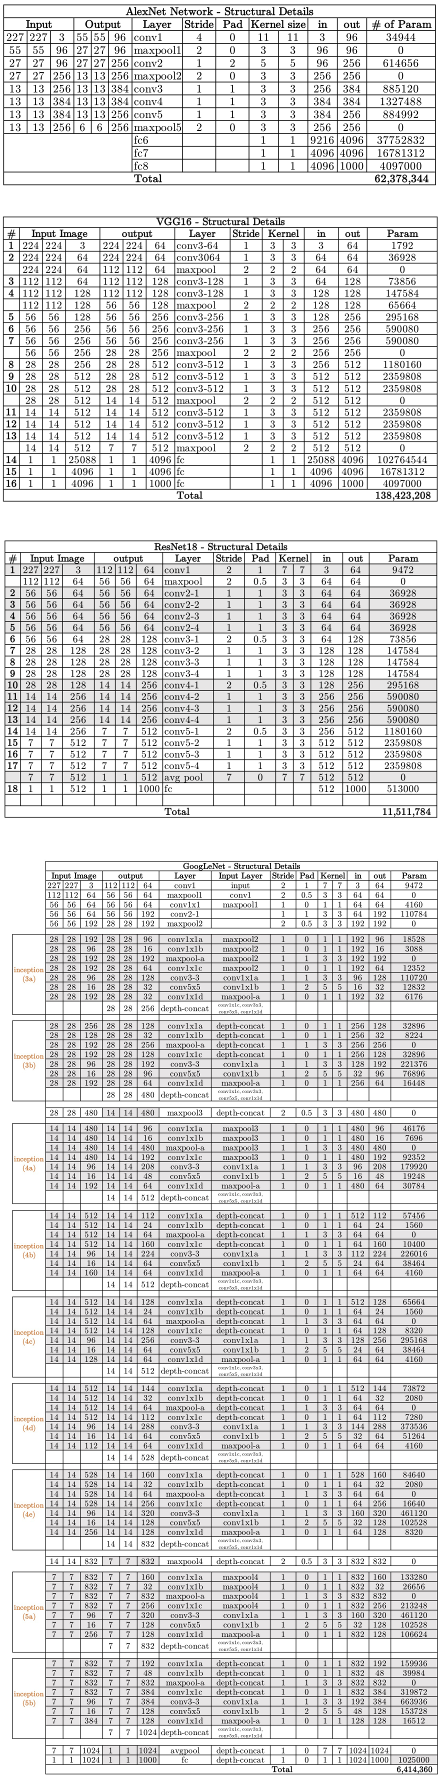
Our Convolutional neural network really consists of two parts: Convolutional layers and fully connected decision layers. Both are connected using a flattening layer that converts an array of 2D images to a single 1D list of numeric values.

In most cases CNNs use a cross-entropy loss on the one-hot encoded output. For a single image the cross entropy loss looks like this:

$$H(y_c,\hat{y}_c)=\sum_{c=1}^{M} y_c\cdot\log(\hat{y}_c) \tag{14.1.2137}$$

where M is the number of classes (i.e. 1000 in ImageNet) and $\hat{y}_c$ is the model's prediction for that class (i.e. the output of the softmax for class c). Due to the fact that the labels are one-hot encoded and y is a $[1000\times 1]$ vector of ones and zeroes, y_c is either 1 or 0. Thus, out of the whole sum only one term will actually be added: the one with $y_c=1$.

There are various architectures of CNNs available which have been key in building algorithms which power and shall power AI as a whole in the foreseeable future. Like LeNet, AlexNet, VGGNet, GoogLeNet, ResNet, ZFNet, SR-CNN:



AlexNet Network - Structural Details

Figure 14.228: **Various type of CNN internal structures (author: Aqeel Anwar)**

14.1.20.8.8 Generative Adversarial Network (GAN)

A "generative adversarial network" (GAN) is a class of machine learning systems invented by Ian Goodfellow and his colleagues in 12014 (holocene calendar). Two neural networks contest with each other in a game (in the sense of game theory, often but not always in the form of a zero-sum game). Given a training set, this technique learns to generate new data with the same statistics as the training set. For example, a GAN trained on photographs can generate new photographs that look at least superficially authentic to human observers, having many realistic characteristics. Though originally proposed as a form of generative model for unsupervised learning, GANs seems also proven useful for semi-supervised learning, fully supervised learning and reinforcement learning.

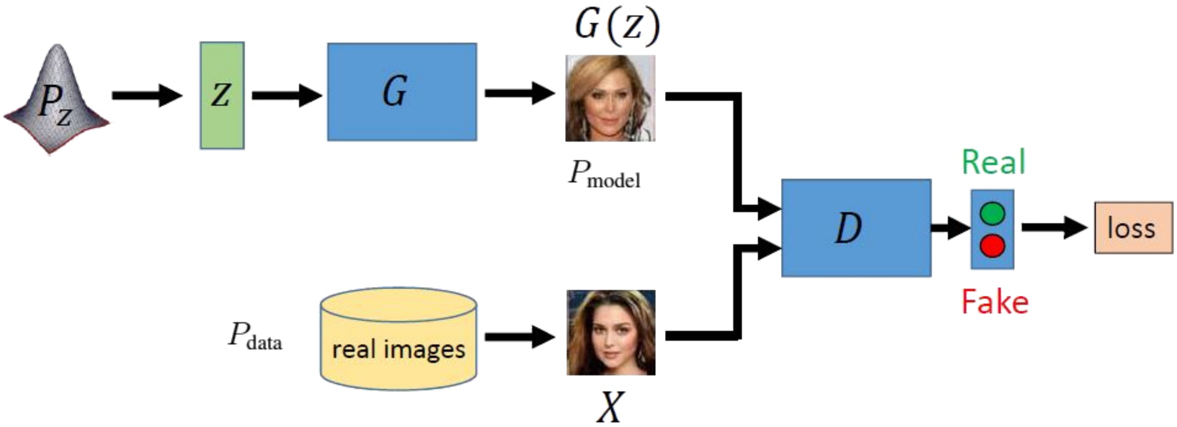

Figure 14.229: **General idea of a GAN**

The generative network generates candidates while the discriminative network evaluates them. The contest operates in terms of data distributions. Typically, the generative network learns to map from a latent space to a data distribution of interest, while the discriminative D network distinguishes candidates produced by the generator G from the true data distribution. The generative network's training objective is to increase the error rate of the discriminative network (i.e., "fool" the discriminator network by producing novel candidates that the discriminator thinks are not synthesized (are part of the true data distribution)).

A known dataset serves as the initial training data for the discriminator D. Training it involves presenting it with samples from the training dataset, until it achieves acceptable accuracy. The generator trains based on whether it succeeds in fooling the discriminator. Typically the generator is seeded with randomized input that is sampled from a predefined latent space (e.g. a multivariate Normal distribution). Thereafter, candidates synthesized by the generator are evaluated by the discriminator. Back-propagation is applied in both networks so that the generator produces better images, while the discriminator becomes more skilled at flagging synthetic images. The generator is typically a deconvolutional neural network, and the discriminator is a convolutional neural network.

Training a vanilla GAN is like a 2-players game, where:

- The discriminator is trying to maximize the cost function $L(D, G)$

- The generator is trying to minimize the cost function $L(D,G)$

The discriminator is the generator's opponent, and performs a mapping $D(x) \in [0,1]$. Its goal is to look at sample images (that could be real or synthetic from the generator), and determine if they are real samples ($D(x)$ closer to 1) or synthetic samples from the generator ($D(x)$ closer to 0). $D(x)$ can be interpreted as the probability that the image is a real training example.

The generator, $G(z)$, has parameters $\theta^{(G)}$, and the discriminator, $D(x)$, has parameters $\theta^{(D)}$. The generator can only control $\theta^{(G)}$, while the discriminator can only control $\theta^{(D)}$.

Remark

Keep in mind that $D(x)$ is simply a function that maps to $[0,1]$. So the possible values of $D(G(z))+D(x)$ range from 0 to 2.

In addition to this, the discriminator and generator have different cost functions they wish to optimize:

- This ought to be intuitive as the generator and discriminator have different goals.
- We denote the discriminator's cost function as $L^{(D)}\left(\theta^{(D)},\theta^{(G)}\right)$. For convenience, we will sometimes denote this as $L(D)$.
- We denote the generator's cost function as $L^{(G)}\left(\theta^{(D)},\theta^{(G)}\right)$. For convenience, we will sometimes denote this as $L(G)$

What is the solution?

- The discriminator wishes to minimize $L^{(D)}$, but can only do so by changing $\theta^{(D)}$
- The generator wishes to minimize $L^{(G)}$, but can only do so by changing $\theta^{(G)}$

This is slightly different from the optimization problems we've described thus far, where we have one set of parameters to minimize one cost function L.

Instead of treating this as an optimization problem, we treat this as a game between two players. The solution to a game is named a "Nash equilibrium". For GANs, a Nash equilibrium is a tuple, $(\theta^{(D)},\theta^{(G)})$ that is:

- A local minimum of $L(D)$ with respect to $\theta^{(D)}$
- A local minimum of $L(G)$ with respect to $\theta^{(G)}$

The simplest type of game to analyse is a zero-sum game, in which the sum of the generator's loss and the discriminator's loss is always zero. In a zero-sum game, the generator's loss is:

$$L(D)+L(G)=0 \Leftrightarrow L(D)=-L(G) \qquad (14.1.2138)$$

The solution for a zero-sum game is named a minimax solution, where the goal is to minimize the maximum loss. Since the game is zero-sum, we can summarize (see proof just below) the entire game by stating that the loss function is explicitly (based on binary cross-entropy as introduced at page 6463):

$$\max_D \min_G \left\{ \mathrm{E}_{x\sim p_{\text{data}}}\left[\underbrace{\log(D(x))}_{\substack{\text{output of the}\\ \text{discriminator for}\\ \text{real data}}}\right] + \mathrm{E}_{z\sim p_z}\left[\log\left(1-\underbrace{D(G(z))}_{\substack{\text{output of the}\\ \text{discriminatorfor}\\ \text{artificial data}}}\right)\right]\right\} \tag{14.1.2139}$$

Often condensed in the following form:

$$(D^*,G^*)=\max_D \min_G L(D,G) \tag{14.1.2140}$$

with obviously:

$$L(D,G)=\{\mathrm{E}_{x\sim p_{\text{data}}}[\log(D(x))]+\mathrm{E}_{z\sim p_z}[\log(1-D(G(z)))]\} \tag{14.1.2141}$$

- The discriminator wants to maximize the objective (i.e., its payoff) such that $D(x)$ is close to 1 and $D(G(z))$ is close to zero.
- The generator wants to minimize the objective (i.e., its loss) so that $D(G(z))$ is close to 1.

The Nash equilibrium (see section Games and Decision Theory page 7395) of this particular game is achieved at:

$$p_{\text{data}}=p_{\text{model}} \tag{14.1.2142}$$

Proof 14.8.2. Let us recall the definition of cross-entropy (see page 6463):

$$H(p,q)=\sum_i p_i\log(q_i)=\mathrm{E}(\log(q_i)) \tag{14.1.2143}$$

Let us rewrite it $H(y,D(x))$ where H remains the cross-entropy x is sampled either from p_{data} or from p_{model} with a probability of 50%. More formally:

$$x\sim\begin{cases} p_{\text{data}}\rightarrow y=1, & \text{with prob 0.5}\\ p_{\text{model}}\rightarrow y=0, & \text{otherwise}\end{cases} \tag{14.1.2144}$$

We consider y to be 1 if x is sampled from the real distribution and 0 if it is sampled from the fake one. Finally, $D(x)$ represents the probability with which D thinks that x belongs to p_{data}. By writing the cross-entropy formula we get:

$$H(y,D(x))=\mathrm{E}_y[-\log(D(x))]=\frac{1}{N}\sum_{i=1}^{N} y_i\log(D(x_i)) \tag{14.1.2145}$$

where N is the size of the dataset. Since each class has $N/2$ samples we can split this sum into two parts:

$$H(y, D(x)) = -\left[\frac{1}{N}\sum_{i=1}^{N/2} y_i \log(D(x_i)) + \frac{1}{N}\sum_{i=N/2}^{N}(1-y_i)\log((1-D(x_i)))\right] \quad (14.1.2146)$$

The first of the two terms represents the samples from the p_{data} distribution, while the second one the samples from the p_{model} distribution. Since all y_i are equally likely to occur, we can convert the sums into expectations:

$$H(y, D(x)) = -\left[\frac{1}{2}\mathrm{E}_{x\sim p_{\text{data}}}[\log(D(x))] + \frac{1}{2}\mathrm{E}_{x\sim p_{\text{model}}}[\log(1-D(x))]\right] \quad (14.1.2147)$$

At this point, we will ignore $1/2$ from the equations since it's constant and thus irrelevant when optimizing this equation. Now, remember that samples that were drawn from p_{model} were actually outputs from the generator (obviously this affects only the second term). If we substitute $D(x), x\sim p_{\text{model}}$ with $D(G(z)), z\sim p_z$ we will get:

$$H(y, D(x)) = -\left[\mathrm{E}_{x\sim p_{\text{data}}}[\log(D(x))] + \mathrm{E}_{z\sim p_z}[\log(1-D(G(z)))]\right] \quad (14.1.2148)$$

This is the final form of the discriminator loss.

■ Q.E.D.

Remark

This whole endeavour was to provide a mathematical formulation to training GANs. In practice there are maaaany tricks that are invoked to effectively train a GAN, that are not depicted in the above equations.

For GANs, in practice this game is implemented in an iterative numerical approach. It involves two steps:

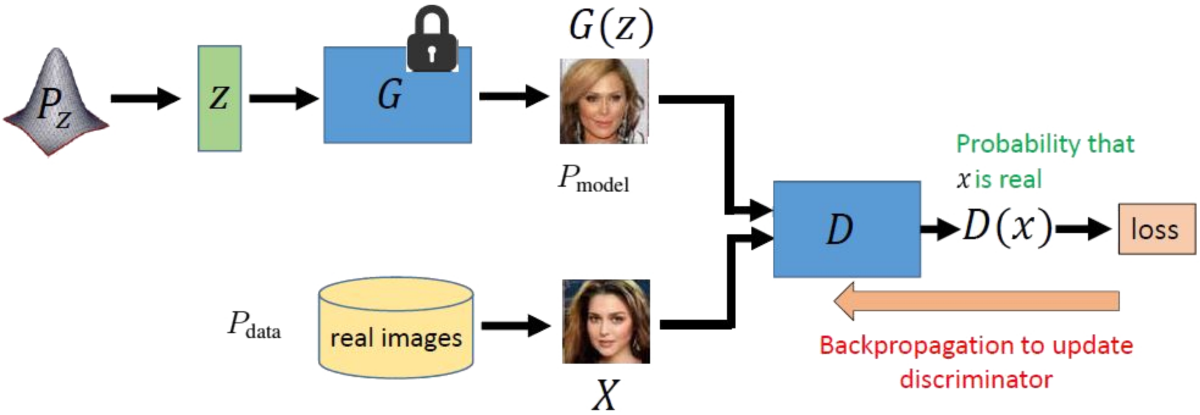

Figure 14.230: General idea of a GAN Discriminator training

Gradient ascent for the discriminator. We modify $\theta^{(D)}$ to maximize the minimax objective:

$$\max_D \left\{ \mathrm{E}_{x\sim p_{\text{data}}} \left[\underbrace{\log(D(x))}_{\substack{\text{output of the}\\ \text{discriminator for}\\ \text{real data}}} \right] + \mathrm{E}_{z\sim p_z}\left[\log\left(1-\underbrace{D(G(z))}_{\substack{\text{output of the}\\ \text{discriminatorfor}\\ \text{artificial data}}}\right)\right]\right\} \tag{14.1.2149}$$

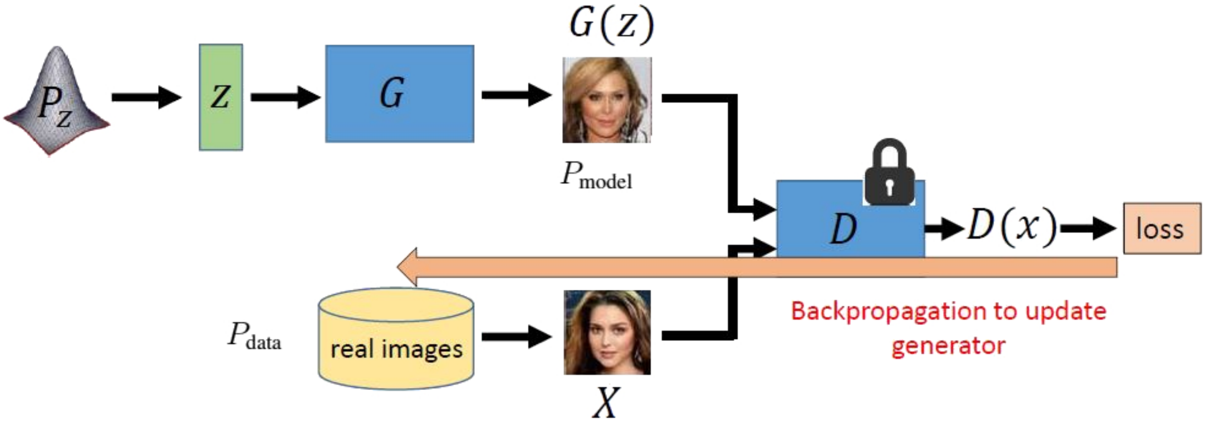

Figure 14.231: **General idea of a GAN Generator training**

Gradient descent on the discriminator. We modify $\theta^{(G)}$ to minimize the minimax objective:

$$\min_G \left\{ \mathrm{E}_{x\sim p_{\text{data}}} \left[\underbrace{\log(D(x))}_{\substack{\text{output of the}\\ \text{discriminator for}\\ \text{real data}}} \right] + \mathrm{E}_{z\sim p_z}\left[\log\left(1-\underbrace{D(G(z))}_{\substack{\text{output of the}\\ \text{discriminatorfor}\\ \text{artificial data}}}\right)\right]\right\} \tag{14.1.2150}$$

For the sake of intuition, consider that instead of optimizing with respect to $\theta^{(D)}$, we get to optimize $D(x)$ for every value of x. Further, assume that p_{data} and p_{model} are non-zero everywhere. What would be the optimal strategy for $D(x)$?

To answer this question, we differentiate with respect to $D(x)$ and set the derivative equal to zero. In particular, we start with:

$$L^{(D)} = \int p_{\text{data}}(x)\log(D(x))\,\mathrm{d}x + \int p_{\text{model}}(x)\log(1-D(x))\,\mathrm{d}x \tag{14.1.2151}$$

Differentiating with respect to $D(x)$, we get:

$$\frac{\partial L^{(D)}}{\partial D(x)} = -\int p_{\text{data}}(x)\frac{1}{D(x)}\mathrm{d}x - \int p_{\text{model}}(x)\frac{1}{1-D(x)})\mathrm{d}x \tag{14.1.2152}$$

We can now set the derivative equal to zero to find the optimal $D(x)$. This leads to:

$$\int p_{\text{data}}(x)\frac{1}{D(x)}\mathrm{d}x = \int p_{\text{model}}(x)\frac{1}{1-D(x)}\mathrm{d}x \tag{14.1.2153}$$

A solution occurs when the integrands are equal for all x, i.e.:

$$p_{\text{data}}(x)\frac{1}{D(x)}=p_{\text{model}}(x)\frac{1}{1-D(x)} \tag{14.1.2154}$$

Rearranging terms, this gives:

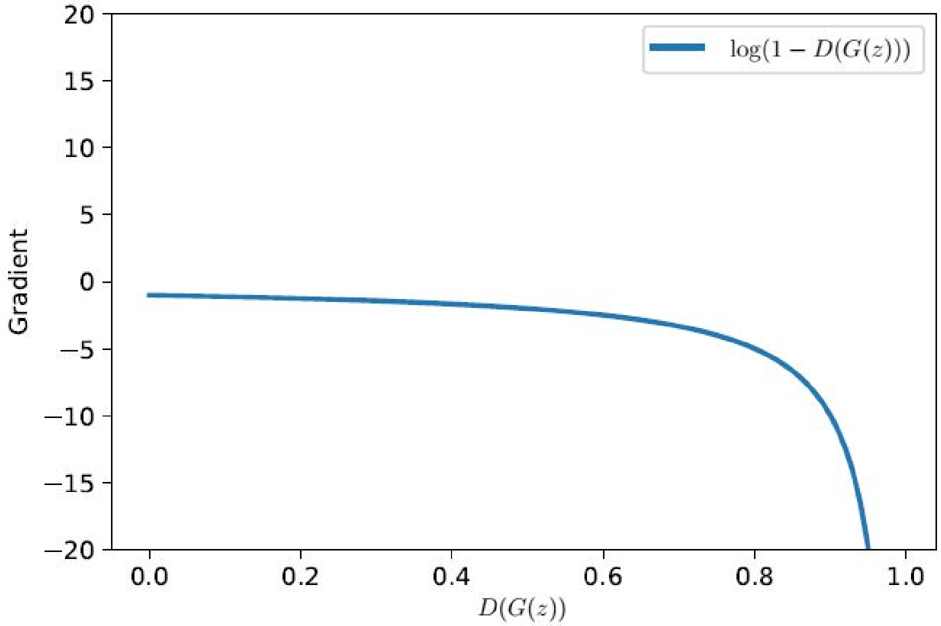
$$D(x)=\frac{p_{\text{data}}(x)}{p_{\text{data}}(x)+p_{\text{model}}(x)} \tag{14.1.2155}$$

If the generator has high enough capacity, it will then move to set $p_{\text{model}}(x)=p_{\text{data}}(x)$ for all x. This results in the output:

$$D(x)=\frac{p_{\text{data}}(x)}{p_{\text{data}}(x)+p_{\text{model}}(x)}=\frac{1}{2} \tag{14.1.2156}$$

This is the Nash equilibrium!

As stated, the current training paradigm has an important limitation. Note that the gradient of $\log(1-D(G(z)))$ is $-\frac{1}{1-D(G(z))}$, and thus has the following gradient as function of $D(G(z))$:



Therefore, if $D(G(z))\cong 0$, as may happen early on in training when the discriminator can tell the difference between real and synthetic examples, the gradient is close to zero. This results in little learning for $\theta^{(G)}$, and thus in practice the generator cost function:

$$\mathrm{E}_{z\sim p_z}\left[\log\left(1-D(G(z))\right)\right] \tag{14.1.2157}$$

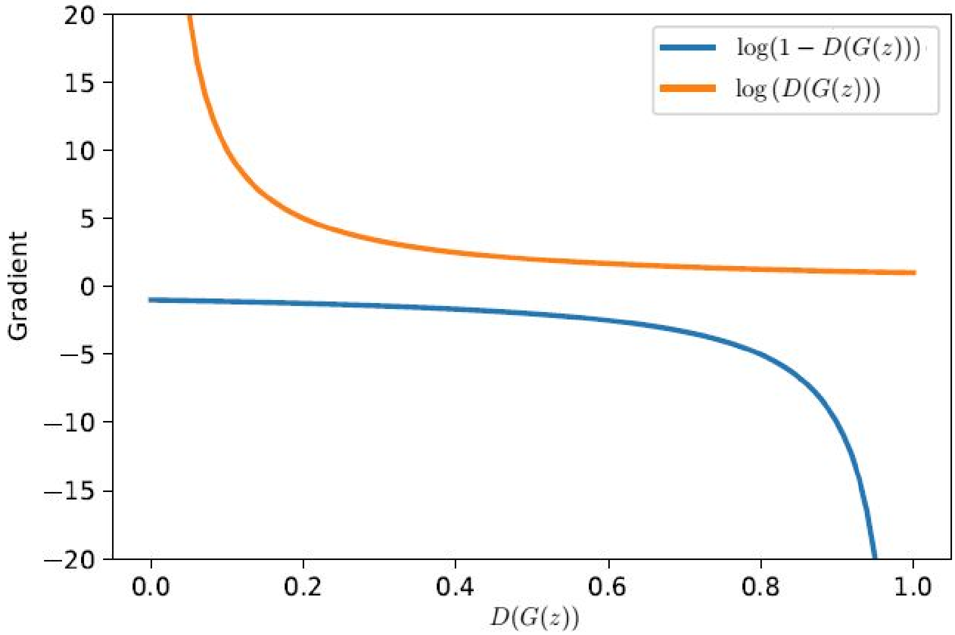
is rarely ever used.

Instead, we opt for a cost function that has a large gradient when $D(G(z))\cong 0$, so that the generator is encouraged to learn much more early in training. This is the cost function:

$$-\mathrm{E}_{z\sim p_z}\left[\log\left(D(G(z))\right)\right] \tag{14.1.2158}$$

This still obtains the same overall goal of being minimized when $D(G(z)) = 1$, but now admits far more learning when the generator performs poorly.

The gradient of this new cost for the generator encourages more learning when the generator performs poorly.



Note that by changing the cost function for the generator network, the game is no longer zero-sum. This is a heuristic change made to the game to solve the practical problem of saturating gradients when the generator isn't doing well!

Remark

There are largely empirical good practices to train a GAN network like the fact to normalize the images between -1 and $+1$, and use $\tanh$ as the output of the generator model, let the prior on z be Gaussian rather than uniform, avoid sparse gradients, avoid using ReLU or maxpool and use LeakyReLU instead and to downsample, increase the stride, etc.

14.1.20.8.9 Objective, cost and loss function

In machine learning (i.e. Statistics...), people talk about objective function, cost function, loss function[79]. These are not very strict terms and they are highly related. However:

- "Loss function", often denoted L, is usually a function defined on a single data point, prediction and label, and measures the penalty. For example:
  - Square loss (also named "quadratic loss", "L_2 loss" or MSE):

    $$L(f(x_i|\theta),y_i)=(f(x_i|\theta)-y_i)^2 \tag{14.1.2159}$$

    used in linear regression.
  - Mean Absolute Error (also named "L_2 loss" or MAE):

    $$L(f(x_i|\theta),y_i)=|f(x_i|\theta)-y_i| \tag{14.1.2160}$$

    used in linear regression.
  - Cross entropy loss:

    $$L(f(x_i|\theta),y_i)=-(y_i\log(p_i)+(1-y_i)\log(1-p_i)) \tag{14.1.2161}$$

    used in binary classification.
  - Hinge loss:

    $$L(f(x_i|\theta),y_i)=\max(0,1-f(x_i|\theta)) \tag{14.1.2162}$$

    used in SVM.
  - Huber loss:

    $$L_\delta=\begin{cases}\frac{1}{2}(y-\hat{y})^2 & \text{if } |(y-\hat{y})|<\delta\\ \delta((y-\hat{y})-\frac{1}{2}\delta) & \text{otherwise}\end{cases} \tag{14.1.2163}$$

    Typically used for regression. It's less sensitive to outliers than the MSE as it treats error as square only inside an interval. There is also a "pseudo-Huber loss" function and a "modified Huber loss".
  - $0/1$ loss:

    $$L(f(x_i|\theta),y_i)=1\Leftrightarrow f(x_i|\theta)\neq y_i \tag{14.1.2164}$$

    used in theoretical analysis.
  - ...
- "Cost function", often denoted J, is usually more general. It might be a sum of loss functions over your training set plus some model complexity penalty (regularization). For example:

---

[79] Not to be confused with the "activation functions" used in neural networks!

- Mean Squared Error:

$$\text{MSE}(\theta)=\frac{1}{N}\sum_{i=1}^{N}(f(x_i|\theta)-y_i)^2 \tag{14.1.2165}$$

- SVM cost function:

$$\text{SVM}(\theta)=||\theta||^2+C\sum_{i=1}^{N}\xi_i \tag{14.1.2166}$$

- ...

Or as we have seen earlier typically for neural networks the following cost functions:

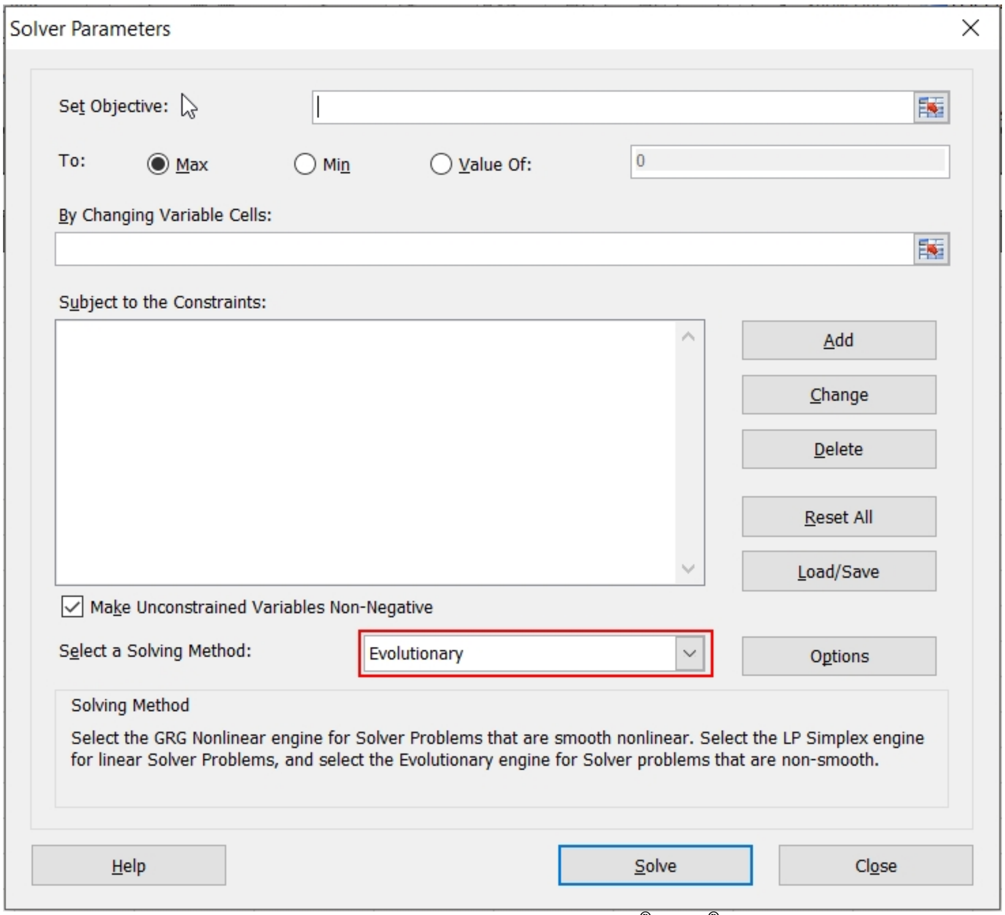
Cost function name	**Mathematical expression**	**Gradient**
Quadratic cost	$J_{\text{MST}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\frac{1}{2}\sum_{i=1}^{n}(\phi_i(z)-y_i)^2$	$\nabla_\phi J_{\text{MST}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum_{i=1}^{n}(\phi_i(z)-y_i)$
Cross-entropy cost	$J_{\text{CE}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=-\sum_{i=1}^{n}[y_i\ln(\phi(z))+(1-y_i)\ln(1-y_i)]$	$\nabla_\phi J_{\text{CE}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum_{i=1}^{n}\frac{\phi_i(z)-y_i}{(1-\phi_i(z))\phi_i(z)}$
Exponential cost	$J_{\text{exp}}\left(W,\vec{b},\vec{y},\vec{\phi},\tau\right)=\tau\exp\left(\frac{1}{\tau}\sum_{i=1}^{n}(\phi_i(z)-y_i)^2\right)$	$\nabla_\phi J_{\text{exp}}\left(W,\vec{b},\vec{y},\vec{\phi},\tau\right)=\frac{2}{\tau}J_{\text{exp}}\left(W,\vec{b},\vec{y},\vec{\phi},\tau\right)\sum_{i=1}^{n}\phi_i(z)-y_i$
Hellinger distance	$J_{\text{HD}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\frac{1}{\sqrt{2}}\sum_{i=1}^{n}\left(\sqrt{\phi_i(z)}-\sqrt{y_i}\right)^2$	$\nabla_\phi J_{\text{exp}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\frac{1}{\sqrt{2}}\sum_{i=1}^{n}\frac{\sqrt{\phi_i(z)}-\sqrt{y_i}}{\sqrt{\phi_i(z)}}$
Kullback-Leibler (KL) cost	$J_{\text{KL}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum_{i=1}^{n}y_i\log\left(\frac{y_i}{\phi_i(z)}\right)$	$\nabla_\phi J_{\text{GKL}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum_{i=1}^{n}\frac{\phi_i(z)-y_i}{\phi_i(z)}$
Generalized KL cost	$J_{\text{GKL}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum_{i=1}^{n}y_i\log\left(\frac{y_i}{\phi_i(z)}\right)-\sum_{i=1}^{n}y_i+\sum_{i=1}^{n}\phi_i(z)$	$\nabla_\phi J_{\text{GKL}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum_{i=1}^{n}\frac{\phi_i(z)-y_i}{\phi_i(z)}$
Itakura-Saito distance cost	$J_{\text{IS}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum_{i=1}^{n}\left(\frac{y_i}{\phi_i(z)}-\log\left(\frac{y_i}{\phi_i(z)}\right)-1\right)$	$\nabla_\phi J_{\text{IS}}\left(W,\vec{b},\vec{y},\vec{\phi}\right)=\sum_{i=1}^{n}\frac{\phi_i(z)-y_i}{\phi_i^2(z)}$
...	...	...

- "Objective function" is the most general term for any function that you optimize during training. For example, a probability of generating training set in maximum likelihood approach is a well defined objective function, but it is not a loss function nor cost function (however you could define an equivalent cost function). For example:
  - MLE (Maximum Likelihood Estimator) is a type of objective function (which you maximize)
  - Divergence between classes can be an objective function but it is barely a cost function, unless you define something artificial

Long story short, we may say that: A loss function is a part of a cost function which is a type of an objective function.

14.1.20.9 Genetic Algorithms

Genetic algorithms (GAs) are iterated stochastic optimization algorithms based on the mechanisms of natural selection and genetics belonging to the family of "evolutionary algorithms". This is an optimization technique that has spread widely since the beginning of the 121st century (holocene calendar) through the version 14.0.6123 of Microsoft® Excel® wherein the solver incorporates an evolutionary algorithm by default as shown by the screenshot below:



Solver Parameters

Set Objective:

To: ● Max ○ Min ○ Value Of: 0

Mutation Rate: 0.075

Population Size: 100

Random Seed: 0

Maximum Time without improvement: 30

☑ Require Bounds on Variables

Figure 14.233: **Screenshot of the evolutionary Microsoft® Excel® 14.0.6123 solver options**

The process of the genetic algorithm is quite simple:

1. We start with an initial population of potential solutions (chromosomes) arbitrarily selected
2. We evaluate their relative performance (fitness)
3. Based on this performance, we create a new population of potential solutions using simple evolutionary operators: selection, crossover and mutation
4. We start this cycle until we find a satisfactory solution

Genetic Algorithms were originally developed by John Holland (11975 according to holocene calendar). This is the book of David E. Goldberg (11989 according to holocene calendar) that we own their popularization. Their fields of application are widespread. Besides the economy (portfolio risk minimization), they are used for optimization functions in finance, in optimal control theory (operational research), in the theory of repetitive and differentials games (namely: in evolutionary games and the prisoner's dilemma) and information retrieval (Google) and search for shortest path in graph theory (Internet routing or GPS). The reason for the large number of applications is clear: simplicity and efficiency. Of course, other stochastic exploration techniques exist, the Monte Carlo can be regarded as a similar concept.

To summarize, Lerman and Ngouenet (11995 according to holocene calendar) identified four main properties that make the fundamental difference between these algorithms and other methods:

1. The genetic algorithms use a coding of the input parameters, not the parameters themselves
2. Genetic algorithms work on a population of points, instead of a single point
3. Genetic algorithms use only the values of the function considered, not its derivative, or other auxiliary knowledge
4. The algorithms use probabilistic transition rules, not deterministic one

The simplicity of their mechanisms, their ease of implementation and efficiency even for complex problems led to a growing number of publication this recent years in the scientific community.

Definitions (#14.1.575):

D1. A "genetic algorithm" is defined by an individual / chromosome / sequence and a potential solution to the given problem.

D2. A "population" is a set of chromosomes or points of the search space

D3. The "environment" is assimilated with the search space

D4. The function that we seek to maximize is named "fitness function"

Before going further, we need to define more formally the above concepts but under the particular case of Binary coding!

The organisms in competition are the "individuals". Given an alphabet $A=\{a_1,a_2,\ldots,a_n\}$, we assume that each individual can be represented by a word of fixed-length l caught in the in A^*.

The word associated with an individual of the population will be named a "chromosome" or "sequence" (the term is not quite equivalent to its biological namesake, however, it is common practice to use the term here too) and thus given by A of the length $l(A)$ with $\forall i\in[1,l]:a_i\in A=\{0,1\}$ (reason: assumption of binary coding).

If there is no risk of confusion, we will identify the terms of "individual" and "chromosome".

The individuals form a population P of size P, denoted by:

$$P=\{A_i\} \tag{14.1.2167}$$

with $i=1\ldots N$. We will make another important statement, that is to say, there is a function f from one sequence with positive values which we denote $f(A)$, named "fitness function" that to any A_i associates real number such that for $i\neq j$:

$$f(A_i)>f(A_j) \tag{14.1.2168}$$

if and only if A_i is better suited to the environment than A_j.

Notice that the term "appropriate" is not defined. For this, we would characterize the environment in which the individuals evolve, what we will not do. In fact, since we assume the existence of such a function and we put it in equivalence to the degree of adaptation, it is automatically set by the definition of f.

We will name "generation" a population at time t, what must be put in relation with the notion of lifetime or age. However, we place ourselves here in the particular case where each individual has a life equal to 1, so the generation $(t+1)$ consists of different individuals from the generationt, we name them obviously the "descendants". Conversely, individuals of generation t are the "ancestors" of the individuals of the generation $(t+1)$. We denote the generation at time t by $P(t)$, thus the population at time t.

Thus, a chromosome is seen as a bit sequence in binary code known as "bit string". In the case of a non-binary coding, such as the real number encoding for example, then the sequence A contains only one point, we have then $A=\{a\}$ with $a\in\mathbb{R}$.

Remark

The fitness (effectiveness) is given by a function with real positive values. In the case of binary encoding, we will often use a function of decoding d that will gives the possibility to transform a binary string to a real number:

$$d:\{0,1\}^l\rightarrow\mathbb{R} \qquad (14.1.2169)$$

afterwards the fitness function is chosen such that it transforms this value into a positive value:

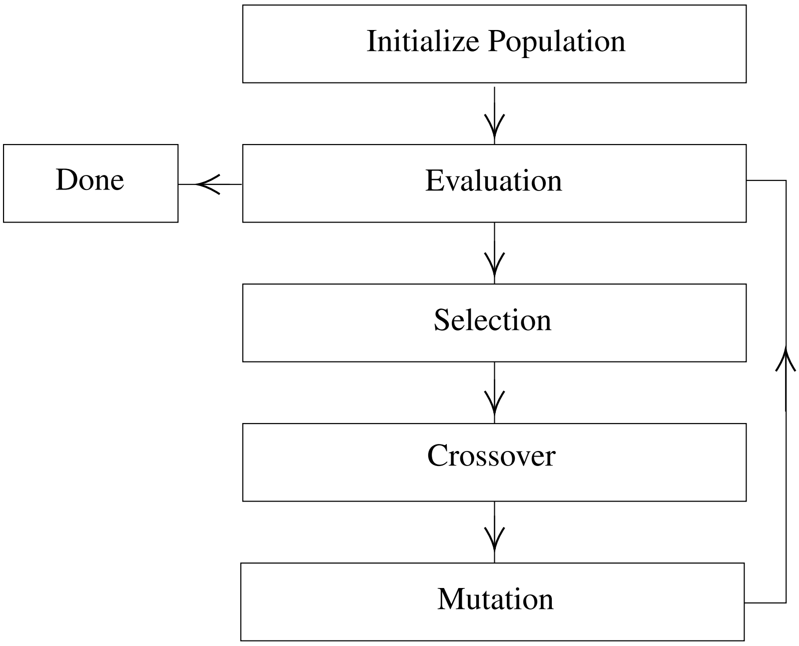
$$f:d\{0,1\}^l\rightarrow\mathbb{R}_+^* \qquad (14.1.2170)$$

The purpose of a genetic algorithm is then simply to find the string that maximizes this function f. Of course, each individual problem will require its own functions d and f.

GAs are then based roughly on the following phases:

1. Initialization: an initial population of N chromosomes is randomly chosen
2. Evaluation: each chromosome is decoded and evaluated
3. Selection: creation of a new population of N chromosomes based on previous step by using an appropriate method of selection.
4. Reproduction: possibility of crossover and mutation in the new population
5. Return to the Evaluation phase until the stop of the algorithm

Or for people that are more visual:



14.1.20.9.1 Encoding and Initial population

There exist three main types of coding:

1. Binary
2. Gray
3. Real

We can easily move from one encoding to another. Some authors do not hesitate, moreover, to draw parallels with biology, by speaking of "genotype" (see section Population Dynamics page 7361) regarding the binary representation of an individual, and "phenotype" (see section Population Dynamics page 7367) with respect to its corresponding real value in the search space.

Let us recall that the simplest transformation (decoding function d) of a binary string A into an integer x is done by the following rule (see section Numbers page 211 or this section page 6274):

$$x = d(A) = \sum_{i=0}^{l} a_i 2^i \qquad (14.1.2171)$$

where l is the number of digits of the string minus 1.

Therefore the chromosome $A = \{1, 0, 1, 1\}$ has trivially for value:

$$1 \cdot 2^3 + 0 \cdot 2^2 + 1 \cdot 2^1 + 1 \cdot 2^0 = 8 + 2 + 1 = 11 \qquad (14.1.2172)$$

Obviously, the function needs to be adapted (by trial and error!) depending on the problem. Thus, if we seek to maximize a function $f : [0, 1] \to [0, 1]$ a possible method would be as follows (the size of the chromosome of course dependent on the desired accuracy):

$$x = d(A) = \sum_{i=1}^{l+1} a_i 2^{-i} \tag{14.1.2173}$$

This can be assimilated to a harmonic series (see section Sequences and Series page 1665). For accuracy to the fifth decimal place, we will put $l = 17 - 1$ since:

$$d\left(\left\{\underbrace{1,\ldots,1,\ldots,1}_{=17}\right\}\right) \cong 0.999992 \to 1 \tag{14.1.2174}$$

Again another way to do would be to choose d such as:

$$x = d(A) = \sum_{i=0}^{l} \frac{a_i 2^i}{2^{l+1}-1} \tag{14.1.2175}$$

Let us give an explanation of this choice:

$$\begin{aligned} &x^n - 1 = (x-1)(1 + x + x^2 + \ldots + x^{n-1}) \\ &\frac{x^n-1}{x-1} = 1 + x + x^2 + \ldots + x^{n-1} = \sum_{i=0}^{n-1} x^i \\ &2^n - 1 = \sum_{i=0}^{n-1} 2^i \Leftrightarrow 1 = \sum_{i=0}^{n-1} \frac{2^i}{2^n-1} \end{aligned} \tag{14.1.2176}$$

Let us put $l = n - 1$:

$$1 = \sum_{i=0}^{l} \frac{2^i}{2^{l+1}-1} \tag{14.1.2177}$$

So, with $l = 16$ we have $2^{17} - 1 = 131071$ and:

$$d\left(\left\{\underbrace{1,\ldots,1,\ldots,1}_{=17}\right\}\right) = \frac{131071}{131071} = 1 \tag{14.1.2178}$$

This last rule can be generalized. Thus, suppose that we seek to maximize ("normalize" would be a more suited term perhaps...) f according to a real variable x. Given $D = [x_{\text{min}}, x_{\text{max}}]$, with $D \subset \mathbb{R}$, the allowed search space with x_{min} and x_{max} the lower and upper bounds of this space. Given prec the precision (decimal) with which we seek x. Given:

$$R = x_{\text{max}} - x_{\text{min}} \tag{14.1.2179}$$

the length (range) of the interval D. We then have to divide this interval at worst in:

$$n = R \cdot 10^{\text{prec}} \tag{14.1.2180}$$

equal sub-intervals to meet accuracy expectations. For example, given $D = [-1, 2]$ so we have $R = 3$, if we wanted a precision $\text{prec} = 6$, then we must divide this interval in $n = 3,000,000$ sub-intervals.

Let k denote the natural integer such that $2^k > n$, which in our example involves $k = 22$ as:

$$2^{21} = 2,097,152 < 3,000,000 < 2^{22} = 4,194,304 \tag{14.1.2181}$$

the transformation of a binary string $A = \{a_1, \ldots, a_l\}$ in a real number x can then be run in three stages:

1. Conversion (base 2 into base 10):

$$x' = \sum_{i=0}^{l} a_i 2^i \tag{14.1.2182}$$

2. Normalization:

$$x'' = x' \frac{x_{\max} - x_{\min}}{2^{l+1} - 1} = \frac{x'R}{2^{l+1} - 1} \tag{14.1.2183}$$

3. Maximization:

$$x = x_{\min} + x'' \tag{14.1.2184}$$

Or what remains the same directly in one step by using:

$$x = x_{\min} + \sum_{i=0}^{l} \frac{a_i 2^i R}{2^{l+1} - 1} \tag{14.1.2185}$$

Therefore for $f : [0,1] \to [0,1]$ and $\forall i, a_i = 1$ we fall back well on:

$$x = 0 + \sum_{i=0}^{l} \frac{2^i \cdot 1}{2^{l+1} - 1} = \sum_{i=0}^{l} \frac{2^i}{2^{l+1} - 1} \tag{14.1.2186}$$

About the initialization phase, the procedure is quite simple. It consists of a random selection of N individuals in the space of allowed individuals. In binary coding, according to the size l of the string, we do for a chromosome l sampling in $\{0,1\}$ with equal probability.

14.1.20.9.2 Operators

Operators play a key role in the possible success of a GA. We number three main one:

1. the selection operator
2. the crossover operator
3. the mutation operator

If the principle of each of these operators is easy to understand, it is difficult to explain the isolated importance of each of these operators in the success of the AG. This is partly due to the fact that each of these operators acts according to various criteria that depends on its own characteristics (fitness of individuals, likelihood of activation of the operator, etc.).

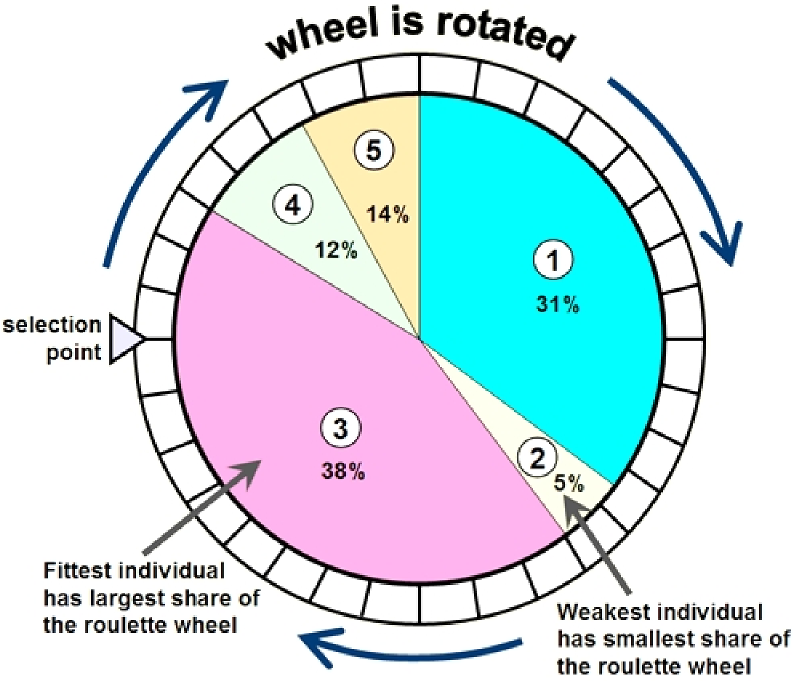
14.1.20.9.2.1 Operator of selection

This operator may be the most important since it allows individuals in a population to survive, reproduce or die. Generally, the probability of survival of an individual will be directly connected to its relative effectiveness in the population. The basic part of the selection process is to stochastically select from one generation to create the basis of the next generation.

There are several methods for reproduction. The most known and used method is undoubtedly the biased David E. Goldberg's (11989 according to holocene calendar) lottery wheel (roulette wheel). According to this method, each chromosome is duplicated in a new population in proportion to its adaptive value. We perform in some way, as many sampling that there are individuals in the population. Thus, in the case of a binary coding, the fitness of a particular chromosome being $f(d(A))$, the probability with which it will be reintroduced into the new population of size N is given by the relative fitness:

$$\frac{f(d(A))}{\displaystyle\sum_{i=1}^{N} f(d(A))} \tag{14.1.2187}$$

Individuals with high fitness value thus have more chance of being selected by the wheel. We speak then of "proportional selection":



wheel is rotated
selection point
5
14%
4
12%
1
31%
3
38%
2
5%
Fittest individual has largest share of the roulette wheel
Weakest individual has smallest share of the roulette wheel

Figure 14.234: **Example of David E. Goldberg's wheel with five individuals with their respective relative fitness**

Obviously the number of times the roulette wheel is spun is equal to the size of the new population.

Each time the wheel stops this gives the fitter individuals the greatest chance of being selected for the next generation and subsequent: "mating pool".

The major drawback of this method lies in the fact that an individual that is not the best may still dominate the selection (imagine the search for maxima of a function in $\mathbb{R}^2$, there may be several of them - maxima - and therefore we could get a wrong selection ...), we will speak rightly then of "premature convergence" and this is one of the most common problems when using genetic algorithms. It can therefore also result in a loss of diversity by the domination of a super-individual. Another drawback is its poor performance towards the end when all individuals are alike.

One solution to this problem lies not in the use of another method of selection but the use of a modified fitness function. So we can use a scaling to decrease or increase artificially the relative difference between the fitness of individuals.

Briefly, there are other methods, the best known being that of the tournament (tournament selection) we draw two random individuals in the population and reproduce the best of both in the new population. We repeat this procedure until the new population P is complete. This method gives good results. However, as important as the selection phase, it does not create new individuals in the population. This is the role of crossover and mutation operators.

14.1.20.9.2.2 Crossover operator

The crossover operator allows the creation of new individuals in a very simple process. It allows the exchange of information between chromosomes (individuals). First, two individuals, which then form a couple, are sample in the new population issued from the selection (or reproduction). Then one (or potentially many) crossing site is randomly draw (number between 1 and $l-1$). Finally, according to a probability P_c that the crossing is done, the end segments (in the case of a single crossing site) of both parents are then exchanged around this site:

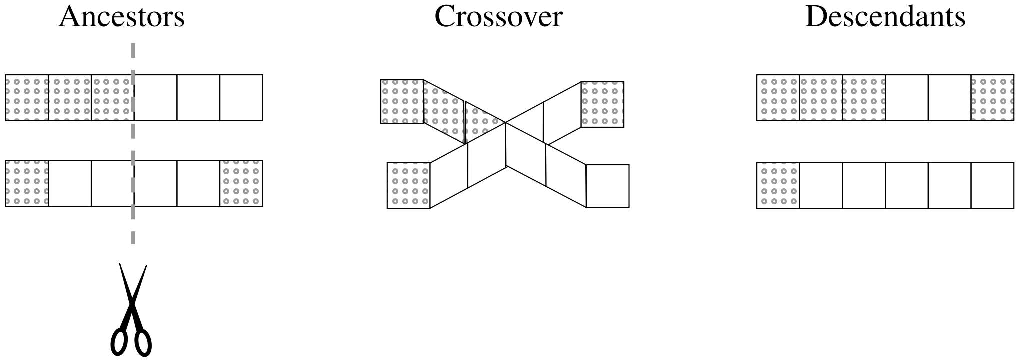


Figure 14.235: **Illustrative example of crossover**

This operator allows the creation of two new individuals. However, an individual selected in the reproduction (selection) is not necessarily subjected to a crossover. The latter is carried out with a certain probability P_c. The more this probability is high and the more the population will undergo a crossover modification.

Anyway, it is possible that the joint action of reproduction and the crossing is insufficient to ensure the success of the GA. Thus, in the case of binary encoding we have chosen so far, some information (i.e. the characters of the alphabet) may disappear from the population. Thus if no individual of the initial population contains a 1 in the last position of the string and that we know a priori that this 1 in the last position is part of the optimal string to find, all possible crosses will never show this 1 initially unknown. In real number coding, such a situation can happen when using a simple crossover operator, it was such that the initial population was between 0 and 40 and that the optimal value was 50. All possible combinations of convex digits belonging to the range $[0, 40]$ will never allow to reach a the number of 50. This is to address, among others, this problem that the mutation operator is used.

As usually the crossover operation uses 2 individuals. So, if you have 20 individuals, we choose 10 pairs to cross, and with a probability of $P_c = 80\%$, on average we're going to cross only 8 pairs.

14.1.20.9.2.3 Mutation operator

The purpose of this operator is to change randomly, with some probability, the value of a component of the individual. In the case of binary encoding, each bit $a_i \in \{0, 1\}$ is replaced following a probability P_m by its inverse $a'_i = 1 - a_i$. This is what is shown in the figure below. Like many crossover positions may be possible, we can very well admit that a same string can undergo several mutations.

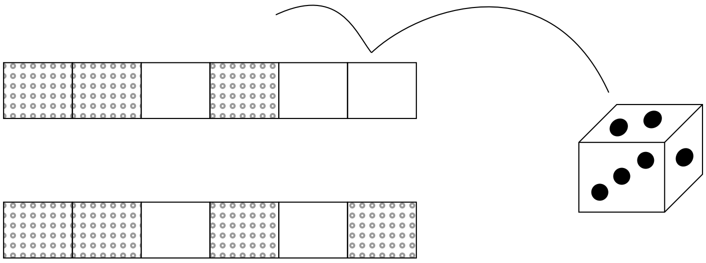

Figure 14.236: Illustrative example of mutation

The mutation is traditionally considered a marginal operator even if somehow it gives to genetic algorithms the ergodic property (i.e. all points of the search space can be achieved). However operator is of great importance. It performs a dual role: perform a local search and / or out a global search (remote search).

The operators of the genetic algorithm are guided by a number of parameters set in advance. The value of these parameters affect the success of failure of a genetic algorithm. These parameters are (the reader can compare this list with the parameters available in the Microsoft® Excel® solver screenshot given earlier above):

- The size of the initial population N, and the coding length l of each individual (in the case of binary encoding). If N is too large, the computation time of the algorithm can be very important, and if N is too small, it may converge too quickly to the wrong chromosome.
- The crossover probability P_c, that depends on the form of the fitness function. Its choice is general heuristic (just like P_m). The higher it is, the more the initial population obviously undergoes significant changes. The generally accepted values are between 0.5 and 0.9.

- The probability of mutation P_m is generally small since a high rate may lead to a suboptimal solution.

  Rather than reducing P_m, another way to avoid the best individuals to be altered is to use explicit report of the elite individuals in a certain proportion. So often, the top 5%, for example, of the population is directly reused directly, the operator of reproduction (selection) or mutation operating then only on the remaining 95%. This is named an "elitist strategy".

Let us now see an example of GA (example of David E. Goldberg - 11989 according to holocene calendar).

✍**Example:**

We want to find the maximum of the function $(f)=x$ on the interval $[0,31]$ where x is an integer. The first step consist in coding the function. For example, we use a binary coding of x, the sequence (chromosome) containing a maximum of 5 bits. Thus, we have $x=2\rightarrow\{0,0,0,1,0\}$, and also $x=31\rightarrow\{1,1,1,1,1\}$. We are therefore seeking maximum of a fitness function (we will choose $f(x)$ itself in this simple example) in a space of $2^5=32$ possible values of x.

1. Sampling and evaluation of the initial population

   We set the size of the population to $N=4$. We draw randomly 4 chromosomes knowing that a chromosome consists of 5 bits, and each bit has a 50% probability of having a value of 0 or 1. The maximum, (randomly) 16 is reached by the second sequence. Let us see how the algorithm will try to improve this result.

   First, we get the following table:

N°	Chromosome	Value	Fitness	$P_i\%$
1	00101	5	5	14.3
2	10000	16	16	45.7
3	00010	2	2	5.7
4	01100	12	12	24.2
Total			**35**	**100**

Table 14.33: **Evolution (mutation) of chromosomes**

   We turn again the David E. Goldberg's wheel 4 times to obtain the following sequence:

Selection (sampling)	Chromosome
1	10000
2	01100
3	00101
4	00101

Table 14.34: **Sampling sequence of chromosomes**

We see here well the risk that we would have to lose the Sequence N°2 from the start... that's the problem with this method. It can converge more slowly than others. However, the reader will notice that we have lost the sequence N°3.

We now turn to the crossover part: the ancestors are randomly selected. We randomly draw a crossover location ("site" or "loci") in the sequence. The crossing then operates at this location with a probability P_c. The table below shows the consequences of this operator assuming chromosomes 1 and 3, afterwards 2 and 4 are paired, and each time the crossing takes place (e.g. with $P_c = 1$):

	$l=2$	$l=3$
Original Sequences	100|00	01|100
	001|01	10|000
Crossed Sequences	10001	01000
	00100	10100

Table 14.35: **Chromosome crossing**

We now turn to the mutation part: in this binary coding example, the mutation is the occasional random modification (low probability) of the value of a bit (bit reversal). We thus draw for each bit a random number between 0 and 1 and if this digit is less than P_m then the mutation takes place. The table below with $P_m = 0.05$ highlights this process:

Old chromosome	Random drawing	New bit	New chromosome
10001	15 25 36 *04* 12	1	10011
00100	26 89 13 48 59	–	00100
01000	32 45 87 22 65	–	01000
10100	47 *01* 85 62 35	1	11100

Table 14.36: **Mutation of chromosomes**

Now that the new population is fully created, we can evaluate it again:

N°	Chromosome	Value	Fitness $f(x)$	P_i%
1	10011	19	19	32.2
2	00100	4	4	6.8
3	01000	8	8	13.5
4	11100	28	28	47.5
Total			**59**	**100**

Table 14.37: **Evaluation of the mutation of chromosomes**

The maximum is now 28 (N°4). So we went from 16 to 28 after a single generation. Of course, we must repeat the procedure from the selection stage until the overall maximum, 31, is obtained, or until that a stop criterion has been satisfied.

Remark

It is possible to prove mathematically, what's remarkable (!!!), that the portions of chromosomes that are found in the best individuals will tend to reproduce ...

The reader interested can also take a look to the MATLAB® companion book where we use GAs to find the optimum of the Rastriging function:

and also for neural networks optimization.

14.1.20.10 Total Unduplicated Reach and Frequency Analysis (TURF)

"TURF Analysis", an acronym for "Total Unduplicated Reach and Frequency", is a type of statistical analysis used for providing estimates of media or market potential and devising optimal communication and placement strategies given limited resources. TURF analysis identifies the number of users reached by a communication, and how often they are reached.

Although originally used by media schedulers to maximize reach and frequency of media spending across different items (print, broadcast, etc.), TURF is also now used to provide estimates of market potential. For example, if a company plans to market a new yoghurt, they may consider launching 10 possible flavours, but in reality, only three might be purchased in large quantities. The TURF algorithm identifies the optimal product line to maximize the total number of consumers who will purchase at least one SKU[80] (Stock Keeping Unit). Typically, when TURF is undertaken for optimizing a product range, the analysis only looks at the reach of the product range (ignoring the Frequency component of TURF).

In order to obtain data on the items being evaluated, ratings/choices may be obtained via quantitative marketing research (such as a survey).

Let us give a companion example! Consider we want to sell three new ice flavours. We did a non-representative survey on 10 people that lead us to the following table:

Individual	**Weight**	**Chocolate (A)**	**Vanilla (B)**	**Pistachio (C)**
1	1	1	0	0
2	1	1	0	0
3	1	1	0	0
4	1	0	1	0
5	1	0	1	0
6	1	0	1	0
7	1	1	1	0
8	1	1	1	0
9	1	0	1	1
10	1	1	1	1

Three possible ice cream flavours available. After a survey, we get:

- Flavour A was chosen by 60% (6/10) of the people
  - 50% (3/6) chose A exclusively
  - $33.\bar{3}\%$ (2/6) chose also B
  - 0% (0/6) chose also C
  - $16.\bar{6}\%$ (1/6) chose also B plus C
- Flavour B was chosen by 70% (7/10) of the people

---

[80] A SKU is a distinct string of letters and numbers that helps retailers identify every product in their inventory and each product's specific traits, like its manufacturer, brand, price, style, color, and size.

  - 42.85% (3/7) chose B exclusively
  - 28.57% (2/7) chose also A
  - 14.29% (1/7) chose also C
  - 14.29% (1/7) chose also A plus C
- Flavour C was chosen by 20% (2/10) of the people
  - 0% (0/2) chose C exclusively
  - 0% (0/2) chose also A
  - 50% (1/2) chose also B
  - 50% (1/2) chose also A plus B

An obvious "macro-result" if we would have to choose only 2 flavour, would be to choose flavours A and B.

However we must also focus on the combinations focus on all combinations of 2 among 3 flavours to check if it match our previous naive macro analysis (and that's may not be always the case!!!).

We then have:

$$C_k^n = \frac{n!}{k!(n-k)!} = \frac{3!}{2!(3-2)!} = 3 \qquad (14.1.2188)$$

to analyse! It's easy to do by hand and lead us to the following reaching rates:

- 100% Would chose A alone, B alone or A and B together
- 70% Would chose A alone, C alone or A and C together
- 70% Would chose B alone, C alone or B and C together

So in this special case. The TURF analysis confirms the naive macro analysis!

Remark

The reader can find this example in our `R` companion book.

TURF analysis allows us to see the effect of the combinations of answers that people make that we may not see in simple percentage choices.

Making decisions based on simple percentage choice can be wrong. TURF analysis then allows us to take into account the complex combinations of choices that people make when selecting products or services.

Obviously, TURF analysis, has many flaws, among other the fact that is purely deterministic. But this can be quite simply resolved using bootstrapping.

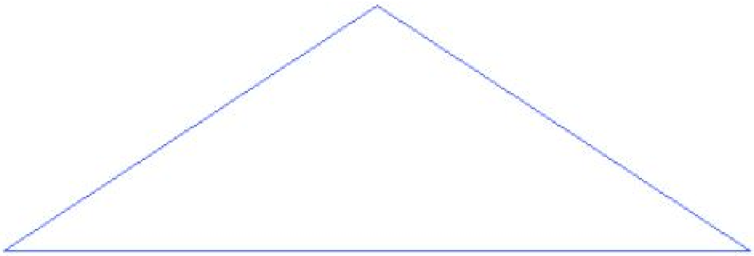
14.2. Fractals

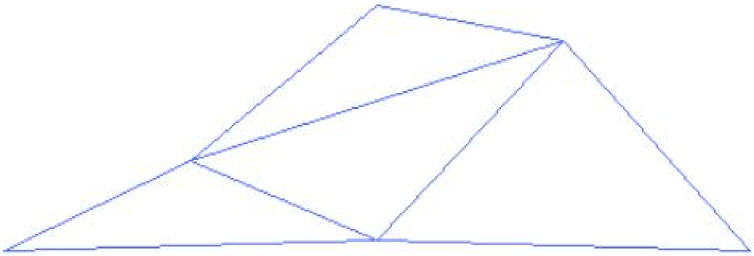
FRACTALS are figures invariant by scale change (we also talk about "self-similar structures") and are the graphic representation of contractant recurrent sequences (for IFS fractals that we will see later) or not divergent (for escape-time fractals as we will see further below).

The basic idea - simple and great ... at the same time - often involves taking a starting point, to build its image through a particular mathematical function, to take the image of the image and so on. The goal is to study how the successive points are allocate in the global target set of the defined function, if they are approaching a limit or if they roam between different values that can we explain, if more points in part of the set than another?

The advantage of this type of questions concerns both the study of the evolution of biological populations than the future of the solar system, 3D computing (the origin being the generation of mountains for 3D landscapes) changes in stock prices or random number generation in particular fields, or even medical diagnostic (especially for brain or heart).

See below a simple example image by image:





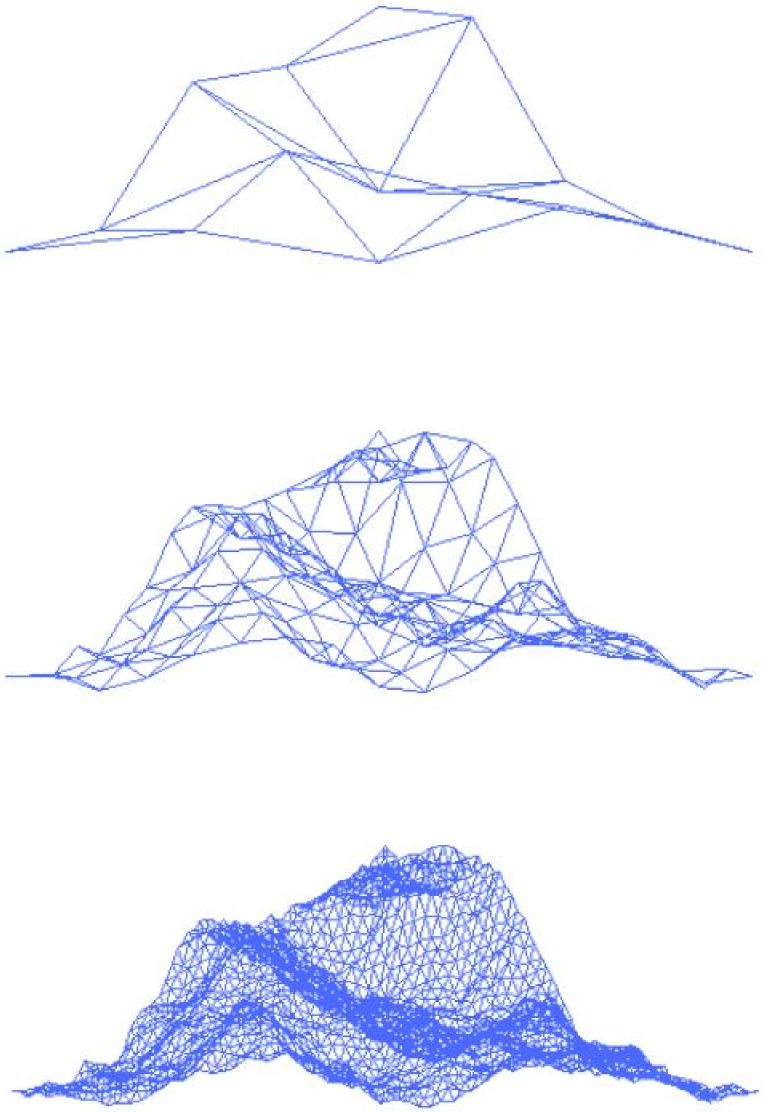


Figure 14.238: **Pseudo-mountains generation from a random fractal (probabilistic fractal)**

For the average person, fractals are used to look pretty. But they have far more serious applications: for example we already saw in this textbook that some of these "attractive" images reproduced physical phenomena (population dynamics for the Feigenbaum's Fractal, turbulence in a fluid with the Lorentz attractor, distribution of galaxies, L-Fractals, clusters and supercluster of galaxies, ...). Fractals have also found applications in music (with software generating fractal music) and movies (3D to generate mountains, fire, grass) productions. In the field of computer graphics, fractals are used to compress images very effectively, with consistent quality regardless of the zoom, they help to create realistic textures, and can afford to dither an image with good results. Fractals are also used to reduce the size of the receive antennas and to extend their effectiveness frequency spectrum (some of our cell phones of the early 121st century (holocene calendar) have fractal receptor of the type "Sierpinski carpet" - see below - because of all types of frequencies they need to manage!). In civil engineering fractals are used for building some sound absorbers walls. And many other things... Finally, in cosmology, fractals are also used to attempt to give a maximum structure size to check if the cosmological principle really holds in our observable universe (see [583]).

This fractal geometry differs from the Euclidean geometry first by its definition: the figures of Euclidean geometry are generally determined by algebraic relations, while the fractal curves are defined recursively as we have already mentioned. Fractals also have fractional dimensions (we have already discussed this topic in the section of Euclidean geometry when defining the concept of dimension). On the other hand, we must not neglect their autosimilar appearance: each part of a fractal can be observed at any scale: each part is (essentially) a copy of the whole.

Remark

The developments that follow could easily have been put in the section of Sequences and Series or even of Functional Analysis or seen as a special case of the section Topology reduces to the Euclidean space (this is why you will find here also many references to the topology section). Our choice is pedagogical as well as for the section of Cryptography, in the sense that it is much more interesting for a high-school student to see an application of abstract concepts of topology in a practical framework (and furthermore aesthetics) where they are absolutely necessary for a proper understanding of the subject rather than in a framework where we can escape them very well without too suffer. The reader will find here some developments and theorems proposed elsewhere in this textbook and this only in the order to avoid having too "turn pages" too much.

Natural fractals are named "non-deterministic objects" because the dynamic process that allows their creation itself varies with time randomly (see the section of Population Dynamics for an excellent example). Nevertheless, we can try to model dynamic systems that lead to fractal objects under a rigorous mathematical form (that is still a good example of the way in which the mathematicians manage to make a simple and intuitive concept into a concrete abstract mathematical model and somewhat confusing as for Knot Theory).

In this section, we will consider the study of two families of fractals that will be in order:

1. Deterministic fractals based on iterated function that are strictly self-similar. They are generated, as we shall see, by the recursive application of contracting functions on subsets of a metric space. The fixed point theorem will guarantee (as we shall also see!) the existence and uniqueness of a "fixed subset" of the metric space, towards which every subset converge.

2. Escape-time fractals (also known as "fractals by induction") that are not strictly self-similar: They are generated as we shall see later by recurring non-divergent sequences. The fixed point theorem serving as guarantee for the non-divergence of the function with respect to the chosen starting points.

14.2.1 IFS Fractals

Let us start by looking at the first family of fractals discovered by Michael Barnsley in 11987 (holocene calendar): the "deterministic iterated function systems IFS".

Of all fractals, figures only those built by iterated function systems usually shows the self-similarity property, meaning that their complexity is invariant under change of scale.

Let us start by "bounding" the thing...

We take an initial geometry E_0 of space E, a function f from E to E such that:

$$f(E_0)\subset E_0 \tag{14.2.1}$$

(which requires that the initial object can not leave its own definition domain through the iteration of the function f) and we create the discrete dynamical system defined by:

$$S_D=\begin{cases} E_0 \\ E_{n+1}=f(E_n) \end{cases} \tag{14.2.2}$$

Under certain conditions we will now see, the sequence of geometric objects (E_0) "tends" to a limit, which is often a fractal object (we will see further below some famous examples).

Naturally, there is a rigorous mathematical framework in which the mentioned conditions and the verb "tends" have a precise definition. In particular, the objects E_n are all compacts of E, that is to say bounded subsets (that we can include in a segment if E is a straight line, in a disk if E is a plane or a ball if E is the three-dimensional space) and closed (every convergent sequence of E_n has its limit in E). We place ourselves then in the compact metric space, equipped with the Hausdorff distance (see below for definition) for which we will show that it is complete when we work with compact sets the plane and of space, and we will check that f is an "Hutchinson operator", i.e. a contraction application from the space of the compact in itself for that distance. It then will then just remain to apply the fixed point theorem.

Dynamic systems of this type are said to be "deterministic", and therefore named "IFS" (iterated function systems deterministic). Let us precise that the limit of the IFS is named the "attractor of the IFS". We can show that under the conditions mentioned above, this attractor does not depend on the shape of the original geometric object (we will see practical examples further below).

Initially, we will limit our study to $\mathbb{R}$ (the general case is given in section Topology) knowing anyway that a generalization to the two-dimensional Euclidean space does not require too big and intellectual work and that the whole complex is isomorphic to it.

Definition (#14.2.576): To enable us to define the boundaries of our fractal functions let us consider $X\subseteq\mathbb{R}$. We say that ξ is the "supremum" of X and denote it by:

$$\xi=\sup(X) \tag{14.2.3}$$

if ξ is the smallest "upper bound" of X (an upper bound of X is a number a that satisfies $\forall x\in X, x\leq a$).

Similarly, we say that ξ is an "infimum" X and denote it by:

$$\xi=\inf(X) \tag{14.2.4}$$

if ξ is the biggest "lower bound" of X (a lower bound of X is a number a that satisfies $\forall x \in X, a \leq x$).

Remark

We often use the following characterization of the supremum:

$$\xi=\sup(X) \tag{14.2.5}$$

if and only if:

$$\forall \varepsilon>0, \exists x \in X: \quad \xi-\varepsilon \leq x \leq \xi \tag{14.2.6}$$

which is almost obvious because we can approach as close as we want of ξ with elements of X (think with small ε). For information, we then also have in the same idea:

$$\xi=\inf(X) \tag{14.2.7}$$

if and only if:

$$\forall \varepsilon>0, \exists x \in X: \quad \xi \leq x \leq \xi+\varepsilon \tag{14.2.8}$$

We consider as intuitive that if $X \subseteq \mathbb{R}$ has an upper bound, that is to say if there exists $a \in \mathbb{R}$ as $\forall x \in X, x \leq a$ (respectively lower bounded), then X has a supremum (respectively infimum).

We will see later that it is this property that will give us the possibility to prove later $\mathbb{R}$ a "complete metric space"!

Remark

By the way, let us underline the importance of taking $\mathbb{R}$ as a definition for metric space for this property to be satisfied. We can in fact notice that it is not verified in the set $\mathbb{Q}$ of rational numbers with the following simple example:

$$X=\left\{X \in \mathbb{Q} \mid x^{2} \leq 2\right\} \tag{14.2.9}$$

which is majorated but has no supremum in $\mathbb{Q}$ because this supremum is in $\mathbb{R}$ as:

$$x \leq \sqrt{2} \tag{14.2.10}$$

Therefore:

$$\sup(X)=\sqrt{2} \tag{14.2.11}$$

This is what makes $\mathbb{Q}$ is not "complete".

Definition (#14.2.577): We say that $X \subseteq \mathbb{R}$ is "bounded" if X is minorated and majorated.

From the definition it follows immediately that X is bounded if and only if there exists a, b with such that $X \subseteq [a, b]$.

Now that the concept of bound is relatively well defined, let see how a sequence can behave near from it.

Definition (#14.2.578): We say that $(a_n)_{\mathbb{N}}$ of $\mathbb{R}$ is an "increasing sequence" ("decreasing" respectively) if:

$$\forall n \in \mathbb{N}: \quad a_n \leq a_{n+1} \tag{14.2.12}$$

respectively:

$$\forall n \in \mathbb{N}: \quad a_n \geq a_{n+1} \tag{14.2.13}$$

We say the sequence $(a_n)_{\mathbb{N}}$ is "monotone" if it is increasing or decreasing as we have already seen in the section Sequences and Series.

Definition (#14.2.579): Given $T = \{n_0, n_1, n_2, \ldots\}$ infinite subset of $\mathbb{N}$ with $n_0 < n_1 < n_2 < \ldots$. We say the sequence $(a_{n_i})_{i \in \mathbb{N}}$ is a "subsequence" of the sequence $(a_n)_{\mathbb{N}}$.

Theorem 14.9. Let us now prove that every sequence in $\mathbb{R}$ admits a monotone subsequence (it's a bit the idea of a fractal!)

Proof 14.9.1. We say that a_m is a "peak" of the sequence if:

$$\forall n \geq m: \quad a_m \geq a_n \tag{14.2.14}$$

Consider the set P of peaks of the sequence $(a_n)_{\mathbb{N}}$.

- If P is infinite then the subsequence $(a_n)_{n \in P}$ is monotone since decreasing.
- If P is finite or empty:

$$m_1 = \max(P) + 1 \tag{14.2.15}$$

(if $P = \varnothing$ we choose any m_1). a_{m_1} is therefore not by construction not a peak, so there exists $m_2 \geq m_1$ such as $a_{m_1} \leq a_{m_2}$. In turn a_{m_2} is not a peak, so there exist $m_3 \geq m_2$ such as $a_{m_2} \leq a_{m_3}$ etc. We see that we define thus as an increasing subsequence.

Definition (#14.2.580): We say that the sequence $(a_n)_{\mathbb{N}}$ "converge" into $a \in \mathbb{R}$ and we note this:

$$\lim_{n \to +\infty} a_n = a \tag{14.2.16}$$

if:

$$\boxed{\forall \varepsilon > 0, \exists n \in \mathbb{N}: \quad n \geq N \Rightarrow |a_n - a| < \varepsilon} \tag{14.2.17}$$

In this case we say that a is the "limit of the sequence" $(a_n)_{\mathbb{N}}$.

■ Q.E.D.

Example:

In the example of the figure below where the sequence seems to converge towards the value 1.13, we observe that for a particular non-zero positive ε, there exists a particular n which we will denote N (which value is 17 in the below example) from which the sequence converges.

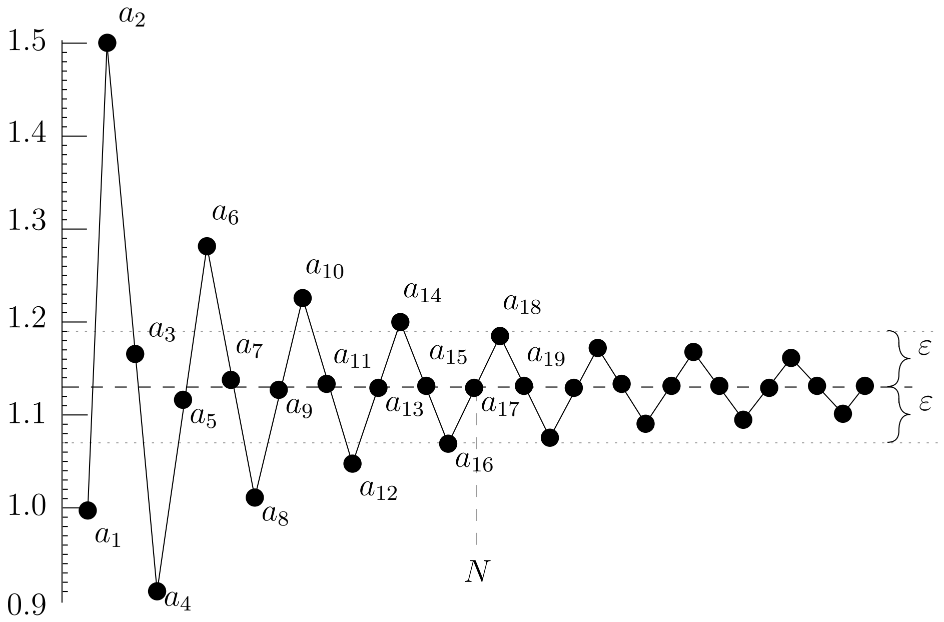

Figure 14.239: **Illustration of the principle of convergence of a sequence**

If there is no a (respectively N) for which the previous relation is true, then we say that the sequence "diverge".

Theorem 14.10. Let us prove now that every increasing sequence $(a_n)_{\mathbb{N}}$ (respectively decreasing) and majorated (resp. minorated) converges.

In other words, we seek to prove that any monotonous and bounded sequence $(a_n)_{\mathbb{N}}$ converges (obviously ... by construction).

Remark

If it does not converge, we could not easily find out what is its lower bound and upper bound ... hence the fact that the need of this theorem becomes trivial.

Proof 14.10.1. This theorem is actually quite intuitive. Consider for this an increasing sequence. We suspect that:

$$a = \sup\{a_0, a_1, a_2, \ldots\} \tag{14.2.18}$$

is the limit of this sequence. Note first of all that $a = \sup\{a_0, a_1, a_2, \ldots\}$ exists because $(a_n)_{\mathbb{N}}$ is majorated (see theorem proved previously).

Given $\varepsilon > 0$. It exists an a_N such tat $a - \varepsilon \leq a_N \leq a$. But in this case as the sequence is increasing, we have $\forall \geq N, a - \varepsilon \leq a_n \leq a$. That is to say $|a_n - a| \leq \varepsilon$. In the case where the sequence is decreasing by proceeding in the same way we prove that $a = \inf a_0, a_1, a_2, \ldots$ is the limit of this sequence.

■ Q.E.D.

Theorem 14.11. And now the important theorem to remember after all this: Every bounded sequence of real numbers has a convergent subsequence (that is intuitive ... but again ... when formalized it becomes sometimes less intuitive...).

This is what mathematicians name the "Bolzano-Weierstrass theorem" and it is extremely important in many areas of mathematics:

Proof 14.11.1. Given $(a_n)_{\mathbb{N}}$ such a sequence. By a previous proposal we know there is a monotonic subsequence which we denote $(b_n)_{\mathbb{N}}$. $(b_n)_{\mathbb{N}}$ is therefore a monotone and bounded sequence and by the previous theorem, $(b_n)_{\mathbb{N}}$ converges.

So if we are unable to determine whether the subsequence converges nor his exact limit (which in practice is often very difficult), we only need to know that the subsequence is monotone and bounded to ensure that it converges (which is most of time much easier).

■ Q.E.D.

Theorem 14.12. Remember that we saw in the section of Sequences and Series that a Cauchy sequence is a sequence $(a_n)_{\mathbb{N}}$ that verifies (we restrict ourselves to the special case of Euclidean distance):

$$\forall \varepsilon > 0, \exists N \in \mathbb{N}: \quad n,m \geq N \Rightarrow |a_n - a_m| \leq \varepsilon \tag{14.2.19}$$

The difference between the two terms of a Cauchy sequence can be made arbitrarily small provided that the indices of these terms are big enough.

We have also proved (again in the section of Sequences and Series) that in the case of a distance in the general topological sense any convergent sequence is a Cauchy sequence (by cons the reciprocal is not always true at the condition that do not complete the set... otherwise the reciprocal is always true). For example, a sequence of rational numbers that converges to a real number is not a Cauchy sequence, except if we complete the set of rationals to get the set of real numbers.

Let us redo the proof restricted to Euclidean distance (the method is exactly the same as the reader will notice):

Proof 14.12.1. Given ε, we must show that there is:

$$N \in \mathbb{N} \quad \text{such that} \quad n,m \geq N \Rightarrow |a_n - a_m| \leq \varepsilon \tag{14.2.20}$$

But $(a_n)_{\mathbb{N}}$ tends to a therefore it exists a $N \in \mathbb{N}$ such that $n \geq N \Rightarrow |a_n - a| \leq \varepsilon/2$. For $n,m \geq N$ we therefore have:

$$|a_n - a_m| \leq |a_n - a| + |a - a_m| \leq \frac{\varepsilon}{2} + \frac{\varepsilon}{2} = \varepsilon \tag{14.2.21}$$

■ Q.E.D.

Theorem 14.13. Let us now prove that every Cauchy sequence is bounded (we never talked about this until now anywhere in this textbook therefore we need to do the proof). Since currently we have just proved that every convergent sequence is a Cauchy sequence...

Proof 14.13.1. If $(a_n)_\mathbb{N}$ is a Cauchy sequence then particularly for $\varepsilon=1$ (randomly) we know that there exist $N\in\mathbb{N}$ such that $n,m\geq N\Rightarrow|a_n-a_m|\leq 1$. So if we fix m, we get:

$$\forall n\geq N:\quad |a_n|\leq 1+|a_m| \tag{14.2.22}$$

■ Q.E.D.

Let us see now the fundamental theorem (it is at this level that there is a huge impact on the understanding of what is actually a fractal!) that can be deduced from the previous lines.

Theorem 14.14. We will show that every Cauchy sequence of real numbers is convergent (by construction ...). We say then that the metric space $\mathbb{R}$ provided with the Euclidean distance (absolute value) is a "complete space".

Remarks

R1. The completeness property is related to the metric (hence this theorem could equally have its place in the section of Topology!): The same space can be complete for a given distance and incomplete for another one. It is therefore important to always specify the distance that we take when we speak of complete space.

R2. Intuitively, a space is complete if it has no holes. The set of rational numbers $\mathbb{Q}$ is by example complete if the real numbers are added to it.

Theorem 14.15. Consider first $(a_n)_\mathbb{N}$ a Cauchy sequence. We have seen just before that $(a_n)_\mathbb{N}$ is bounded and then that by the Bolzano-Weierstrass theorem, there exists a convergent subsequence $(a_{n_i})_{i\in\mathbb{N}}$. Let us denote by a the limit of the subsequence $(a_{n_i})_{i\in\mathbb{N}}$. We will now prove that the sequence $(a_n)_\mathbb{N}$ is convergent of limit a.

Proof 14.15.1. Given $\varepsilon>0$, there exist a $N\in\mathbb{N}$ such as (application of the definition of convergence for a subsequence):

$$i\geq N\Rightarrow|a_{n_i}-a|\leq\frac{\varepsilon}{2} \tag{14.2.23}$$

For this same ε it exists $M\geq 0$ (application of the definition of convergence for a Cauchy sequence):

$$M\geq 0,p,q\geq M\Rightarrow|a_p-a_q|\leq\frac{\varepsilon}{2} \tag{14.2.24}$$

Given $C=N+M$. We choose $i\geq C$. We then have $|a_{n_i}-a|\leq\varepsilon/2$ and for $n,i>C$:

$$|a_n-a_{n_i}|\leq\frac{\varepsilon}{2} \tag{14.2.25}$$

So by the triangle inequality (see section Vector Calculus page 1828), for any $n\geq C$:

$$|a_n-a|\leq|a_n-a_{n_i}|+|a_{n_i}-a|\leq\frac{\varepsilon}{2}+\frac{\varepsilon}{2}=\varepsilon \tag{14.2.26}$$

This means precisely that $(a_n)_\mathbb{N}$ converges to a.

■ Q.E.D.

Basically it is an intuitive result but at the time when real numbers were not known or not rigorously defined it was a different story! In fact, it is simply enough complete any set by the real numbers to get a complete space. Moreover, some mathematicians define the set of real number saying that it is the set for which every Cauchy sequence converges...

Definition (naive #581): An "accumulation point" or "cluster point" is a point which we can approach as much as we want thanks to elements of a given set X (we will approach it for example with a sequence). However, this accumulation point can be both inside and outside of X (all items within X are obviously limit points). A good image is to see a series that approach this accumulation point and define circles around it that are becoming smaller and smaller containing elements of the sequence.

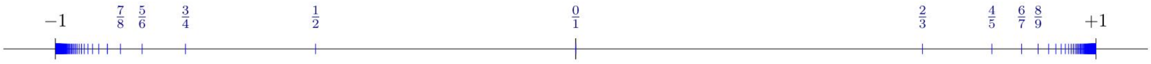
We can imagine as an example a sequence defined by the set X of rational numbers $\mathbb{Q}$ which tends to an irrational or to a transcendental number (these two points being elements not belonging to the set of rational $\mathbb{Q}$). So in this case, the accumulation point is outside X (the set of rational $\mathbb{Q}$). By cons, any accumulation point that would be a rational number for a sequence of rational number will necessarily ... in X (that is to say $\mathbb{Q}$).

✍**Example:**

With respect to the usual Euclidean topology, the sequence of rational numbers:

$$x_n = (-1)^n \frac{n}{n+1} \tag{14.2.27}$$

has no limit (i.e. does not converge) when $n \rightarrow \pm\infty$, but has two accumulation points (which are considered limit points here), that are -1 and $+1$:



Therefore, comes the following definition (for more details see the section Topology page 2446):

Definition (formal #582): Given $X \subseteq \mathbb{R}^n$. We say that $x \in \mathbb{R}^n$ is an "accumulation point" to X if for all ball $\mathcal{B}(x,r)$ of radius r center on x we have (for more details see the section Topology):

$$X \cap B(x,r) = \varnothing \tag{14.2.28}$$

The set of all accumulation points (of a sequence) to X is the "limit set" of X and denoted by $\bar{X}$. We have obviously (it suffice to conceptualize it in an abstract way for all possible ball) $X \subseteq \bar{X}$.

✍**Example:**

Let us consider the interval $]0,1]$ with the ball $B(0,1)$. The intersection between the ball and the interval is not zero, we can say that 0 is an accumulation point! But now let us take a sequence $1/n$ for example in the interval $]0,1]$. This sequence tends to zero but 0 is not in interval. It is a good example of $X \subseteq \bar{X}$.

We can therefore make the proposition:

Theorem 14.16. Let us prove now that $x \in \mathbb{R}^n$ is adherent to X if and only if there is a sequence $(u_n)_{\mathbb{N}}$ in X converging to x (note that the previous example shows that x is not necessarily in X).

In fact, we will instead prove (if we can say it is a proof..) that if we choose an accumulation point x then we can always find a sequence inX converging to x.

Proof 14.16.1. If $x \in \mathbb{R}^n$ is adherent to X then let us consider the following concentric balls $B\left(x,\dfrac{1}{n}\right)$ with $n \geq 1$ such as:

$$X \cap B\left(x,\frac{1}{n}\right) = \varnothing \tag{14.2.29}$$

and then there are always elements u_n that satisfy:

$$u_n \in \left(X \cap B\left(x,\frac{1}{n}\right)\right) \tag{14.2.30}$$

with whom we can create a sequence by the infinity of existing sequences.

■ Q.E.D.

Definition (#14.2.583): We say that $X \subseteq \mathbb{R}^n$ is a "closed space" if $X = \bar{X}$.

From the previous proposals it follows that in any closed space F, a sequence $(x_n)_{\mathbb{N}}$ that converges has its limit in F.

We consider as if trivial that if $(F_i)_I$ is a family of closed indexed spaces on any set I, then $\bigcap_I F_i$ is closed.

Definition (#14.2.584): $X \subseteq \mathbb{R}^n$ is a "compact space" if X is closed and bounded.

The following theorem gives a characterization of the compact from the sequences:

Theorem 14.17. $X \subseteq \mathbb{R}^n$ is compact if and only if any sequence $(x_n)_{\mathbb{N}}$ of X possess a subsequence that converges in X.

Proof 14.17.1. First let us prove that X is closed:

If X is compact and $(x_n)_{\mathbb{N}}$ is a sequence of X then by the Bolzano-Weierstrass theorem, $(x_n)_{\mathbb{N}}$ has a convergent subsequence of limit $x \in \mathbb{R}^n$. But since X is closed, we have $x \in X$. Conversely, let us assume that any sequence $(x_n)_{\mathbb{N}}$ of X has a subsequence which converges in X.

Then X is closed because if $x \in \bar{X}$ there is a sequence $(x_n)_{\mathbb{N}}$ of X which tends to x. By assumption, $(x_n)_{\mathbb{N}}$ has a subsequence that converges $y \in X$. The sequence $(x_n)_{\mathbb{N}}$ being convergent all the sub-sequences converge to the same value, therefore $x = y \in X$ (is this not great?!!). Thus $X = \bar{X}$ that is to say X is closed!

Let us now prove that X is bounded:

Let us suppose the opposite. So there exists a sequence $(x_n)_{\mathbb{N}}$ of X such that $||x_n|| \geq n$. But in this case, no subsequence of $(x_n)_{\mathbb{N}}$ is convergent, which is a contradiction! So X is bounded. Finally, X is compact!!!

■ Q.E.D.

A property of compacts is that if we consider $(A_n)_{\mathbb{N}}$ a decreasing sequence of non-empty compacts, that is to say $A_{n+1} \subseteq A_n$, then $\bigcap_{\in \mathbb{N}} A_n$ is a non-empty compact. We will pass trough the proof that is relatively trivial by the definition of the concept of Adherence Set that oblige that compacts are by construction non-empty...!

✍**Example:**

We build the Cantor set C as follows:

We begin by considering the closed bounded interval $C_0 = [0, 1]$ of $\mathbb{R}$ which is therefore a compact space (bounded and closed set). We split C_0 into three equal parts and we remove the middle interval. This gives us all the set:

$$C_1 = [0, 1/3] \cup [2/3, 1] \tag{14.2.31}$$

which can be also considered also as the application of a contracting scaling factor of $1/3$ on the closed bounded interval of departure of which we translate the center of homothety.

We start again with the two intervals $[0, 1/3]$, $[2/3, 1]$ for:

$$C_2 = [0, 1/9] \cup [2/9, 1/3] \cup [2/3, 7/9] \cup [8/9, 1] \tag{14.2.32}$$

disjoint union of 4 intervals. And so on... So we get a decreasing sequence C_n of compact. We define:

$$C = \bigcap_{n \geq 20} C_n \tag{14.2.33}$$

Thanks to the previous proposal, we know that C is not empty and is compact which shows that the compacts are not all "trivial" as intervals. The Cantor set (because he had played by doing the drawing below starting from the bottom) is an example of (compact) fractal:

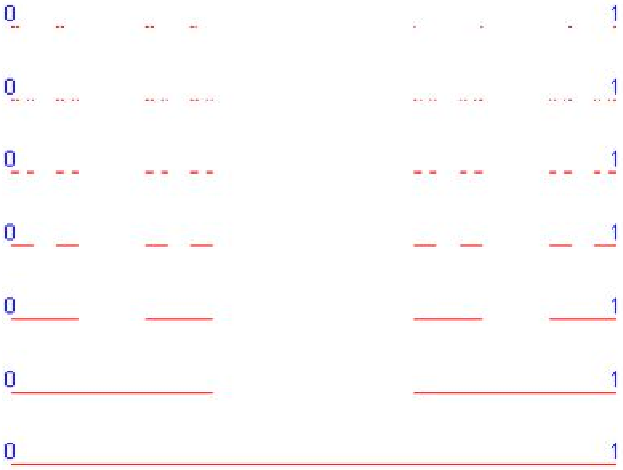


Figure 14.240: **Cantor set with Maple™ 4.00b**

that is possible to get with the following Maple™ 4.00b code:

```
 >with(plots):
line := proc(a::  list, b::  list)
local plotoptionen, n;
if nargs > 2 then
plotoptionen := seq(args[n], n=3 ..  nargs)
else
plotoptionen := NULL
fi;
plot([a, b], style=line, plotoptionen);
end:

cree_segment := (a,b,h) -> line([a,h],[b,h],color=black):
f1:=x->x/3:  f2:=x->(x+2)/3:

f := s -> s union map(f1, s) union map(f2, s):

sequence_de_segments := proc(l,h)
local accu, i;
accu := NULL;
for i to nops(l) by 2 do
accu := accu,cree_segment(l[i], l[i+1], h) od;
accu
end:
 >Cantor:= proc(n) local s, i;
>option remember;
>s:=sequence_de_segments([0,1], 1);
>for i from 1 to n do
>s:=sequence_de_segments(sort([op((f@@i)(0,1))]), (1-i/n)), >s;
>od;
```

```
>display(sunionseq(textplot([[0,(i+1/2)/n, '0'], [1, (i+1/2)/n,
'1']]
), i=0 ..  n), color=blue,axes=NONE,thickness=7)
>end:

>Cantor(7);
```

It is very interesting to notice that we converges to the Cantor fractal (in terms of geometry but also in term of values!) whatever the chosen starting compact we start from (the closed bounded interval) and also ... whatever the chosen contractor factor!

Benoît Mandelbrot also observed this type of self similar structure in the analysis of electrical signals transmitted at his (junior) time when working for IBM on copper cables (IBM had transmission information loss problems).

Now let us look for finish how behave compactis vis-à-vis continuous applications (we need this to prove how to determine the distance from a point to a set which we will need absolutely after to determine the properties of the Hausdorff distance).

Let us recall (see section Topology page 2460) that an application $f: X \mapsto \mathbb{R}^m$ whatever $X \subseteq \mathbb{R}^n$ is delta-epsilon continuous on a point $x \in X$ if:

$$\forall \varepsilon > 0, \exists \delta > 0, \forall y \in X: \quad d(x,y) \leq \delta \Rightarrow d(f(x), f(y)) \leq \varepsilon \tag{14.2.34}$$

This reflects the fact that for y close enough to x, $f(y)$ is arbitrarily close to $f(x)$. We also say that f is continuous on X if it is continuous at each point of X.

Theorem 14.18. Given $f: X \mapsto \mathbb{R}^m$ a delta-epsilon continuous application on $x \in X$ and $(x_n)_{\mathbb{N}}$ a sequence of X with:

$$\lim_{n \to +\infty} x_n = x \in X \tag{14.2.35}$$

Then the sequence $f(x_n)$ converges and (this proposal is very important!):

$$\boxed{\lim_{n \to +\infty} f(x_n) = f(x)} \tag{14.2.36}$$

In other words, if we use as a set of starting values of a convergent sequence, then the function that take as input the values of this sequence will converge too!

Proof 14.18.1. Given $\varepsilon > 0$. f is delta-epsilon continuous on x, so there exists $\delta > 0$ such that:

$$d(x_n, x) \leq \delta \Rightarrow d(f(x_n), f(x)) \leq \varepsilon \tag{14.2.37}$$

The sequence $(x_n)_{\mathbb{N}}$ tends to x therefore it exists $N \in \mathbb{N}$ such that:

$$n \leq N \Rightarrow d(x, x_n) \leq \delta \tag{14.2.38}$$

If follows that $n \geq N$, we have:

$$d(f(x_n), f(x)) \leq \varepsilon \tag{14.2.39}$$

■ Q.E.D.

If we now consider a compact $X \subseteq \mathbb{R}^n$ and $f : X \mapsto \mathbb{R}^n$ a continuous application. The application $f(X)$ is compact. In particular $\sup(f)$ and $\inf(f)$ will be reached by definition and by construction of a compact (closed and bounded set) which is equal to its adherence.

Theorem 14.19. In other words, a continuous real-valued function on a compact always reaches its supremum or infimum.

Proof 14.19.1. We will do the proof in two steps:

- Let us prove that $f(X)$ is closed.

  Indeed, given $f(x_n)$ a sequence that tends to $y \in \overline{f(X)}$ (we take theadherence to hope to prove that it is equal to the set itself) then X being compact, then $(x_n)_\mathbb{N}$ has a convergent subsequence $(x_{n_i})_{i\in\mathbb{N}}$. Let us put:

  $$\lim_{i\rightarrow+\infty} x_{n_i} = x \in X \qquad (14.2.40)$$

  The function f is delta-epsilon continuous, therefore:

  $$\lim_{i\rightarrow+\infty} f(x_{n_i}) = f(x) \qquad (14.2.41)$$

  But as:

  $$y = \lim_{n\rightarrow+\infty} f(x_n) = \lim_{i\rightarrow+\infty} f(x_{n_i}) \qquad (14.2.42)$$

  we have:

  $$y = f(x) \in f(X) \qquad (14.2.43)$$

  This proves that:

  $$f(X) = \overline{f(X)} \qquad (14.2.44)$$

  and therefore that $f(X)$ is closed.

- Let us now prove that $f(X)$ is bounded.

  For this let us suppose the contrary. There is therefore a sequence $f(x_n)$ such that:

  $$||f(x_n)|| \geq n \qquad (14.2.45)$$

  for every natural integer n (precisely because it is assumed unbounded). Given $(x_{n_i})_{i\in\mathbb{N}}$ a convergent subsequence of $(x_n)_\mathbb{N}$ with:

  $$\lim_{i\rightarrow+\infty} x_{n_i} = x \in X \qquad (14.2.46)$$

  Then:

  $$\lim_{i\rightarrow+\infty} f(x_{n_i}) = f(x) \qquad (14.2.47)$$

and it follows:

$$\lim_{i \to +\infty} ||f(x_{n_i})|| = ||f(x)|| \tag{14.2.48}$$

but this is in contradiction with:

$$\lim_{i \to +\infty} ||f(x_{n_i})|| = \lim_{i \to +\infty} n_i = +\infty \tag{14.2.49}$$

Therefore $f(X)$ is bounded. Then $f(X)$ being closed is bounded and therefore is compact.

■ Q.E.D.

Now let apply this result (because this is what interests us in fractal spaces) to calculate the distance from a point to a set:

Theorem 14.20. Given $x \in \mathbb{R}^n$, the application $f : \mathbb{R}^n \mapsto \mathbb{R}$ defined by $f(y) = d(x, y)$ is continuous.

Proof 14.20.1. For $(y, z) \in \mathbb{R}^2$, the triangle inequality gives us:

$$d(x,y) \leq d(x,z) + d(z,y) \Rightarrow d(x,y) - d(x,z) \leq d(z,y) \tag{14.2.50}$$

By changing the roles of y, z we get:

$$d(x,z) - d(x,y) \leq d(z,y) \tag{14.2.51}$$

and therefore:

$$|d(x,z) - d(x,y)| \leq d(z,y) \tag{14.2.52}$$

Therefore for a given $\varepsilon > 0$, $d(z,y) \leq \varepsilon$ implies:

$$|d(x,z) - d(x,y)| \leq \varepsilon \tag{14.2.53}$$

That is to say:

$$|f(z) - f(y)| \leq \varepsilon \tag{14.2.54}$$

and f is therefore continuous on y.

■ Q.E.D.

Definition (#14.2.585): For $x \in \mathbb{R}^n$ and $A \subseteq \mathbb{R}^n$ we define the distance x to A as being the value:

$$d(x,A) = \inf\{d(x,a) | a \in A\} \tag{14.2.55}$$

Theorem 14.21. If $x \in A$ then $d(x,A) = 0$ (should me almost trivial). The reciprocal is not true. Indeed in the case $x = 0$ and $A =]0,1]$ we have indeed $d(x,A) = 0$ but $x \in A$. So we have the following important proposal:

$$d(x,A) = 0 \Leftrightarrow x \in \bar{A} \tag{14.2.56}$$

Proof 14.21.1. The fact that $d(x,A)=0$ implies the existence of a sequence $(a_n)_{\mathbb{N}}$ of elements of A such that:

$$\lim_{n\rightarrow+\infty} d(x,a_n)=0 \tag{14.2.57}$$

which means

$$\lim_{n+\infty} a_n=x \tag{14.2.58}$$

therefore $x\in\bar{A}$ (see previous developments).

Conversely, if $x\in\bar{A}$ then for every $\varepsilon>0$ there exists $a\in A$ such as $d(x,a)\leq\varepsilon$. But $d(x,A)\leq d(x,a)\leq\varepsilon$. Thus for any $\varepsilon>0$, $d(x,A)\leq\varepsilon$. That is to say:

$$d(x,A)=0 \tag{14.2.59}$$

■ Q.E.D.

In general the distance from x to A is not reached. That is to say that there is no $a\in A$ such that $d(x,A)=d(x,a)$. To check this, it is sufficient to consider the example $x=-1$ and $A=]0,1]$. We have in this example $d(x,A)=1$ but for any $a\in A$, $d(x,a)>1$. If A is compact, the situation is obviously different according to the following proposal (the most important for the Hausdorff distance in our point of view):

Theorem 14.22. If $A\subseteq\mathbb{R}^n$ is compact, there exist $a\in A$ such that $d(x,A)=d(x,a)$. Therefore:

$$d(x,A)=\min\{d(x,y)|y\in A\} \tag{14.2.60}$$

Proof 14.22.1. The application $f:A\mapsto\mathbb{R}$ defined by $f(a)=d(x,a)$ is continuous as previously proved. Therefore $f(A)$ is compact (see a previous proposal). Thus, f reaches its bounds, that is to say, there is $a\int A$ such that $f(a)=\inf(f(A))$. Therefore:

$$d(x,a)=f(a)=\inf(f(A))=d(x,A) \tag{14.2.61}$$

■ Q.E.D.

Remark

This previous proposition does not say that a is unique, in general in fact it is not!

14.2.1.1 Fractals Metric Space

Fractals are often perceived by people as pretty drawings on paper, but when we look in detail the geometry of fractal, we need a particular space to study them, much like the biologist who puts small worms on a wafer to observe the worms in detail to the microscope. We will do the same for our fractals by placing them in a place they like...

This place is likely to be a subspace of $\mathbb{R}^2$ or $\mathbb{R}^3$, since in the end it will produce drawings... And to illustrate this we often will place ourselves in $\mathbb{R}^2$ (with the Euclidean metric), and unless otherwise stated, we always consider the case where (X,d) is a complete metric space.

Let us collect different items in order to construct this space:

Definition (#14.2.586): We define $\mathcal{H}(X)$ as the space whose points are the compacts subsets of X other than X itself. From now, we will name "fractal" any element of $\mathcal{H}(X)$.

✍**Example:**

It is immediate that if $x,y\in\mathcal{H}$, then $x\cup y\in\mathcal{H}$ but $x\cap y$ is not necessarily in $\mathcal{H}$. It is sufficient to see the figure below with the two compact sets of $\mathbb{R}^2$ (closed and bounded therefore) below. There are therefore two points of $\mathcal{H}$.. Their union is still a compact, and therefore:

$$z=x\cup y\in\mathcal{H}(\mathbb{R}^2) \tag{14.2.62}$$

By cons, if the sets are disjoint (as here), $x\cap y=\varnothing$ and therefore x, y are not a point of $\mathcal{H}(\mathbb{R}^2)$ (see previous theory).

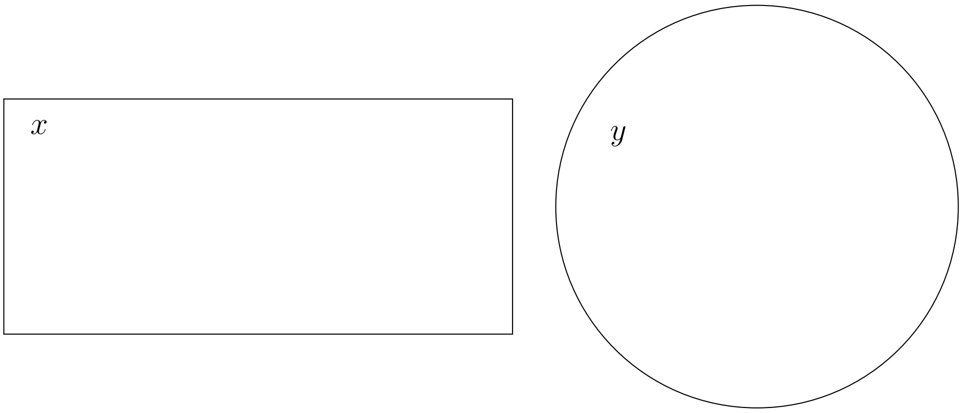

Figure 14.241: **Source: IFS and L-System V. Rezzonico, C. Hebeisen**

Another example involves taking the Cantor fractal...

Definition (#14.2.587): Given $x\in X$ and $B\in\mathcal{H}(X)$, we define the distance $d(x,B)$ of a point x to a set B by:

$$d(x,B)=\min\{d(x,y)|y\in B\} \tag{14.2.63}$$

Remarks

R1. This definition is quite general and applies to any non-empty subset of X, by replacing $\min$ by $\inf$. But in our specific case, we are interested in taking precisely $\mathcal{H}(X)$ as a subspace.

R2. This distance is well defined (is exists) as B is non-empty and compact.

R3. It is trivial to see that if this distance is zero, then $x\in\bar{B}$.

Example:

Illustration in the case where $X=\mathbb{R}^2$:

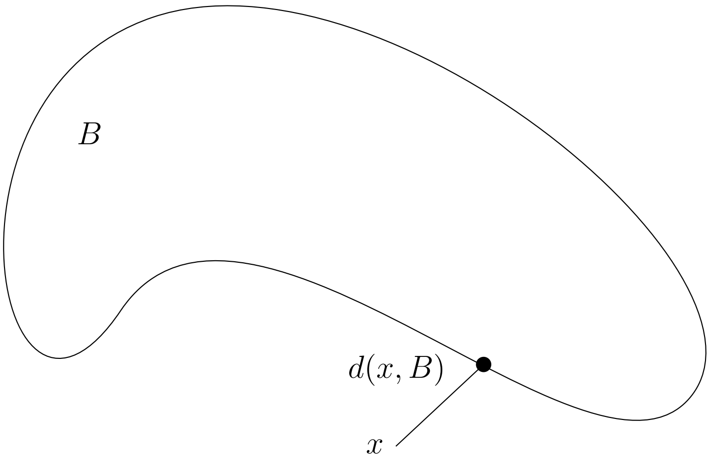

Figure 14.242: **Source: IFS and L-System V. Rezzonico, C. Hebeisen**

Definition (#14.2.588): Given $A,B\in\mathcal{H}(X)$. We define and denote the distance from A to B by:

$$d(A,B)=\max\{d(x,B)|x\in A\} \tag{14.2.64}$$

Remarks

R1. This definition is quite general and applies to any non-empty subset of X, by replacing $\min$ by $\inf$. But in our specific case, we are interested in taking precisely $\mathcal{H}(X)$ as a subspace.

R2. We notice that this distance does not provide a $\mathcal{H}(X)$ metric: indeed, $d(A,B)\neq d(B,A)$ in general (take for example the Cantor fractal where some compact we have $A\subset B$ with $A\neq B$, then we have $d(A,B)=0$ but $d(B,A)>0$).

Definition (#14.2.589): Given $A,B\in\mathcal{H}(X)$. We define and denote "Hausdorff distance" between two sets $A,B\in\mathcal{H}(X)$ by:

$$h(A,B)=\max\{d(A,B),d(B,A)\} \tag{14.2.65}$$

This time, by this definition, we have well a metric on $\mathcal{H}(X)$.

Indeed, let us check that the five properties of a distance are satisifed (see section Topology page 2450):

Given $A,B,C\in\mathcal{H}(X)$. Clearly we have without proof[81] (symmetry, nullity and separation on the diagonal):

---

[81] But let us know as always if you want we put the proofs

$$\begin{gathered}h(A,B)=h(B,A)\\ h(A,A)=d(A,A)=0\\ h(A,B)=0\Leftrightarrow A=B\end{gathered}\tag{14.2.66}$$

Moreover, since A and B are compact, $h(A,B)=d(A,B)$ (see on of the previous proposals) for a given $a\in A$ and a given $b\in B$. But, since $d(a,b)>0$ by definition, we have (property of positivity) finally $h(A,B)>0$ such that $a\in A,A\notin B$:

$$h(A,B)=\max\{d(A,B),d(B,A)\}\geq d(A,B)=\max\{d(a,B)|a\in A\}\geq d(a,B)>0\tag{14.2.67}$$

as B is closed.

Finally, since $h(A,B)=d(a,b)$ (see the extension of one of previous proposals), the triangle inequality is necessarily respected and then:

$$h(A,B)\leq h(A,B)+h(C,B)\tag{14.2.68}$$

So h is indeed a metric of $\mathcal{X}$, which makes $(\mathcal{H}(X),h)$ a metric space. This is a first step in the desired direction, we now have the tools to compare two sets belonging to $\mathcal{X}(X)$ by the Hausdorff distance between them. If the two are not "too different", so intuitively that distance should be fairly small.

If we choose a strictly contracting function $f:X\mapsto X$ of constant λ (see section Topology page 2459). Then, the application:

$$T_\lambda:\mathcal{H}(X)\mapsto\mathcal{H}(X)\tag{14.2.69}$$

defined by:

$$T_\lambda(A)=f(A)\tag{14.2.70}$$

is by onstruction also strictly contracting of constant λ.

Given $f_i:\mathbb{R}^2\mapsto\mathbb{R}^n$, $i\leq i\leq k$ strictly contracting applications of contraction constant $0\leq\lambda_i<1$. Then, there exists a unique compact $A\in\mathcal{H}(\mathbb{R}^n)$ such that:

$$A=T_{\lambda_1,\ldots,\lambda_k}(A)=f_1(A)\cup\ldots\cup f_k(A)\tag{14.2.71}$$

(A is the unique fixe point of $T_{\lambda_1,\ldots,\lambda_k}$) and for any compact B, we have:

$$\lim_{m\to+\infty}T_{\lambda_1,\ldots,\lambda_k}(B)=A\tag{14.2.72}$$

where $T^m_{\lambda_1,\ldots,\lambda_k}(B)$ is the m-th iteration of B by $T_{\lambda_1,\ldots,\lambda_k}$.

This result derives from the fixed-point theorem (see section Sequences and Series page 1781) applied to the space $\mathcal{H}(\mathbb{R}^n)$ that is complete.

With the same notation, we say that $f_1,\ldots,f_k$ is an IFS (Iterated Function Systems) coding of the compact A. Thus the functions $f_1,\ldots,f_k$ define the compact A. What is surprising, as we will see in the following examples, is that the $f_1,\ldots,f_k$ are usually quite simple (as homotheties of the plan) while the compact A is in many cases relatively or very "complicated" visually speaking.

If case $k=1$ is without interest, we would have $A=(x)$ where x is the fixed point of f_1. With $k=2$ we already obtain nontrivial results.

Remark

When the iterative contracting functions are all homotheties we speak then of "Sierpinski's fractal". Thus, the Cantor fractal belongs to the family of Sierpinski's fractals.

A frequently used method for to generate IFS fractals (as it will be the case below with Maple™ 4.00b[82]) is to consider a point in the plane (x_n, y_n) on which we can without conditions or constraints apply an affine transformation to get a new point such that:

$$\begin{aligned} x_{n+1} &= ax_n + by_n + e \\ y_{n+1} &= cx_n + dy_n + f \end{aligned} \tag{14.2.73}$$

where a, b, c, d, e and f are any constants, and (x_0, y_0) is given (chosen).

We can therefore consider an application T that describes our transformation, and in matrix form we can write the previous system as follows:

$$T\begin{pmatrix} x \\ y \end{pmatrix} = \begin{bmatrix} a & b \\ c & d \end{bmatrix}\begin{pmatrix} e \\ f \end{pmatrix} \tag{14.2.74}$$

or even:

$$W(\bar{x}) = A\vec{x} + \vec{b} \tag{14.2.75}$$

So in general, the vector $\vec{b}$ above simply describes a translation, and the matrix A is the composition of a rotations and a scaling (see section Euclidean Geometry page 2640). Computer programs (as it will be the case in the examples below), thus often require that the knowledge of the six parameters a, b, c, d, e and f that can for majority be equal to zero.

---

[82] But if some readers have reproduced all the example below in C++ they are welcome to share their code

14.2.2 Fractals Visualization

14.2.2.1 Cantor's Fractal (Cantor Set)

Let us come back now on Cantor's Fractal but see now from the point of view of the application of two iterative contracting functions f_1, f_2 (thus corresponding to $k=2$).

So we start from the following closed bounded set (then a compact as it is bounded):

$$[[0,1]] \tag{14.2.76}$$

Therefore:

Figure 14.243: **Start set of Cantor's Fractal**

So now by definition we split in three equal parts and we remove the middle interval. This gives us the set:

$$[[0,1/3],[2/3,1]]=[0,1/3]\cup[2/3,1] \tag{14.2.77}$$

Therefore:

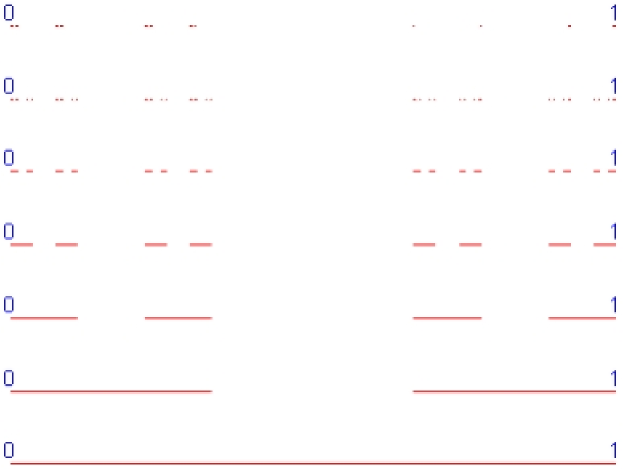

Figure 14.244: **First iteration of Cantor's Fractal**

We can see that $[0,1/3]$ can be obtained by the following homothety (scaling) application of factor $1/3$ centered at $(0,0)$:

$$f_1=h_{(x,y)}^{\lambda}=h_{(0,0)}^{1/3} \tag{14.2.78}$$

and that $[2/3,1]$ can be obtained by the following homothety (scaling) of factor $1/3$ centered at $(1,0)$:

$$f_2=h_{(x,y)}^{\lambda}=h_{(1,0)}^{1/3} \tag{14.2.79}$$

and so on, and we get as we already know (see Maple™ 4.00b code already given above):

Figure 14.245: Cantor attractor after 6 iterations

Which corresponds using the formalism seen earlier to:

$$\begin{aligned}&A_0=[0,1]\\&A_1 f_1([0,1])\cup f_2([0,1])=[[0,1/3],[2/3,1]]\\&A_2=f_1(A_1)\cup f_2(A_1)=\ldots\\&\quad\ldots\end{aligned} \tag{14.2.80}$$

This process is continued ad infinitum, where the n-th set is

$$C_n=\frac{C_{n-1}}{3}\cup\left(\frac{2}{3}+\frac{C_{n-1}}{3}\right) \tag{14.2.81}$$

with obviously $C_0=[0,1]$.

But let us see that it works with any compact of $\mathbb{R}$ as a square for example with the following Maple™ 4.00b code (we always show all the details of Maple™ 4.00b, because nothing says that readers have the software or that the software will still exist in 50 years for reproductibility purposes...).

Remark

It seems that there may be sometimes issues by copying and pasting the below code into Maple™ 4.00b. If it's the case one your computer, just rewrite it from scratch directly in the Maple™ console.

```
>transforme_point := proc(t, p)
[t[1]*p[1]+t[2]*p[2]+t[5], t[3]*p[1]+t[4]*p[2]+t[6]]
end:

>IFSS := proc(n, liste_de_transformations,col)
local i, j, k, s, seq_square:
seq_square :=[[0,0],[1,0],[1,1],[0,1]];
for j to n do
s := NULL;
for i to nops(liste_de_transformations) do
s := s,
seq(transform_square(liste_de_transformations[i],
op(k, [seq_square])),
k=1 .. nops([seq_square]))
od;
seq_square := s
od;
plots[polygonplot]([seq_square], axes=none, color=col,
scaling=constrained)
end:
```

```
>cantor:=[[evalf(1/3),0,0,evalf(1/3),0,0],[evalf(1/3),0,0,evalf(1/3),
evalf(2/3),0]]:
```

```
>IFSS(1, cantor,blue);
```

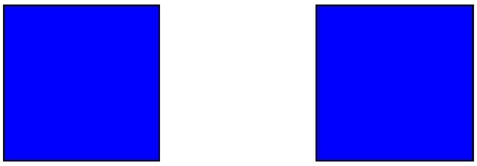

Figure 14.246: **First iteration on the Cantor set with squares**

```
>IFSS(2, cantor,blue);
```

Figure 14.247: **Second iteration on the Cantor set with squares**

```
>IFSS(3, cantor,blue);
```

Figure 14.248: **Third iteration on the Cantor set with squares**

etc.

So, whatever the starting set, the sequence of compact obtained by successive application of these two plane homotheties always converge (in the sense of the Hausdorff distance) to the same compact/attractor (assimilated to the fixed of the Fixed point theorem...) named Cantor's fractal or Cantor set (thus belonging to the family of Serpienski fractals). The latest figure above is a good approximation of this set.

The Cantor set being self-similar, consisting of $N=2$ congruent subsets, each when magnified by a factor of $M=3$ yields the original set. Hence the fractal dimension (see section Euclidean Geometry page 2555) of the Cantor set is:

$$d=\frac{\log(2^n)}{\log(3^n)}=\frac{n\log(2)}{n\log(3)}\cong 0.631 \tag{14.2.82}$$

14.2.2.2 Triangle Sierpinski Fractal

To build the Sierpinski fractal (which can be found as curiosity sometimes on the seashell Cymbiola innexa REEVE), based on three iterative contracting functions f_1, f_2, f_3 (thus corresponding to $k=3$), we assume for example three following points of $\mathbb{R}^2$:

$$[[0,0],[1,0],[0.5,1]] \tag{14.2.83}$$

Which gives with Maple™ 4.00b:

The Sierkpinski Triangle consists of 3^n subsets with magnification factor 2^n. So the fractal dimension is:

$$d=\frac{\log(3^n)}{\log(2^n)}=\frac{n\log(3)}{n\log(3)}\cong 1.585 \tag{14.2.84}$$

```
>plots[polygonplot]( [[0, 0], [1, 0], [0.5, 1]],axes=none,color=black,
scaling=constrained);
```

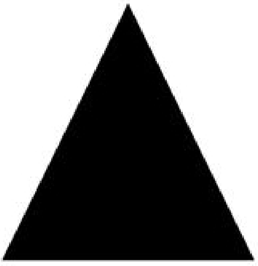

Figure 14.249: Start set of triangle Sierpinski fractal

This is a triangle, but we could start from any shape and we always arrive at the same result as we will see later.

We apply on each set a contracting function of factor 0.5, this gives the triangle:

$$[[0,0],[0.5,0],[0.25,0.5]] \tag{14.2.85}$$

and we denote that this homothety (scaling) of factor 0.5 and center $(0,0)$ on the original triangle by:

$$f_1=h_{(x,y)}^{\lambda}=h_{(0,0)}^{1/2} \tag{14.2.86}$$

We do now on this triangle a translation of 0.5 in the direction of the x-axis, which gives the triangle:

$$[[0.5,0],[1,0],[0.75,0.5]] \tag{14.2.87}$$

which corresponds to a scaling factor of 0.5 and center (1.0) on the original triangle:

$$f_2=h_{(x,y)}^{\lambda}=h_{(1,0)}^{1/2} \tag{14.2.88}$$

We now translate $[[0,0],[0.5,0],[0.25,0.5]]$ of 0.25 along the x-axis and of 0.5 according to the y-axis to have:

$$[[0.25,0.5],[0.75,0.5],[0.5,1]] \tag{14.2.89}$$

which corresponds to a scaling factor of 0.5 of center $(0.5,0.75)$ on the original triangle:

$$f_3=h_{(x,y)}^{\lambda}=h_{(0.5,0.75)}^{1/2} \tag{14.2.90}$$

With Maple™ 4.00b it now gives for the three triangles:

```
>plots[polygonplot]([[[0,0],[0.5,0],[0.25,0.5]],[[0.5,0],[1,0],[.75,0.5]],
[[0.25,0.5],[0.75,0.5],[0.5,1]]], axes=none,color=black,
scaling=constrained);
```

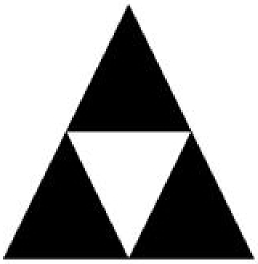

Figure 14.250: First iteration on the Sierpinksi triangle

and so on...:

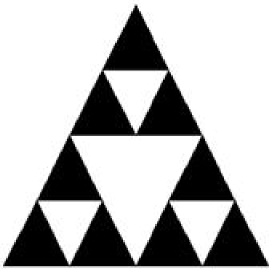

Figure 14.251: Second iteration on the Sierpinksi triangle

and so on...:

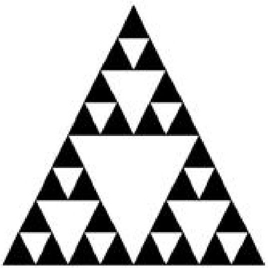

Figure 14.252: Third iteration on the Sierpinksi triangle

and so on...:

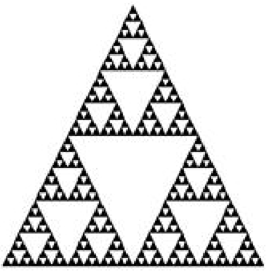

Figure 14.253: **Fourth iteration on the Sierpinksi triangle**

and so on (the triangles begins to be quite small to see a difference without zoom)...:

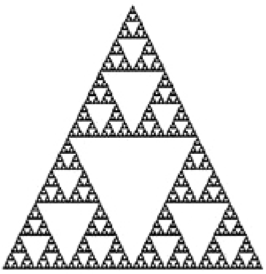

Figure 14.254: **Sixth iteration on the Sierpinksi triangle**

Which corresponds by taking the formalism seen previously:

$$\begin{aligned} A_0 &= [[0,0],[1,0],[0.5,1]] \\ A_1 &= f_1([0,0]) \cup f_2([1,0]) \cup f_3([0.5,1]) \end{aligned} \quad (14.2.91)$$

We can make the same remark as when we have study the Cantor's Fractal: whatever the starting set, the sequence of compact obtained by successive application of these three plane homotheties always converge (in the sense of the Hausdorff distance) to the same compact/attractor (assimilated to the fixed of the Fixed point theorem...) named Sierpinski fractal. The latest figure above is a good approximation of this set.

Let's see this with a Maple™ 4.00b code (once again if the copy/paste from the book in Maple™ 4.00b does not work, simply rewrite the code in the Maple™ console):

```
>transforme_triangle := proc(t, triangle)
local i;
[seq(transforme_point(t, triangle[i]), i=1 ..  3)] end:

>IFS := proc(n, liste_de_transformations,col)
local i, j, k, s, sequence_de_triangles:
options ‘Copyright by Alain Schauber, 1996‘;
sequence_de_triangles := [[0, 0], [1, 0], [0.5, 1]];
for j to n do
s := NULL;
for i to nops(liste_de_transformations) do
s:= s,
seq(transforme_triangle(liste_de_transformations[i],
op(k, [sequence_de_triangles])),
k=1 .. nops([sequence_de_triangles]))
od;
sequence_de_triangles := s
od;
plots[polygonplot]([sequence_de_triangles], axes=none, color=col,
scaling=constrained)
end:
```

```
>triangle_de_Sierpinski:=[[0.5,0,0,0.5,0,0],[0.5,0,0,0.5,0.5,0],
[0.5,0,0,0.5,0.25,0.5]]:
```

```
>IFS(6, triangle_de_Sierpinski,blue);
```

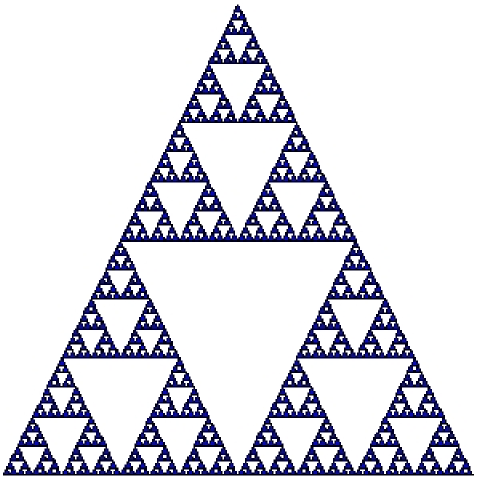

Figure 14.255: **Sierpinski triangle attractor**

And this time we don't start from a triangle but from a square (IFS Square) with the following Maple™ 4.00b code:

```
>transforme_square := proc(t, square)
local i;
[seq(transforme_point(t, square[i]), i=1 .. 4)] end:
```

```
>IFS := proc(n, liste_de_transformations,col)
local i, j, k, s, seq_square:
seq_square := [[0, 0], [1, 0], [1, 1],[0, 1]];
for j to n do
s := NULL;
for i to nops(liste_de_transformations) do
s:= s,
seq(transform_square(liste_de_transformations[i],
op(k, [seq_square])),
k=1 .. nops([seq_square]))
od;
```

```
seq_square := s
od;
plots[polygonplot]([seq_square], axes=none, color=col,
scaling=constrained)
end:
```

```
>square_Sierpinski:=[[0.5,0,0,0.5,0,0],[0.5,0,0,0.5,0.5,0],
[0.5,0,0,0.5,0.25,0.5]]:
```

```
>IFS(1, square_Sierpinski,green);
```

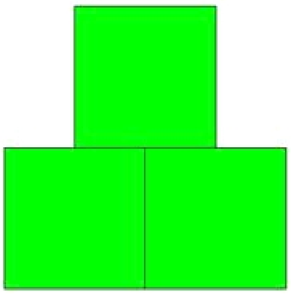

Figure 14.256: **First iteration on the Sierpinksi square**

```
>IFS(2, square_Sierpinski,green);
```

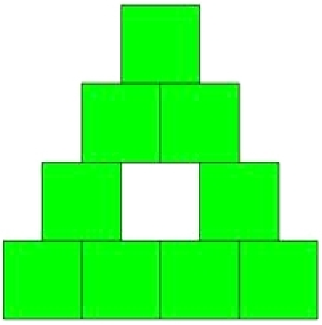

Figure 14.257: **Second iteration on the Sierpinksi square**

```
>IFS(3, square_Sierpinski,green);
```

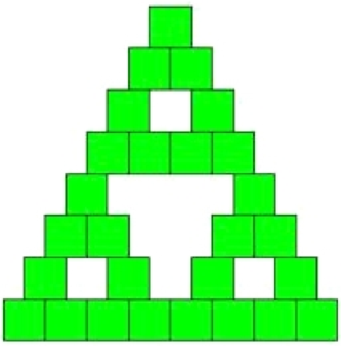

Figure 14.258: **Third iteration on the Sierpinksi square**

and so on until...:

```
>IFS(6, square_Sierpinski,green);
```

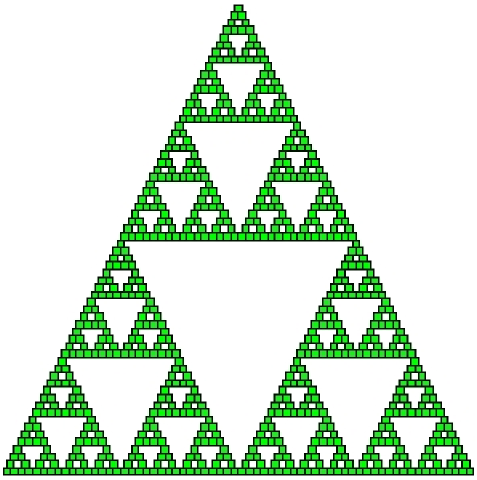

Figure 14.259: Sixth iteration on the Sierpinksi square

Basically, the Sierpinski fractal can obviously be also seen as a triangle to which the middle of the triangle is removed and where for each of the remaining triangles, we restart the process!

14.2.2.3 Sierpinski carpet fractal

The Sierpinski carpet is the attractor of eight contracting iterative functions of homothety of ratio $1/3$ centered at the vertices and sides of a square in which can be any put any plane geometric shape.

This time in $\mathbb{R}^2$ we consider the eight homotheties (h):

$$h_{(0,0)}^{1/3}, h_{(0,0.5)}^{1/3}, h_{(0,1)}^{1/3}, h_{(0.5,1)}^{1/3}, h_{(1,1)}^{1/3}, h_{(1,0.5)}^{1/3}, h_{(1,0)}^{1/3}, h_{(0.5,0)}^{1/3}, \tag{14.2.92}$$

and we start for example from the four following points:

$$[[0,0],[1,0],[1,1],[0,1]] \tag{14.2.93}$$

that corresponds to a filled square (but we can choose anything else!):

Figure 14.260: Start set of Sierpinski carpet fractal

After application of the eight homotheties functions (we leave to the reader the manual calculations in the same we way we have already do it for the triangle), we get the following form of eight squares:

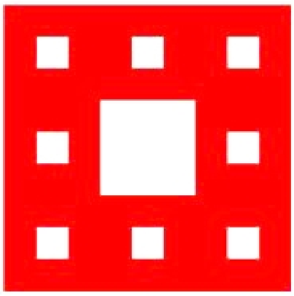

Figure 14.261: **Second iteration of Sierpinski carpet fractal**

and applying again the eight homotheties (fortunately there are computers...):

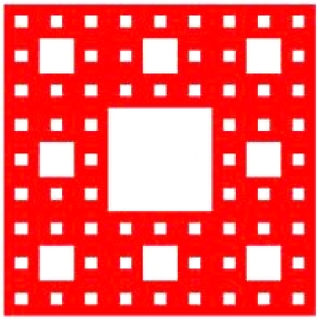

Figure 14.262: **Third iteration of Sierpinski carpet fractal**

and again:

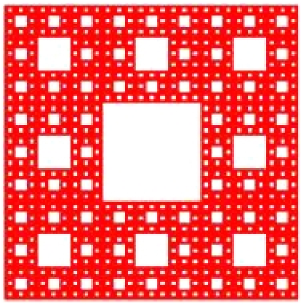

Figure 14.263: **Fourth iteration of Sierpinski carpet fractal**

etc.

The resulting fixed point (attractor) is obviously named the "Sierpinski's carpet" and this is the shape of the receiving antenna of the majority of our cell phones in the early 121st century (holocene calendar).

The above figures can be obtained successively with the following Maple™ 4.00b code (if the copy/paste form the book in Maple™ 4.00b does not work, simply rewrite the code in the Maple™ console):

```
>transforme_point := proc(t, p)
[t[1]*p[1]+t[2]*p[2]+t[5], t[3]*p[1]+t[4]*p[2]+t[6]]
end:
```

```
>transform_square := proc(t, square)
local i;
[seq(transforme_point(t, square[i]), i=1 ..  4)]
end:
```

```
>IFSS := proc(n, liste_de _transformations,col)
local i, j, k, s, seq_square:
seq_square :=[[0,0],[1,0],[1,1],[0,1]];
for j to n do
s := NULL;
for i to nops(liste_de_transformations) do
s := s,
seq(transform_square(liste_de _transformations[i],
op(k, [seq_square])),
k=1 ..  nops([seq_square]))
od;
seq_square := s
od;
plots[polygonplot]([seq_square], axes=none, color=col,
scaling=constrained)
end:
```

```
> dywan:= [[evalf(1/3),0,0,evalf(1/3),0,0],[evalf(1/3),0,0,evalf(1/3),
evalf(1/3),0],[evalf(1/3),0,0,evalf(1/3),evalf(2/3),0],
[evalf(1/3),0,0,evalf(1/3),0,evalf(2/3)], [evalf(1/3),0,0,evalf(1/3),evalf(1/3),
evalf(2/3)],[evalf(1/3),0,0,evalf(1/3), evalf(2/3),evalf(2/3)],
[evalf(1/3),0,0,evalf(1/3),0,evalf(1/3)], [evalf(1/3),0,0,evalf(1/3),evalf(2/3),eva
```

```
>IFSS(0, dywan, blue);
```

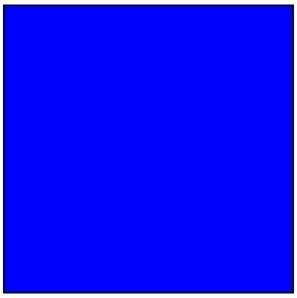

Figure 14.264: **Start set of Sierpinski carpet fractal**

```
>IFSS(1, dywan, blue);
```

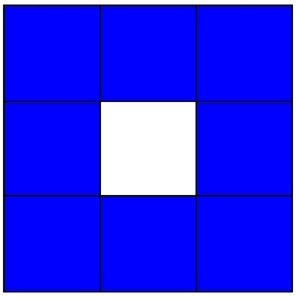

Figure 14.265: First iteration of Sierpinski carpet fractal

```
>IFSS(2, dywan, blue);
```

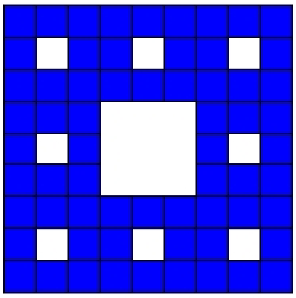

Figure 14.266: Second iteration of Sierpinski carpet fractal

```
>IFSS(3, dywan, blue);
```

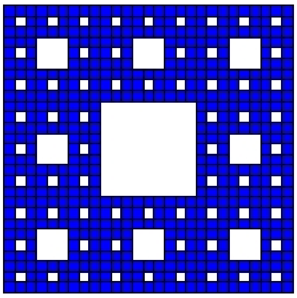

Figure 14.267: Third iteration of Sierpinski carpet fractal

```
>IFSS(4, dywan, blue);
```

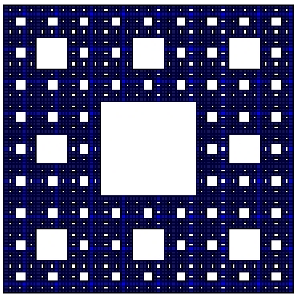

Figure 14.268: Fourth iteration of Sierpinski carpet fractal

14.2.2.4 Fractal spirals

We just saw two fractals of the Sierpinski's fractal family therefore based solely on contracting homotheties. Let us now see a fractal that combines rotation and scaling contraction.

In $\mathbb{R}^2$ we consider the two applications of homotheties (h) and rotations (R) as follows:

$$h_{(0.25,0.5)} \circ R^{5\pi/6}_{(0.25,0.5)} \qquad h_{(0.5,0.5)} \circ R^{\pi/6}_{(0.5,0.5)} \tag{14.2.94}$$

With a triangle and always with Maple™ 4.00b, this gives us (if the copy/paste form the book in Maple™ 4.00b does not work, simply rewrite the code in the Maple™ console):

```
>transforme_triangle := proc(t, triangle)
local i;
[seq(transforme_point(t, triangle[i]), i=1 ..  3)]
end:
```

```
>IFS := proc(n, liste_de_transformations,col)
local i, j, k, s, sequence_de_triangles:
options ‘Copyright by Alain Schauber, 1996‘;
sequence_de_triangles := [[0, 0], [1, 0], [0.5, 1]];
for j to n do
s := NULL;
for i to nops(liste_de_transformations) do
s := s,
seq(transforme_triangle(liste_de_transformations[i],
op(k, [sequence_de_triangles])),
k=1 ..  nops([sequence_de_triangles]))
od;
sequence_de_triangles := s
od;
plots[polygonplot]([sequence_de_triangles], axes=none, color=col,
scaling=constrained)
end:
```

```
>a:=evalf(5*Pi/6);b:=evalf(Pi/6);
>c1x:=0.25;c1y:=0.5;c2x:=0.5;c2y:=0.5;
>h1:=0.2;h2:=0.95;
>spirale:=[[h1*cos(a),-h1*sin(a),h1*sin(a),h1*cos(a),(1-h1*cos(a))*c1x
+h1*sin(a)*c1y,-h1*sin(a)*c1x+(1-h1*cos(a))*c1y],[h2*cos(b),-h2*sin(b),h2*sin(b),
h2*cos(b),(1-h2*cos(b))*c2x+h2*sin(b)*c2y,-h2*sin(b)*c2x+(1-h2*cos(b))*c2y]]:
```

```
>IFS(1,spirale,blue);
```

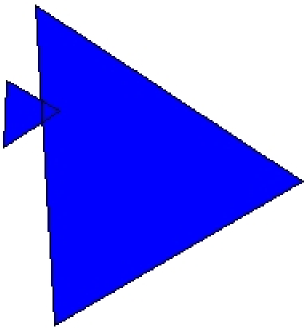

Figure 14.269: **First iteration of spiral fractal**

and as the convergence is very slow, we will give the results by step of 5 iterations.

```
>IFS(6,spirale,blue);
```

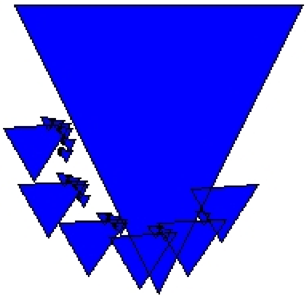

Figure 14.270: **Sixth iteration of spiral fractal**

```
>IFS(11,spirale,blue);
```

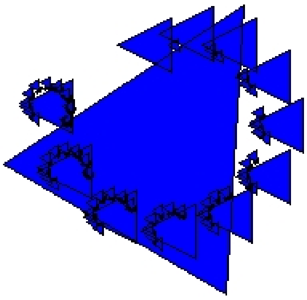

Figure 14.271: **Eleventh iteration of spiral fractal**

```
>IFS(16,spirale,blue);
```

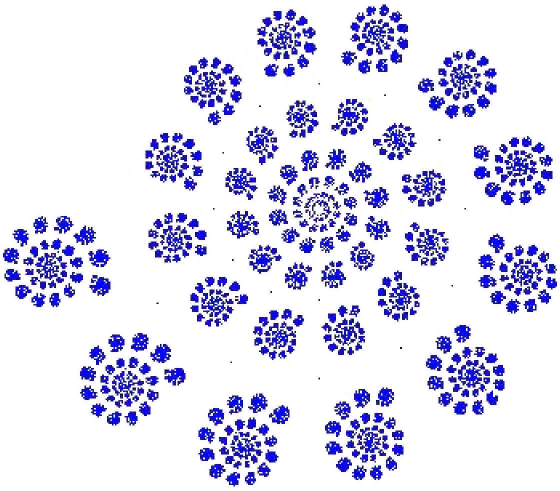

Figure 14.272: Sixteenth iteration of spiral fractal

14.2.2.5 Von Koch fractal (Koch snowflake)

Still, in fractal obtained by contracting homotethies (h) and rotation (R) but to which we add now a translation (T), the Von Koch curve is a well known fractal, it can be obtained by the following applications (we already met this fractal in the section of Euclidean Geometry when we have introduced the concept of fractal dimension):

$$h^{1/3}_{(0,0)} \qquad h^{1/3}_{(1,0)} \qquad T_{(1/3,0)}\circ h^{1/3}_{(0,0)}\circ R^{\pi/3}_{(0,0)} \qquad T_{(-1/3,0)}\circ h^{1/3}_{(1,0)}\circ R^{-\pi/3}_{(1,0)} \tag{14.2.95}$$

Here is the corresponding Maple™ 4.00b code (if the copy/paste form the book in Maple™ 4.00b does not work, simply rewrite the code in the Maple™ console):

```
>koch := proc(p::  numeric)
local m, n, k, l, s, h, x, y, pts, t, i;
h := 3^(-p);
pts := table([]):  # [0, 0];
pts[0]:=[0,0];
x := 0; y := 0;
for n from 0 to (4^p) do
m := n;
s := 0;
for l from 0 to p-1 do
t := irem(m, 4);
m := iquo(m, 4);
s := s+irem((t+1), 3) - 1
od; # end of for l
x := evalhf(x+cos(Pi*s/3)*h);
y := evalhf(y+sin(Pi*s/3)*h);
pts[n+1] := [x, y];
od;
[seq(pts[i], i=0 ..  n-1)];
end:
```

```
>plot(koch(0), scaling=constrained, style=LINE, axes=NONE,
color=blue,thickness=2);
```

Figure 14.273: **Start set of Von Koch fractal**

```
>plot(koch(1), scaling=constrained, style=LINE, axes=NONE,
color=blue,thickness=2);
```

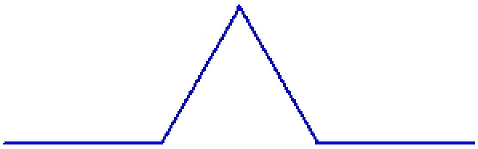

Figure 14.274: **First iteration of Von Koch fractal**

```
>plot(koch(2), scaling=constrained, style=LINE, axes=NONE,

```

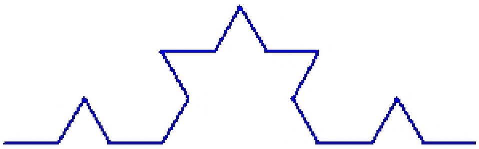

Figure 14.275: **Second iteration of Von Koch fractal**

```
>plot(koch(3), scaling=constrained, style=LINE, axes=NONE,
color=blue,thickness=2);
```

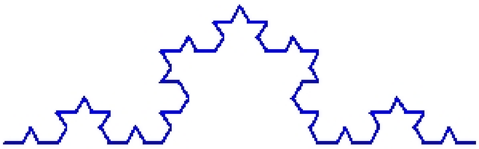

Figure 14.276: **Third iteration of Von Koch fractal**

etc. etc. Until the following attractor:

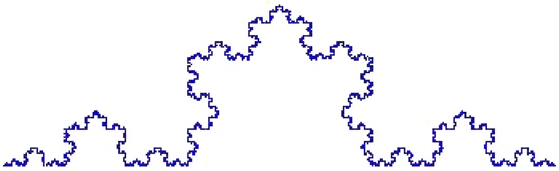

Figure 14.277: Fourth iteration of Von Koch fractal

The Koch snowflake (see figure below) is a variant of the Von Koch line and thab can be constructed by starting with an equilateral triangle, then recursively altering each line segment as follows:

1. Divide the line segment into three segments of equal length.
2. Draw an equilateral triangle that has the middle segment from step 1 as its base and points outward.
3. Remove the line segment that is the base of the triangle from step 2.

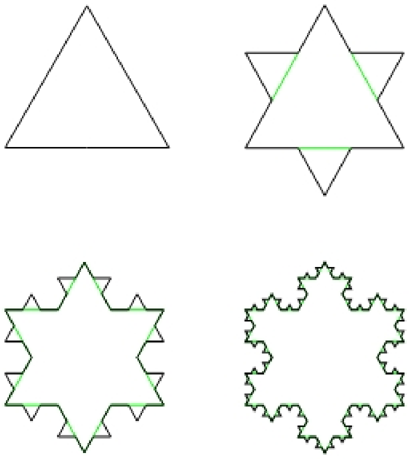

Figure 14.278: Von Koch snowflake (source: Wikipedia)

After each iteration, the number of sides of the Koch snowflake increases by a factor of 4, so the number of sides after n iterations is given by:

$$N_n = N_{n-1} \cdot 4 = 3 \cdot 4^n \tag{14.2.96}$$

If the original equilateral triangle has sides of length s, the length of each side of the snowflake after n iterations is:

$$S_n = \frac{S_{n-1}}{3} = \frac{s}{3^n} \tag{14.2.97}$$

the perimeter of the snowflake after n iterations is therefore of:

$$P_n = N_n \cdot S_n = 3 \cdot s \cdot \left(\frac{4}{3}\right)^n \tag{14.2.98}$$

The Koch curve has an infinite length because the total length of the curve increases by one third with each iteration. Thas is to say:

$$\lim_{n\to+\infty} P_n=\lim_{n\to+\infty} 3\cdot s\cdot\left(\frac{4}{3}\right)^n=+\infty \tag{14.2.99}$$

The funny thing is that the area is finite... when the perimeter is infinite...

Indeed, in each iteration a new triangle is added on each side of the previous iteration, so the number of new triangles added in iteration n is:

$$T_n=3\cdot 4^{n-1}=\frac{3}{4}\cdot 4^n \tag{14.2.100}$$

The area of each new equilateral triangle added in an iteration is one ninth of the area of each equilateral triangle added in the previous iteration, so the area of each equilateral triangle added in iteration n is:

$$a_n=\frac{a_{n-1}}{9}=\frac{a_0}{9^n} \tag{14.2.101}$$

where a_0 is the area of the original equilateral triangle. The total new area added in iteration n is therefore:

$$b_n=T_n\cdot a_n=\frac{3}{4}\cdot\left(\frac{4}{9}\right)^n\cdot a_0 \tag{14.2.102}$$

The total area of the snowflake after n iterations is then obviously:

$$A_n=a_0+\sum_{k=1}^{n} b_k=a_0\left(1+\frac{3}{4}\sum_{k=1}^{n}\left(\frac{4}{9}\right)^k\right)=a_0\left(1+\frac{1}{3}\sum_{k=0}^{n-1}\left(\frac{4}{9}\right)^k\right) \tag{14.2.103}$$

Collapsing the geometric sum of the type $\sum x^n$ using (see section Sequences and Series page 1656):

$$S_n=\sum u_0q^n=\frac{1-q^{n+1}}{1-q} \tag{14.2.104}$$

we get:

$$A_n=a_0\left(1+\frac{3}{5}\left(1-\left(\frac{4}{9}\right)^n\right)\right)=\frac{a_0}{5}\left(8-3\left(\frac{4}{9}\right)^n\right) \tag{14.2.105}$$

The limit of the area is then immediate:

$$\lim_{n\to+\infty} A_n=\lim_{n\to+\infty}\frac{a_0}{5}\cdot\left(8-3\left(\frac{4}{9}\right)^n\right)=\frac{8}{5}\cdot a_0 \tag{14.2.106}$$

So the area of the Koch snowflake is $8/5$ of the area of the original triangle.

What is so disturbing with Von Koch fractal is that we start from a line of finite length, to arrive at the end to a line of infinite length if we reiterate infinitly structure but it has a finished surface ... it's a "pathological" curve as the mathematicians say sometimes.

The Koch curve is legendary because it was used by Mandelbrot to write an article about the problem of measuring the length of the coasts of sea coasts (because the most the basic unit of measurement taken was small, more the perimeter ot the coast was great). He proposed to consider the coasts as fractals for which it is impossible to measure the perimeter but "fractal tree" or in other words: the fractal dimension.

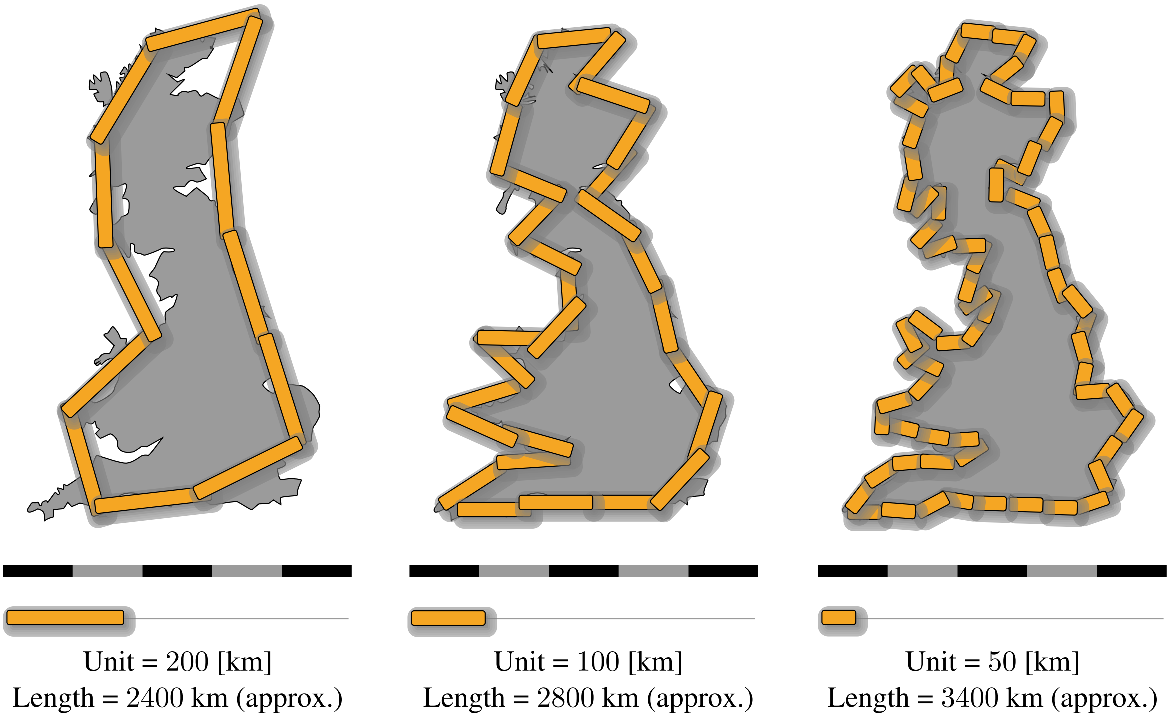
The Koch Curve consists of 4^n subsets with magnification factor 3^n. So the fractal dimension is:

$$d=\frac{\log(4^n)}{\log(3^n)}=\frac{n\log(3)}{n\log(4)}\cong 1.2619 \tag{14.2.107}$$

14.2.2.5.1 Coastline paradox

It is now the right moment in our point of view to speak about the "coastline paradox" that is the counterintuitive observation that the coastline of a landmass does not have a well-defined length. This results from the fractal-like properties of coastlines. The first recorded observation of this phenomenon was by Lewis Fry Richardson and it was expanded by Benoit Mandelbrot.

More concretely, the length of the coastline depends on the method used to measure it. Since a landmass has features at all scales, from hundreds of kilometers in size to tiny fractions of a millimeter and below, there is no obvious size of the smallest feature that should be measured around, and hence no single well-defined perimeter to the landmass. Various approximations exist when specific assumptions are made about minimum feature size.



Unit = 200 [km]
Length = 2400 km (approx.)
Unit = 100 [km]
Length = 2800 km (approx.)
Unit = 50 [km]
Length = 3400 km (approx.)

Figure 14.279: Coastline paradox

The length of "true fractal" therefore always diverges to infinity, as if one were to measure a coastline with infinite, or near-infinite resolution, the length of the infinitely smaller bends of the coastline would add up to infinity. However, this figure relies on the assumption that space can be subdivided indefinitely. The truth value of this assumption - which underlies Euclidean geometry and serves as a useful model in everyday measurement - is a matter of philosophical speculation, and may or may not reflect the changing realities of 'space' and 'distance' on the atomic level (approximately the scale of a nanometer). The Planck length, many orders of magnitude smaller than an atom, is proposed as the smallest measurable unit possible in the universe.

In reality, permanent features of the coastline of order of size 1 cm or less do not exist, because of erosion and other action of the sea. In most places the minimum size is much larger than this. Thus the concept of an infinite fractal is not applicable to the coastline. For practical considerations, an appropriate choice of minimum feature size is on the order of the units being used to measure. If a coastline is measured in kilometers, then small variations much smaller than one kilometer are easily ignored.

14.2.2.6 Natural fractals

Besides the purely mathematical aspect of fractals, we can find, via heuristics, contracting applications for fractal shapes similar to that we can find in nature. Let us see some examples with Maple™ 4.00b always taking first for common basis of all fractals that follow, the following procedures (if the copy/paste form the book in Maple™ 4.00b does not work, simply rewrite the code in the Maple™ console):

```
>transforme_point := proc(t, p)
[t[1]*p[1]+t[2]*p[2]+t[5], t[3]*p[1]+t[4]*p[2]+t[6]]
end:

>transforme_triangle := proc(t, triangle)
local i;
[seq(transforme_point(t, triangle[i]), i=1 ..  3)]
end:

>transform_square := proc(t, square)
local i;
[seq(transforme_point(t, square[i]), i=1 ..  4)]
end:

>IFS := proc(n, liste_de_transformations,col)
local i, j, k, s, sequence_de_triangles:
options `Copyright by Alain Schauber, 1996`;
sequence_de_triangles := [[0, 0], [1, 0], [0.5, 1]];
for j to n do
s := NULL;
for i to nops(liste_de_transformations) do
s := s,
seq(transforme_triangle(liste_de_transformations[i],
op(k, [sequence_de_triangles])),
k=1 ..  nops([sequence_de_triangles]))
od;
sequence_de_triangles := s
od;
plots[polygonplot]([sequence_de_triangles], axes=none, color=col,
scaling=constrained)
end:

>IFSS := proc(n, liste_de_transformations,col)
local i, j, k, s, seq_square:
seq_square :=[[0,0],[1,0],[1,1],[0,1]];
for j to n do
s := NULL;
for i to nops(liste_de_transformations) do
s := s,
seq(transform_square(liste_de_transformations[i],
op(k, [seq_square])),
k=1 ..  nops([seq_square]))
od;
seq_square := s
od;
plots[polygonplot]([seq_square], axes=none, color=col,
scaling=constrained)
end:
```

14.2.2.6.1 Branch

We start from:

```
>rameau:=[[.387,.430,.430,-.387,.2560,.5220],
[.441,-.091,-.009,-.322,.4219,.5059], [-.468,.020,-.113,.015,.4,.4]]:
```

And we get:

```

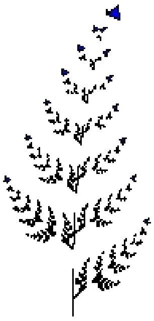

Figure 14.308: Eighth iteration set for fern fractal

etc. Unitl we get:

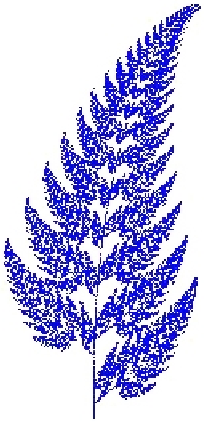

Figure 14.309: Attractor set for fern fractal

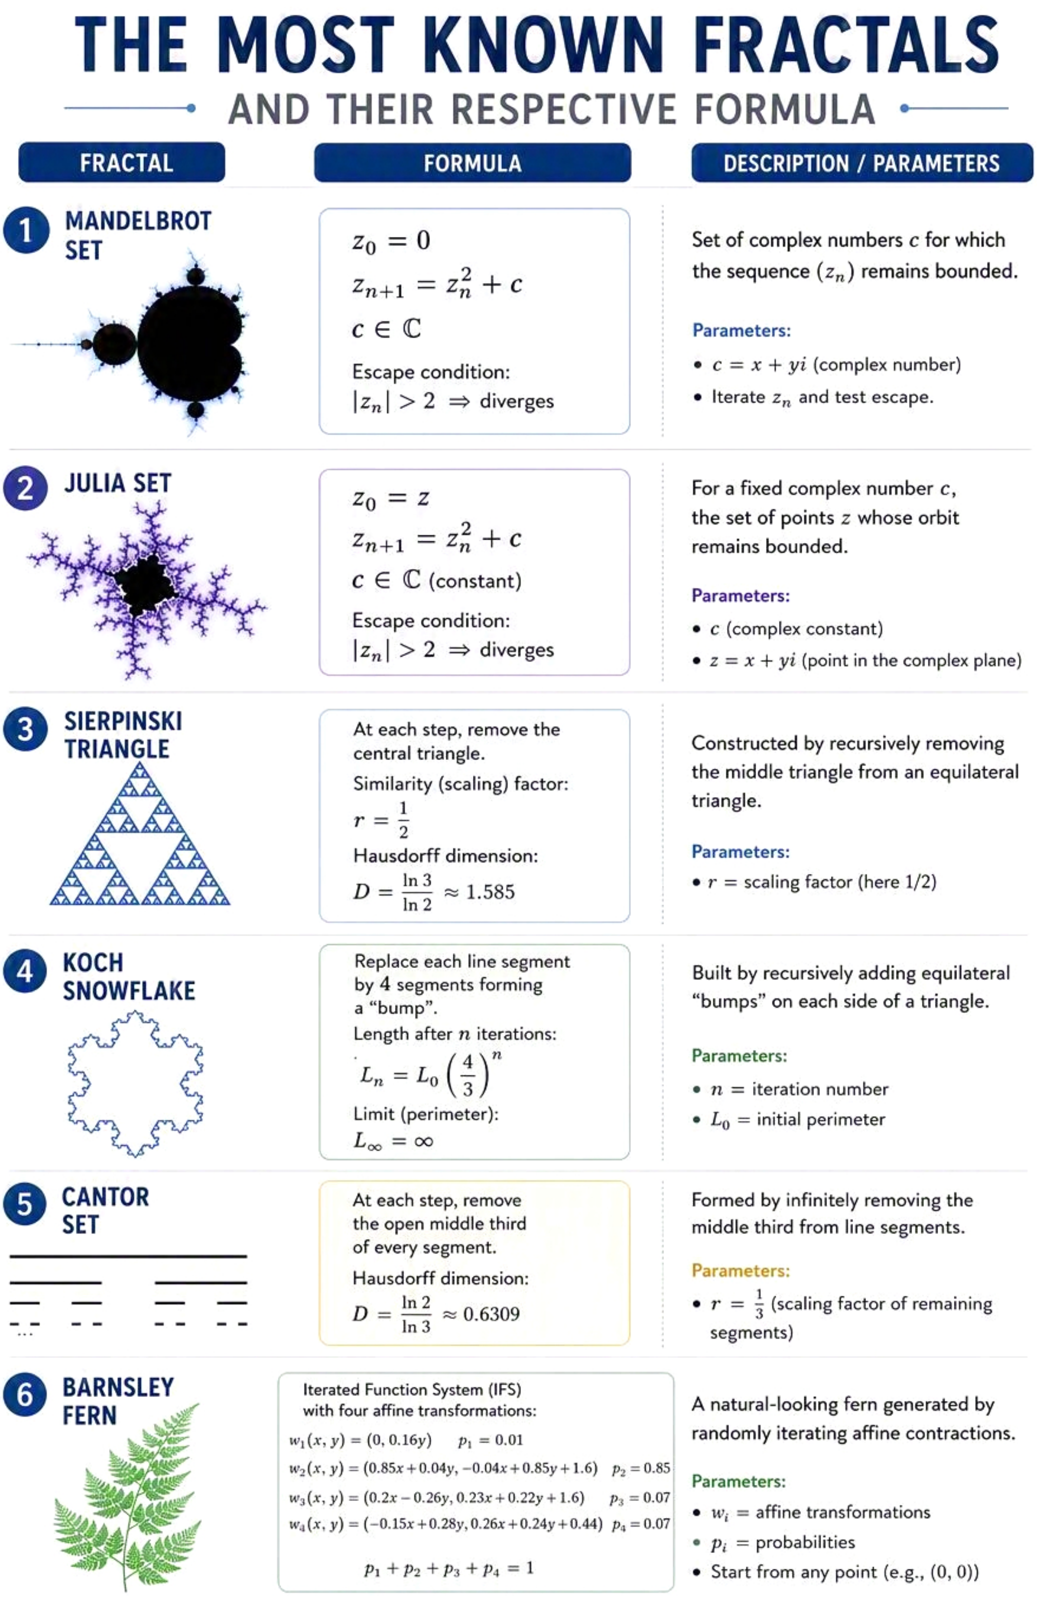
and we will stop here because the examples of IFS and natural fractals are uncountable...



THE MOST KNOWN FRACTALS

AND THEIR RESPECTIVE FORMULA

FRACTAL	FORMULA	DESCRIPTION / PARAMETERS
1 MANDELBROT SET	$z_0 = 0$ $z_{n+1} = z_n^2 + c$ $c \in \mathbb{C}$ Escape condition: $\lvert z_n \rvert > 2 \Rightarrow$ diverges	Set of complex numbers c for which the sequence (z_n) remains bounded. Parameters: • $c = x + yi$ (complex number) • Iterate z_n and test escape.
2 JULIA SET	$z_0 = z$ $z_{n+1} = z_n^2 + c$ $c \in \mathbb{C}$ (constant) Escape condition: $\lvert z_n \rvert > 2 \Rightarrow$ diverges	For a fixed complex number c, the set of points z whose orbit remains bounded. Parameters: • c (complex constant) • $z = x + yi$ (point in the complex plane)
3 SIERPINSKI TRIANGLE	At each step, remove the central triangle. Similarity (scaling) factor: $r = \frac{1}{2}$ Hausdorff dimension: $D = \frac{\ln 3}{\ln 2} \approx 1.585$	Constructed by recursively removing the middle triangle from an equilateral triangle. Parameters: • r = scaling factor (here 1/2)
4 KOCH SNOWFLAKE	Replace each line segment by 4 segments forming a "bump". Length after n iterations: $L_n = L_0 \left(\frac{4}{3}\right)^n$ Limit (perimeter): $L_\infty = \infty$	Built by recursively adding equilateral "bumps" on each side of a triangle. Parameters: • n = iteration number • L_0 = initial perimeter
5 CANTOR SET	At each step, remove the open middle third of every segment. Hausdorff dimension: $D = \frac{\ln 2}{\ln 3} \approx 0.6309$	Formed by infinitely removing the middle third from line segments. Parameters: • $r = \frac{1}{3}$ (scaling factor of remaining segments)
6 BARNSLEY FERN	Iterated Function System (IFS) with four affine transformations: $w_1(x,y) = (0, 0.16y) \quad p_1 = 0.01$ $w_2(x,y) = (0.85x + 0.04y, -0.04x + 0.85y + 1.6) \quad p_2 = 0.85$ $w_3(x,y) = (0.2x - 0.26y, 0.23x + 0.22y + 1.6) \quad p_3 = 0.07$ $w_4(x,y) = (-0.15x + 0.28y, 0.26x + 0.24y + 0.44) \quad p_4 = 0.07$ $p_1 + p_2 + p_3 + p_4 = 1$	A natural-looking fern generated by randomly iterating affine contractions. Parameters: • w_i = affine transformations • p_i = probabilities • Start from any point (e.g., (0, 0))

Figure 14.310: **Summary of most well knows basic fractals**

14.2.3 Escape Time Algorithm Fractals

Several methods have been proposed to construct fractal images as we mentioned at the beginning of this section. The are generally three way of generating fractals that are well known:

- Iterated function systems (seen previously)
- Escape time fractals (we will see now)
- Random fractals

So we will now focus on the methods named "escape time methods".

For this, we place ourselves in the complex plane $\mathbb{C}$ consisting of the points $M(x,y)$ of affix:

$$z=x+\mathrm{i}y \tag{14.2.108}$$

Afterwards we consider a complex sequence defined by:

$$u(0)=z_0 \tag{14.2.109}$$

and:

$$u(n+1)=f(u(n)) \tag{14.2.110}$$

the function f being a complex continuous function. We will assumed that f is build in such a way that is has a fixed point x_0, that is to say that there exists x_0 such as:

$$f(x_0)=x_0 \tag{14.2.111}$$

It is therefore simply the application of fixed-point theorem already mentioned several times before. Under some conditions on f and equation, we find that the following points does not diverge (which means it is not interested in points that converge but to those who do not diverge!). This method is the basis for the construction of Mandelbrot and Julia Sets.

Building a fractal image from such a set of defined sequences, is equivalent to study for each pair (x,y) of the plane the behaviour of the sequence itself. We then associates a color to each result (that is to say, each pair (x,y)) representing the "speed" of divergence of the sequence.

To study the convergence of a series, we look at his first n elements, if we detect that the divergence conditions are satisfied then we can say that this sequence diverges, otherwise this result is potentially convergent. We notice that more n is big, the more accurate are the results (but the computing time will be great).

The simplest algorithm for generating a representation of an escape time fractal (set) consist in repeating a calculation performed for each x, y point in the plot area and based on the behaviour of that calculation, a color is chosen for that pixel.

The x and y locations of each point are used as starting values in a repeating, or iterating calculation (described in detail below). The result of each iteration is used as the starting values for the next. The values are checked during each iteration to see whether they have reached a critical "escape" condition. If that condition is reached, the calculation is stopped, the pixel is drawn, and the next x, y point is examined. For some starting values, escape occurs quickly, after only a small number of iterations. For starting values very close to but not in the set, it may take hundreds or thousands of iterations to escape. For values within the Mandelbrot Set, escape will never occur. The programmer or user must choose how much iteration, or "depth", they wish to examine. The higher the maximal number of iterations, the more detail and subtlety emerge in the final image, but the longer time it will take to calculate the fractal image.

Escape conditions can be simple or complex. Because no complex number with a real or imaginary part greater than 2 can be part of the set, a common bailout is to escape when either coefficient exceeds2. A more computationally complex method that detects escapes sooner, is to compute distance from the origin using the Pythagorean theorem, i.e., to determine the absolute value, or modulus, of the complex number. If this value exceeds 2, the point has reached escape. More computationally intensive rendering variations include the Buddhabrot method, which finds escaping points and plots their iterated coordinates.

The color of each point represents how quickly the values reached the escape point. Often black is used to show values that fail to escape before the iteration limit, and gradually brighter colors are used for points that escape. This gives a visual representation of how many cycles were required before reaching the escape condition.

To render such an image, the region of the complex plane we are considering is subdivided into a certain number of pixels. To color any such pixel, let c be the midpoint of that pixel. We now iterate the critical point under the chosen function, checking at each step whether the orbit point has modulus larger than R the convergence radius. When this is the case, we know that c does not belong to the escape time fractal, and we color our pixel according to the number of iterations used to find out. Otherwise, we keep iterating up to a fixed number of steps, after which we decide that our parameter is "probably" in the escape time fractal, or at least very close to it, and color the pixel black.

In pseudocode, this algorithm would look as follows. The algorithm does not use complex numbers and manually simulates complex-number operations using two real numbers, for those who do not have a complex data type. The program may be simplified if the programming language includes complex-data-type operations.

Algorithm 18: Escape Time Fractal pseudocode algorithm

```
Data: I,R
for each pixel $(P_x, P_y)$ on the screen do
    $x_0 =$ scaled $x$ coordinate of pixel ;
    $y_0 =$ scaled $y$ coordinate of pixel ;
    $x = 0.0$;
    $y = 0.0$;
    iteration= $0$;
    max_iteration= $I$;
    while $x^2 + y^2 < R^2$ AND $i <$ max_iteration do
        $x = \Re(z(x,y)) + x_0$;
        $y = \Im(z(x,y)) + y_0$;
        $i := i + 1$;
    color := palette[iteration];
plot $(P_x, P_y$, colors);
```

14.2.3.1 Mandelbrot Set

We construct the Mandelbrot Set through iterations in the complex plane (this is named also "holomorphic dynamics"). The function is of the form:

$$\boxed{f(z) = z^2 + c} \tag{14.2.112}$$

where c a constant parameter such that $c \in \mathbb{C}$ (so we double the argument of the initial complex number we squared its norm!).

The first term of the sequence is zero. So we have the following defined by:

$$z_0 = 0 \quad \text{and} \quad z_{n+1} = z_n^2 + c \tag{14.2.113}$$

Why do we start with $z_0 = 0$?: Because zero is the critical point of $z^2 + c$, that is to say the point satisfying the extremum:

$$\frac{\mathrm{d}(z^2 + c)}{\mathrm{d}z} = 0 \tag{14.2.114}$$

For each point of affix $x + \mathrm{i}y$ of the plane, we study the above sequence for $c = x + \mathrm{i}y$. If the sequence diverges, we say that the tested point does not belong to the Mandelbrot Set, if the sequence converges, we say that the point belongs to the Mandelbrot Set defined then by (the definition and name is due to Adrien Douady, in tribute to Benoît Mandelbrot):

$$\boxed{\begin{cases} z_n = z_{n-1}^2 + c \\ z_0 = 0, c \in \mathbb{C} \end{cases}} \tag{14.2.115}$$

To reproduce a basic representation of the Mandelbrot fractal, we associate to c complex values of the plane. It is generally considered the portion of the complex plane having as real part, values between -2.5 and 1.5, and as imaginary part, values between -1.5 and 1.5. This portion of the complex plane is divided so to form a grid whose elements will be associated with values of c. For each value of c, we get a result that modules can converge (bounded sequence) or diverge (non-bounded sequence).

In practice, it is considered that sequence of modules converges if the first 30 modules are less than 2 ($R=2$ in the previous pseudocode), that is to say $|z_{30}|\leq 30$. When the sequence of the modules converges (bounded sequence), we color in black the grid point. After considering all points of the grid, we get a set of blackened points named: "Mandelbrot Set" or "Mandelbrot fractal" as we already know and denoted by $\mathcal{M}$. What constitutes a remarkably curious result!

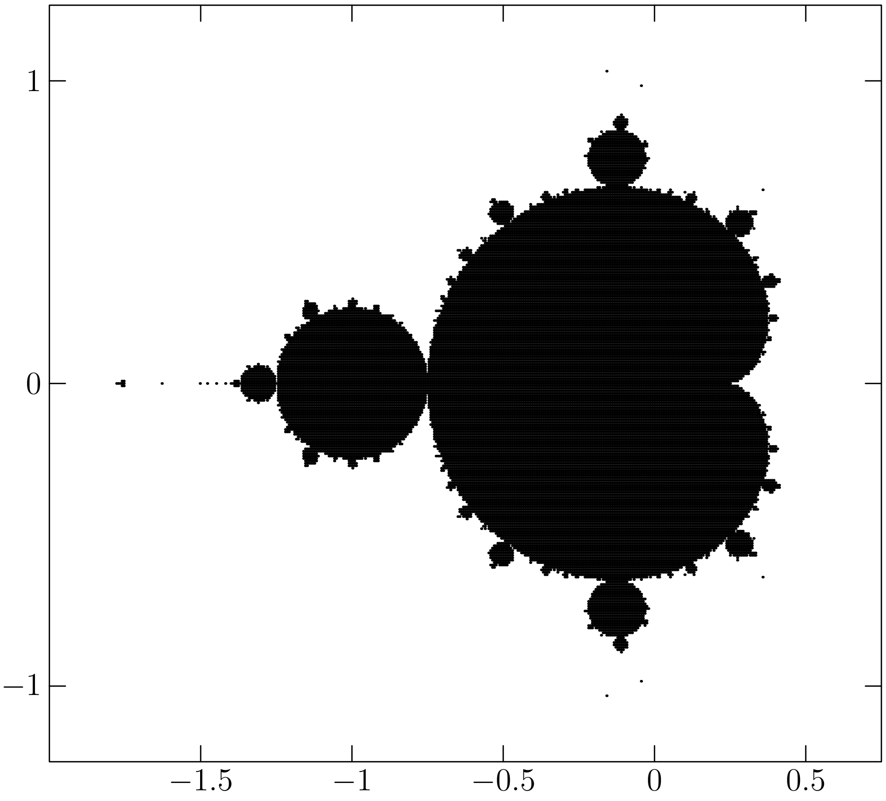


Figure 14.311: **Bichromic Mandelbrot Fractal**

We can also color the points outside the Mandelbrot Set using colors that depend on the number of terms calculated before obtaining a module greater than or equal to 2. The Module points of the same color can be interpreted as points away at the same speed of the Mandelbrot Set.

Remark

The list of z_i generated by the iteration is named the "orbit" of z_0.

We can also discover the Mandelbrot fractal in-deep using the following Maple™ 4.00b code derived from the earlier pseudocode (available usually in high-school). The reader just have to copy the program below on a Maple™ worksheet and indicate instead of -2..1..$1.5-1.5$ of the last line, the range of the real and imaginary parts of c he wants to discover:

```
>restart:  with(plots):
>couleur:=proc(a,b)
local x,y,xi,yi,n;
x:=a;
y:=b;
for n from 0 to 30 while evalf(x^2+y^2) < 4 do;
xi:=evalf(x^2-y^2+a);
yi:=evalf(2*x*y+b);
x:=xi;
y:=yi;
od;
n
end:
```

You will therefore get the following result (the equivalent code for MATLAB® and `R` are given in the companion books about MATLAB® and `R`):

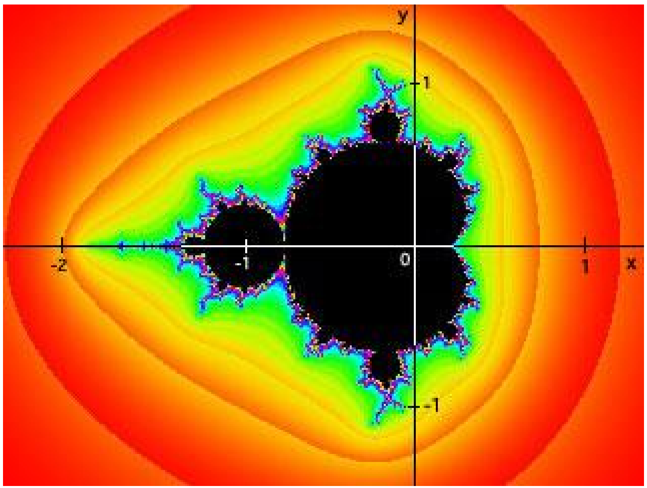

Figure 14.312: **Mandelbrot Fractal with Maple™ 4.00b**

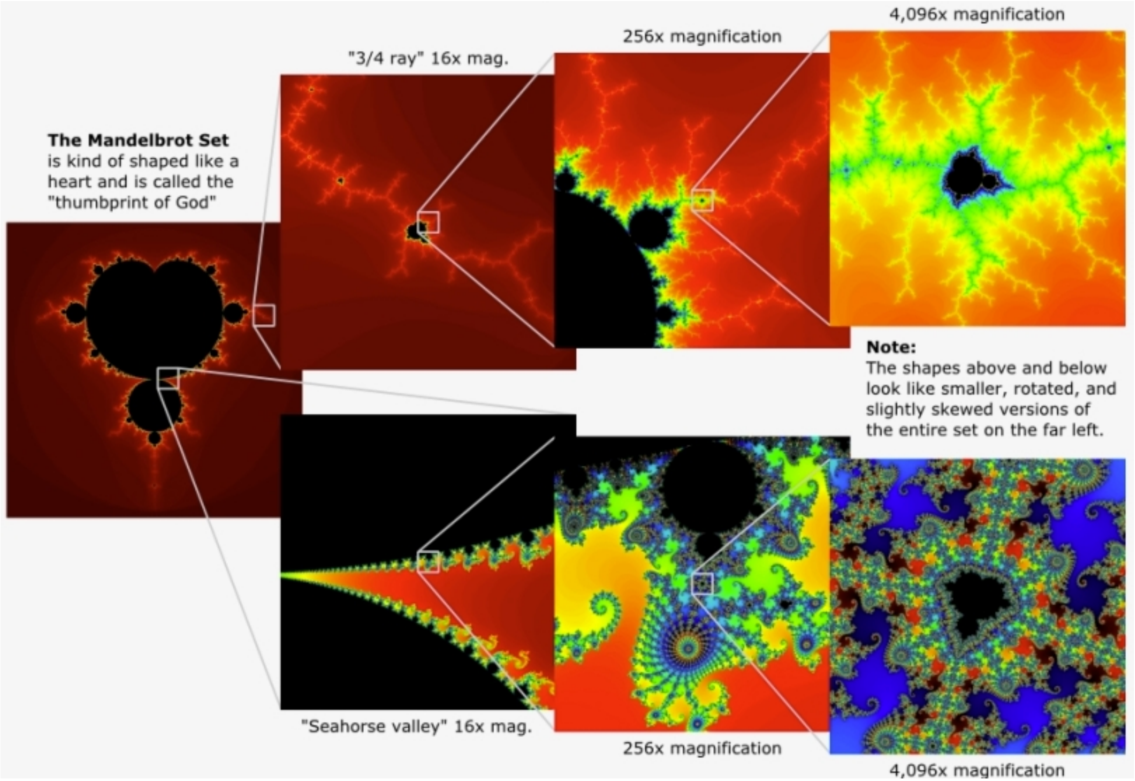
The Mandelbrot Set is self-similar in the vicinity of points named "Misiurewicz points":



The Mandelbrot Set
is kind of shaped like a
heart and is called the
"thumbprint of God"
"3/4 ray" 16x mag.
256x magnification
4,096x magnification
Note:
The shapes above and below
look like smaller, rotated, and
slightly skewed versions of
the entire set on the far left.
"Seahorse valley" 16x mag.
256x magnification
4,096x magnification

Figure 14.313: **Self-Similarity of Mandelbrot Fractal**

It seems also that it is possible to prove (we are still searching for the proof...) that the Mandelbrot fractal real axes can be put in correspondence with the logistic bifurcation diagram that we have studied in the section of Population (see page 7327) Dynamics such that (it's a perfect example of chaos producing order!):

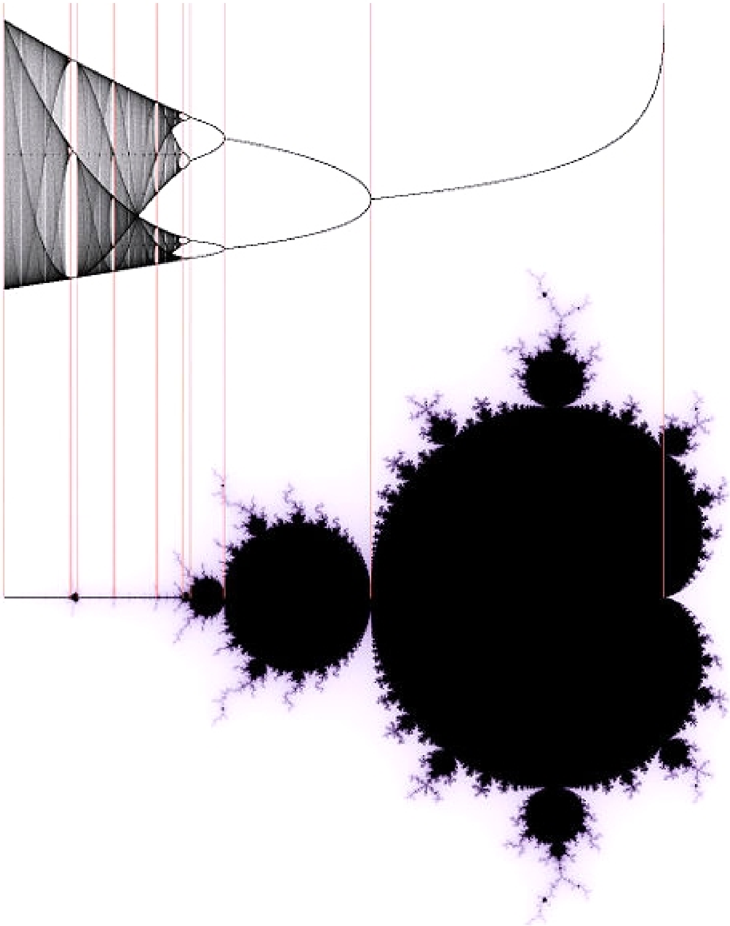


Figure 14.314: **Mandelbrot-Logistic bifurcation correspondence (source: Wikipedia)**

The functions are obviously both quadratic. In fact, the Mandelbrot Set can be recoded into the form of the Logistic map (and vice versa).

Indeed, the Mandelbrot Fractal is obtained by iterating:

$$z_{n+1}=z_n^2+c \tag{14.2.116}$$

and we know that the logistic bifurcation is obtained by iterating:

$$x_{n+1}=rx_n(1-x_n)=rx_n-rx_n^2 \tag{14.2.117}$$

So let us put in the Mandelbrot function the (anticipated) change of variable such that z_n is dependent of x_n and r but c must as constant also be only dependent of the constant r:

$$z_n=\mathrm{i}r\left(x_n-\frac{1}{2}\right)\qquad\text{and}\qquad c=\frac{1}{4}r \tag{14.2.118}$$

Then:

$$\begin{aligned}z_{n+1}=z_n^2+c&=\left(\mathrm{i}r\left(x_n-\frac{1}{2}\right)\right)^2+\frac{1}{4}r=-r\left(x_n-\frac{1}{2}\right)^2+\frac{1}{4}r\\&=-r\left(x_n^2-x_n+\frac{1}{4}\right)+\frac{1}{4}r=-rx_n^2+rx_n-r\frac{1}{4}+r\frac{1}{4}=rx_n-rx_n^2\end{aligned} \tag{14.2.119}$$

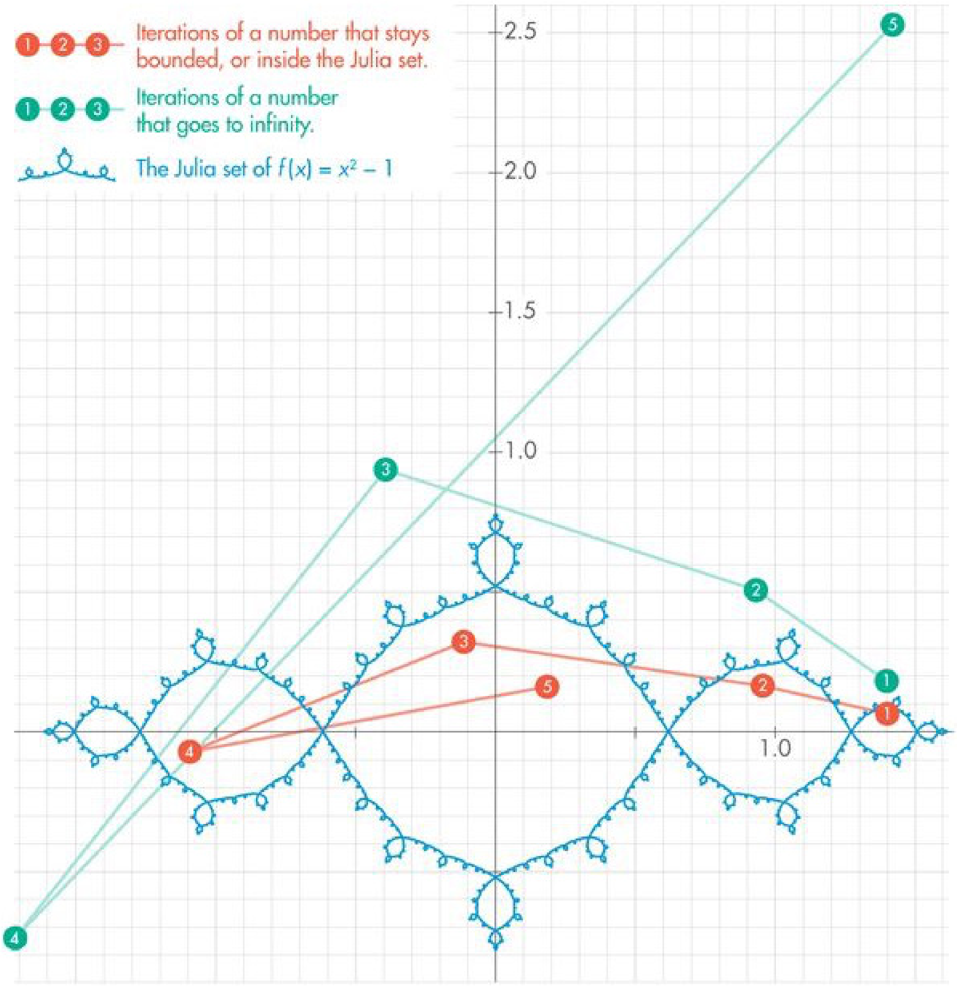
14.2.3.2 Julia Set

The Julia Set is built almost in the same way that the Mandelbrot Set (since the Julia Set is actually a subset of it after investigation!). In the Mandelbrot Set, c scans the plane. For the Julia Set, c is fixed during the computation of the image. To each c corresponds a particular set that will be denoted $J(c)$. What varies this time is z_0, which takes the value of the point to test. It is therefore z_0 that scans the plan.

A point of initial coordinates (x_0, y_0) and affix $x+\mathrm{i}y$ belongs to $J(c)$ if and only if the sequence defined by:

$$z_0 = x+\mathrm{i}y \quad \text{and} \quad z_{n+1} = z_n^2 + c \tag{14.2.120}$$

converge (is bounded).



① ② ③ Iterations of a number that stays bounded, or inside the Julia set.
① ② ③ Iterations of a number that goes to infinity.
The Julia set of f(x) = x² − 1

Figure 14.315: **Makingofa Julia Set**

In fact, the Mandelbrot Set is the set of points c such that the Julia Set of parameter c is connex to, that is to say we can always found a c such that when starting with z_0 in the Mandelbrot Set is equivalent after a few iterations as starting with a fixed $z_0 \neq 0$ and a given c (thus the Mandelbrot Set generalizes all the Julia Sets !!!). So the figure of the Mandelbrot Set contains figures all the Julia Sets, which is remarkable (but logic ...!):

If again we adapt the pseudocode given earlier, we get to a given scale factor the fractal shown below (obtained through the small Maple™ 4.00b code below and already used earlier for the Mandelbrot fractal):

```
>restart; with(plots):
>julia:= proc(c,x, y)local z, m;
z:= evalf(x+y*I);
for m from 0 to 30 while abs(z) < 3 do
z:= z^2 + c
od;
m
end:

>J:= proc(d)
global phonyvar;
phonyvar:= d;
(x, y) -> julia(phonyvar, x, y)
end:

>plot3d(0, -2..2, -1.3..1.3, style=patchnogrid,orientation=[-90,0],
grid=[270, 270],scaling=constrained, color=J(-1.25));
```

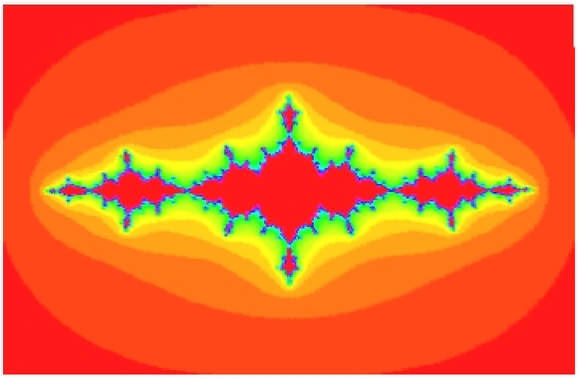

Figure 14.316: **Julia Fractal with Maple™ 4.00b**

and to show that the Mandelbrot Set contains all the Julia Sets we have qualitatively:

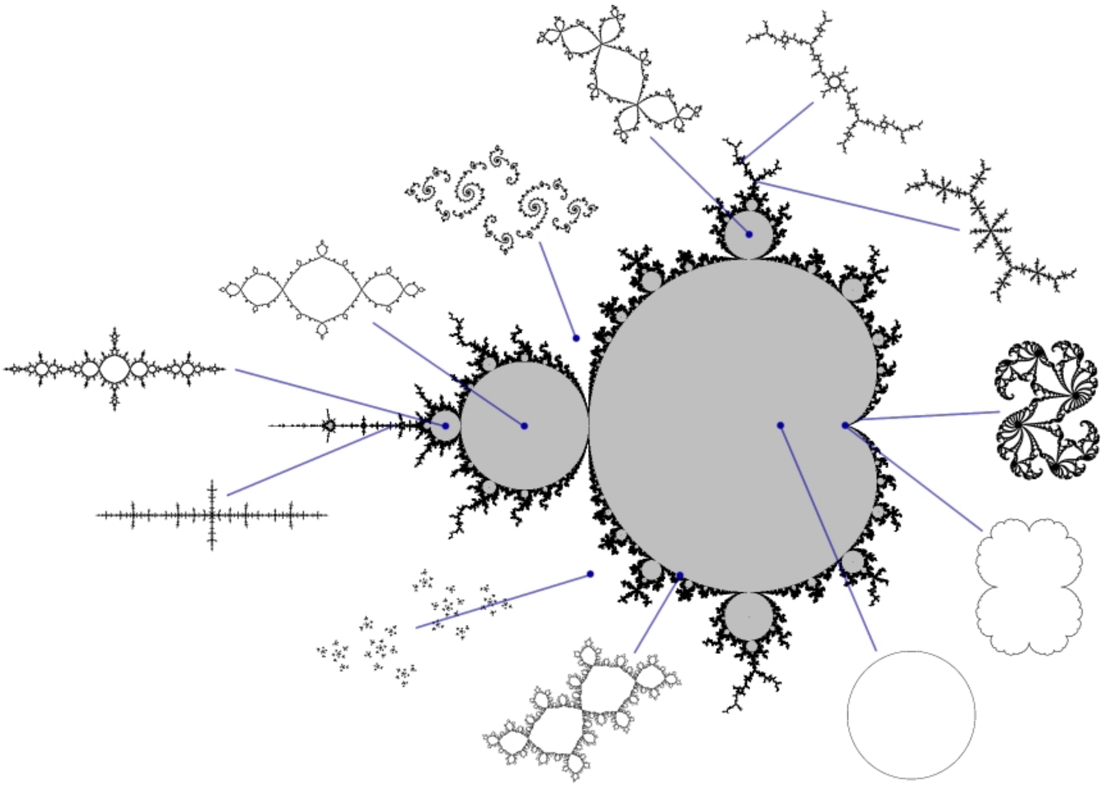

Figure 14.317: Illustration of "fatherhood" ... of the Mandelbrot Set

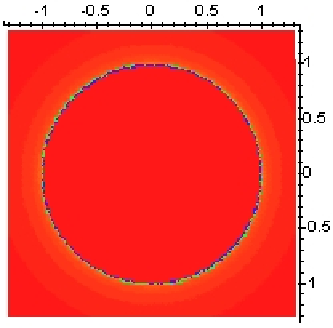
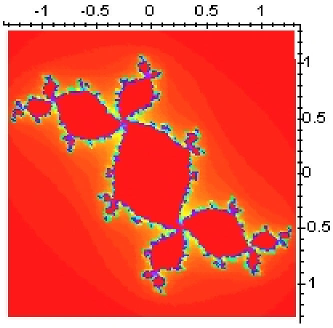
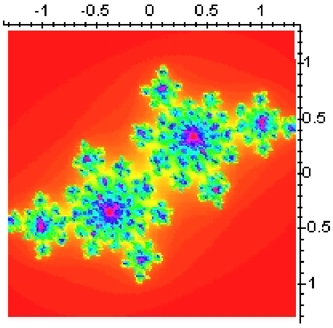
So we must be able to write a single algorithm (see below) that achieves all of Julia fractals by simply selecting a good starting point as shown in the following figures (we can see on top right the "Douady's Rabbit Fractal" also named "dragon fractal":



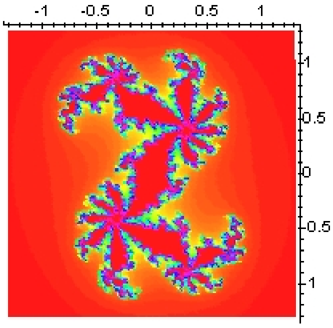
$z_0 = 0 + i0$



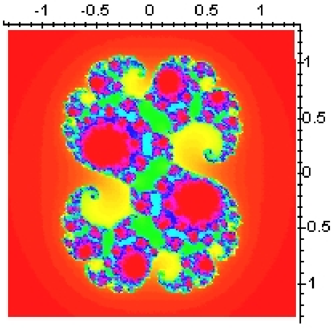
$z_0 = -0.123 + i0.745$



$z_0 = -0.414 - i0.612$



$z_0 = 0.382 + i0.147$



and so on...

$z_0 = 0.284 - i0.0122$

That we get with the following Maple™ 4.00b code:

```
>couleur:=proc(a,b)
local x,y,xi,yi,n;
global reel,imaginaire;
x:=a;
y:=b;
for n from 0 to 100 while evalf(x^2+y^2)<4 do;
xi:=evalf(x^2-y^2+reel);
yi:=evalf(2*x*y+imaginaire);
x:=xi;
y:=yi;
od;
n;
```

```
end:

>reel:=-0.181;
>imaginaire:=-0.667;

>plot3d(0,(-13/10)..(13/10),(-13/10)..(13/10),orientation=[-90,0],
style=patchnogrid,scaling=constrained,axes=framed,numpoints=20000
,color=couleur);
```

14.2.3.3 Newton Set

Newton Sets are also so named because they arise from the resolution of the problem looking for zeros of a function by the Newton's method (see section Numerical Methods page 6612).

Given f a function with values in $\mathbb{C}$ and differentiable in $\mathbb{C}$, we take z_0 in $\mathbb{C}$ such that:

$$\boxed{z_{n+1}=z_n\frac{f(z_i)}{f'(z_i)}} \tag{14.2.121}$$

There are then two ways to proceed:

1. Either we focus on $|z_0-z_i|$ and then we do same as before.
2. Either we wonder to which zero r_k the sequence converges and we focus on $|z_i-z_k|$.

If again we translate our pseudocode algorithm, into Maple™ language we get to a given scale factor the fractal shown below with Maple™ 4.00b:

```
>restart:
>newton:= proc(x, y)
local z, m;
z:= evalf(x+y*I);
for m from 0 to 50 while abs(z^3-1) >= 0.001
do
z:= z - (z^3-1)/(3*z^2)
od;
m
end:

>plot3d(0,-2..2,-1.5..1.5,orientation=[-90,0],grid=[250, 250],
style=patchnogrid,scaling=constrained,color=newton);
```

14.3. Logical Systems

THE reader familiar with the purpose of this textbook should not expect to see here any schemes of buttons, switches, timing diagrams or MIL standard wiring diagrams. We will remain in a purely formal framework of logical systems and their tools.

Definitions (#14.3.590):

D1. We speak of "asynchronous logic model" (commonly named "sequential logic model") when the outputs of a system depends on the chronological order in which the entries will succeed.

D2. We speak of "combinatorial logic model" when the outputs of a system depend only on the combination of the input variables.

> **Remark**
>
> We differentiate the "strict logic" of "fuzzy logic" that will both be defined in the details later.

14.3.1 Strict Logic

Consider first a set which we will denote by $\mathcal{B}$ with two elements (more formally denoted by $\perp, \top$).

Definitions (#14.3.591):

D1. A "strict logic variable" or "boolean variable" is an element of $\mathcal{B}$ that has only two states 0 and 1 (as opposed to a fuzzy variable whose value can be between 0 and 1). It is represented by Latin uppercase letters or lowercase Latin letters (depending on your choice).

D2. A multivariate "logic function F" of n variables applies $\mathcal{B}^n$ in $\mathcal{B}$ such that:

$$F : \mathcal{B}^n \mapsto \mathcal{B} \tag{14.3.1}$$

It combines to a n-tuple of logical variables $(b_0, b_1, \ldots, b_{n-1})$ a value $F(b_0, b_1, \ldots, b_{n-1})$.

D3. There are different ways of expressing a logic function ("Boolean function"). A function of n variables is fully described by stating the values of this function for the set (or the subset of definition) of the combinations of the n-tuple variables:

$$F(0, \ldots, 0, 0), F(0, \ldots, 0, 1), F(0, \ldots, 1, 0), F(1, \ldots, 1, 1) \tag{14.3.2}$$

This statement usually takes the form of a table with $n+1$ columns and no more than 2^n lines, each line exposing a combination of variables and the corresponding value of the function. The following table gives the general form of a "truth table" function of three variables completely defined through a function F (we already saw some simple examples in the section of Proof Theory at page 131):

A	B	C	$F(A,B,C)$
0	0	0	$F(0,0,0)$
0	0	1	$F(0,0,1)$
0	1	0	$F(0,1,0)$
0	1	1	$F(0,1,1)$
1	0	0	$F(1,0,0)$
1	0	1	$F(1,0,1)$
1	1	0	$F(1,1,0)$
1	1	1	$F(1,1,1)$

Table 14.38: **Generic truth table**

The elements of input of the systems will be considered as Boolean variables on which we can build a ring structure set, that by adding a particular axiom, we can bring to an algebra (in the computational sense and the set one!) commonly named "Boolean Algebra" as we will see now.

So Boolean Algebra is an algebra on itself (with a ring structure as we will define it rigorously later) proposing to translate signals with a value of the type $0/1$ (assimilated to: True/False) in mathematical expressions. For this, we define each elementary signal by "logical variables" and their treatment by "logical functions". Methods ("truth tables") exists to define the operations that we want to achieve, and to transcribe the result into an algebraic expression. Thanks the rules we will see later, these expressions can be simplified. This will allow to represent with simple symbols a logic circuit capable of performing basic arithmetic operations, that is to say a circuit that design the core components (at logic level) regardless of the realization through transistors (physical level).

14.3.1.1 Boolean Algebra

Boolean Algebra (or "Boolean ring" to a given axiom...) is therefore a structure which is most often used in electronic (or microelectronics/optoelectronics) this is why some people name it sometimes "Switching Algebra" or "logic gates". Therefore, a processor is composed of transistors for performing functions on digital signals. These transistors assembled together form components for performing simple functions. From these components it is possible to create circuits performing fairly complex operations. Boolean Algebra (named after the English mathematician George Boole 11815-11864 according to holocene calendar) is a mean to create more or less easily such circuits.

Remark

It would be better before you start reading this chapter, to read at least in diagonal the subsection about Logic in the section of Proof Theory (see page 131) and on algebraic structures in the section of Set Theory (see page 378).

It is necessary for a rigorous definition of a Boolean Algebra to give it in terms of abstract algebra.

Reminder: A "Boolean Algebra" $(\mathcal{B}, \vee, \wedge)$ is a set containing two particular elements $\perp, \top$, (abstract forms the 0 and 1) and has two internal composition laws, $\vee, \wedge$ (AND and logical OR) and verifies the following axioms to form a ring structure such that $\forall a, b, c \in \mathcal{B}$:

A1. Associativity: $(a \vee b) \vee c = a \vee (b \vee c)$ and $(a \wedge b) \wedge c = a \wedge (b \wedge c)$

A2. Commutativity: $a \vee b = b \vee a$ and $a \wedge b = b \wedge a$

A3. Absorption: $a \wedge (a \vee b) = a$ and $a \vee (a \wedge b) = a$

A4. Distributivity: $(a \vee b) \wedge c = (a \wedge c) \vee b \wedge c$ and $(a \wedge b) \vee c = (a \vee c) \wedge (b \vee c)$

A5. Idempotence: $a \vee a = a$ and $a \wedge a = a$

A6. Completation (or inversion): a has a complement (negation) denoted by $\neg a$ or $\bar{a}$ (NOT) such as: $a \wedge \neg a = \top$ and $a \vee \neg a = \perp$

Remark

The first four axioms establish a ring structure. The fifth axiom (idempotence) added to the first four defines the concept of "Boolean Algebra".

Strictly speaking to form a Boolean Algebra we required a symmetrical element (see section Set Theory page 417) with one of the two fundamental operators and we cannot do this directly with the two previous operators previously defined. That is why the real operators of Boolean Algebra are normally the $\wedge$ (AND) and the Δ (symmetric difference), denoted in Boolean Algebra by the symbol $\oplus$, the latter one being given by the logic operation:

$$x \Delta y = (x \wedge \bar{y}) \vee (y \wedge \bar{x}) \tag{14.3.3}$$

but to simplify, in the early school grades, it is common that we do implicitly reference to it without going into details.

It follows that the binary set $(\mathcal{B}, 0, 1)$ is therefore relatively to the laws $\vee, \wedge$ an "Abelian group". (see section Set Theory page 421) Therefore, $(\mathcal{B}, \vee)$ being an Abelian group, the law $\wedge$ being associative and distributive with respect to $\vee$, $(\mathcal{B}, \vee, \wedge)$ is therefore a "commutative ring with unit" (see section Set Theory page 426) since $\mathcal{B}$ has a neutral element relatively to the law $\vee$.

Remarks

R1. Thus, the operations $\vee, \wedge$ admits each a neutral element such that the value 1 is the neutral element of $\wedge$ and 0 the neutral element of $\vee$.

R2. The two operations that we usually use to form a Boolean Algebra are the "inclusive OR" rigorously denoted $\vee$ but more frequently denoted by the addition sign "$+$" and the "inclusive AND" rigorously denoted by $\wedge$ but more frequently denotey by the multiplication sign "$\cdot$".

The preceding axioms may, however been proved from the "axioms of the definition":

A1. Negation: $\top\neg\bot$ and $\bot\neg\top$

A2. Double complentation: $\neg\neg a=\bar{\bar{a}}=a$

A3. Neutral element 1: $\top$ is the neutral element of $\wedge$

A4. Neutral element 2: $\bot$ is the neutral element of $\vee$

A5. De Morgan theorem: $\neg(a\vee b)=\neg a\wedge\neg b$ and $\neg(a\wedge b)=\neg a\vee\neg b$

Remark

De Morgan's theorem can be proved using a simple truth table or algebraically as we will see just a little further below.

It thus follows the following dual expressions:

$$\left.\begin{array}{l}0\cdot 0=0\\1+1=1\end{array}\right\}\text{dual expression}$$

$$\left.\begin{array}{l}1\cdot 1=1\\0+0=0\end{array}\right\}\text{dual expression} \tag{14.3.4}$$

$$\left.\begin{array}{l}1\cdot 0=0\\0+1=1\end{array}\right\}\text{dual expression}$$

$$\left.\begin{array}{l}\bar{0}=1\\\bar{1}=0\end{array}\right\}\text{dual expression}$$

We name these expressions "dual expressions" because by replacing in one equation logic equation, the 0 by the 1, the $\cdot$ by $+$ and inversely, by this same equation remains verified.

Theorem 14.23. Let us see now what we name the "constants theorem" that consists to prove that:

$$\begin{aligned}a\cdot 0&=0\\a\cdot 1&=a\\a+0&=a\\a+1&=1\end{aligned} \tag{14.3.5}$$

Proof 14.23.1. The proof is trivial (if necessary the reader can quickly do a truth table) as it comes from the same property of the concept of "Boolean ring" and the identity element 1 relative to the $\wedge$ and its neutral element 0 relative to $\vee$.

■ Q.E.D.

Theorem 14.24. We have:

$$a+\bar{a}b=a+b \tag{14.3.6}$$

Proof 14.24.1. The distributivity brings us to write:

$$a+\bar{a}b=(a+\bar{a})(b+\bar{b}) \tag{14.3.7}$$

and applying the complementation:

$$(a+\bar{a})(a+b)=1(a+b) \tag{14.3.8}$$

applying commutativity:

$$1(a+b)=(a+b)1 \tag{14.3.9}$$

and finally by applying the theorem of constants:

$$(a+b)1=a+b \tag{14.3.10}$$

■ Q.E.D.

This proof will allow us to prove the famous "consensus theorem":

Theorem 14.25. In Boolean Algebra, the consensus theorem or rule of consensus is the identity:

$$\begin{gathered} ax+b\bar{x}+ab=ax+bx \\ (a+x)(b+\bar{x})(a+b)=(a+x)(b+\bar{x}) \end{gathered} \tag{14.3.11}$$

Proof 14.25.1. To verify the consensus theorem relative to the logical product:

$$ax+b\bar{x}+ab=ax+bx \tag{14.3.12}$$

we can make use of a Venn diagram where we can see trivially that the therm term ab is contained in the other two:

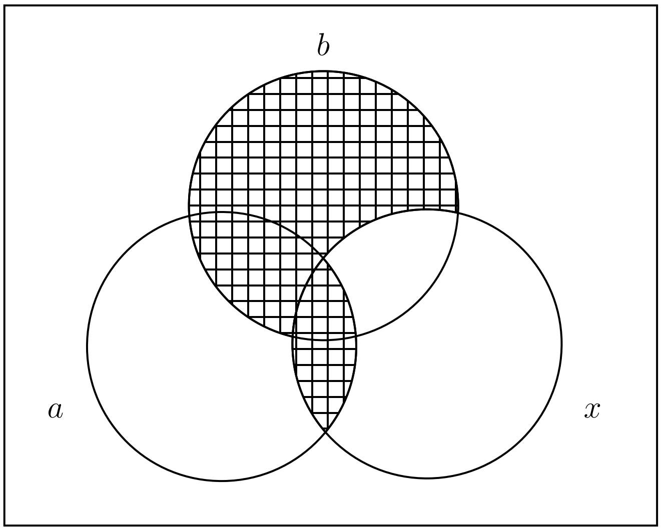

Figure 14.319: **Venn diagram of the consensus theorem**

Or more formally with other notations:

$$\begin{aligned}xy\vee\bar{x}z\vee yz&=xy\vee\bar{x}z\vee(x\vee\bar{x})yz\\&=xy\vee\bar{x}z\vee xyz\vee\bar{x}yz\\&=xy\vee xyz\vee\bar{x}z\vee\bar{x}yz\\&=xy(1\vee z)\vee\bar{x}z(1\vee y)\\&=xy\vee\bar{x}z=xy\vee\bar{x}z\end{aligned}\tag{14.3.13}$$

Proceeding the request of a reader we can also build a truth table:

$\boldsymbol{x}$	$\boldsymbol{y}$	$\boldsymbol{z}$	$\boldsymbol{xy\vee\bar{x}z\vee yz}$	$\boldsymbol{xy\vee\bar{x}z}$
0	0	0	0	0
0	0	1	1	0
0	1	0	0	0
0	1	1	1	0
1	0	0	0	0
1	0	1	0	0
1	1	0	1	0
1	1	1	1	0

Table 14.39: **Consensus theorem truth table**

Proceeding also with a Venn diagram, the reader will see without problem that we also have:

$$(a+x)(b+\bar{x})(a+b)=(a+x)(b+\bar{x})\tag{14.3.14}$$

■ Q.E.D.

Theorem 14.26. And finally the very famous "Shannon's theorem" (not to be confused with the Shannon theorem in signal theory!):

$$\begin{aligned}a+b&=ab+a\bar{b}+\bar{a}b\\ab&=(a+b)(a+\bar{b})(\bar{a}+b)\end{aligned}\tag{14.3.15}$$

Proof 14.26.1. We begin with the first relation:

$$\begin{aligned}a+b&=ab+a\bar{b}+\bar{a}b\\&=ab+a\bar{b}+\bar{a}b+ab\\&=a(b+\bar{b})+b(\bar{a}+a)\\&=a1+b1\\&=a+b\end{aligned}\tag{14.3.16}$$

and for the second relation:

$$\begin{aligned}ab&=(a+b)(a+\bar{b})(\bar{a}+b)\\&=(aa+a\bar{b}+ab+b\bar{b})(\bar{a}+b)\\&=(a+a(\bar{b}+b)+0)(\bar{a}+b)\\&=(a+a1+0)(\bar{a}+b)\\&=a(\bar{a}+b)=a\bar{a}+ab=ab\end{aligned}\tag{14.3.17}$$

■ Q.E.D.

Theorem 14.27. Now let us come back on the De Morgan theorems previously presented as axioms:

$$\overline{(a+b)}=\bar{a}\bar{b} \qquad \overline{(ab)}=\bar{a}+\bar{b} \tag{14.3.18}$$

These two relations therefore express that the inverse (or opposite) of product (or respectively the sum) of two variables is equal to the sum (respectively the product) of the inverse of these same variables.

Proof 14.27.1. Suppose $\overline{(a+b)}=\bar{a}\bar{b}$ is true. So under the relations $\bar{a}+a=1$ and $\bar{a}a=1$ (axiom of complementation) we must have:

$$\begin{aligned}(a+b)+\bar{a}\bar{b}&=1\\(a+b)\bar{a}\bar{b}&=0\end{aligned} \tag{14.3.19}$$

So we need to prove that these relations are true:

$$\begin{aligned}(a+b)+\bar{a}\bar{b}&=(a+b+\bar{a})(a+b+\bar{b})=(a+\bar{a}+\bar{b})(a+b+\bar{b})\\&=(1+b)(a+1)=1\end{aligned} \tag{14.3.20}$$

and:

$$(a+b)\bar{a}\bar{b}=a\bar{a}\bar{b}+\bar{a}b\bar{b}=0 \tag{14.3.21}$$

The second De Morgan theorem can be proven in the same way (we can put the details on request).

■ Q.E.D.

Remark

These two theorems can be extended to as many variables as we want.

Corollary 14.27.1. As immediate corollary we have:

- $ab=\overline{\bar{a}+\bar{b}}$
- $a+b=\overline{\bar{a}\bar{b}}$
- $ab=\overline{\overline{ab}}$
- $a+b=\overline{\overline{a+b}}$
- $\overline{a+b+c+\ldots}=\bar{a}\bar{b}\bar{c}\ldots$
- $\overline{abc\ldots}=\bar{a}+\bar{b}+\bar{c}+\ldots$

The logical expressions, as we have seen it until now thanks to the previous axioms, properties and theorems, can always be writtent into two different forms (by paling also with the negations $\neg$):

1. Under the form of a sum of logical products, also named "normal disjcontive form NDF", such as for example:

$$F=\sum_i\prod_i(b_i)=\bar{a}\bar{c}\bar{d}+\bar{a}c\bar{d} \tag{14.3.22}$$

   The constitutive terms of this polynomial are in this example the monomials $\bar{a}\bar{c}d, \bar{a}c\bar{d}$. The variables or complementary variables of the monomials are the "letters": $\bar{a}, \bar{c}, d, c\bar{d}$.

   Remark

   If each (all) of the product contains all the input variables in a direct or complementary form, then the form is named "first canonical form" or "disjonctive canonical form". Each of the products is therefore named the "minterm" (therefore in the previous relation, there are 2 minterms).

   Obviously if we consider that each term and its negation is equivalent to 0 and 1 if we have one variable, the first canonical form has two terms (2^1), if we have two variables, the first canonical form has four terms (2^n) and if n variables we have 2^n terms.

2. In the form of a product of logical sum, also named "normal conjunctive form NCF":

$$F=\prod_i\sum_i(b_i)=(\bar{a}+\bar{c}+d)(\bar{a}+c+\bar{d}) \tag{14.3.23}$$

   Remark

   If each (all) of the sums contains all the input variables in a direct or complementary form, the form is named "second canonical form" or "conjunctive canonical form". Each of the sum is therefore named the "maxterm".

   Obviously if we consider that each term and it negation is equivalent to 0 and 1 if we have one variable, the second canonical form has two terms (2^1), if we have two variables, the second canonical form has four terms (2^n) and if n variables we have 2^n terms.

   Therefore, in other words, a normal disjonctive form is either a litteral and its complementary (one letter) or a disjonction of formulas written as conjonction of litterals. A conjonctive form is either a litteral (one letter) and its complementary, or a conjonction of formulas written as disjonction of litterals.

The simplification methods we will see later aim to minimize the number of letters of the expressions so as to reduce the number of inputs of our logic system logic and therefore also the number of its components.

Remark

The algebraic simplification of an expression is to transform it so as to minimize the number of letters by applying theorems proven previously.

To simplify expressions (or identify them) a known technique is therefore to use the "Karnaugh tables" that we will see further below in details.

14.3.1.2 Logical Functions (Boolean operators)

So when we talk about Boolean Algebra unless other indication, we refer to the three basic Boolean operations (AND, OR, NOT) and some other logic functions arising from them for which we have the following symbols as defined in circuit theory (MIL norm representation if no error...):

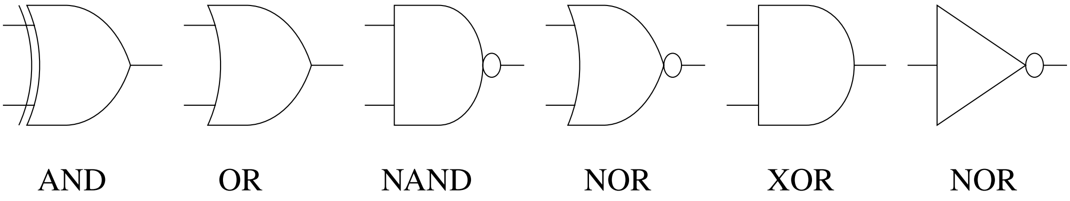

Figure 14.320: **Logic MIL Gates**

and their respective "truth tables":

AND (∧) Truth Table		
AND	**0**	**1**
0	0	0
1	0	1

Table 14.40: **AND (∧) Truth table**

OR (∨) Truth Table		
OR	**0**	**1**
0	0	1
1	1	1

Table 14.41: **OR (∨) truth table**

NOT (¬) Truth Table	
NOT	**-**
0	0
1	1

Table 14.42: **NOT (¬) truth table**

All others known (common) "logic functions" can be composed of these two basic operators. Such that by definition (given with their standard definition in the first line and with their different algebraic forms under their respective truth table):

$$\neg(a\wedge b)=\overline{a\cdot b}=\bar{a}+\bar{b}$$

NOT-AND (NAND)**:** NOT (a AND b)		
NAND	**0**	**1**
0	1	0
1	1	0

Table 14.43: **NOT-AND truth table**

$$\neg(a\vee b)=\overline{a+b}=\bar{a}\cdot\bar{b}$$

NOT-OR (NOR)**:** NOT (a OR b)		
NAND	**0**	**1**
0	1	0
1	0	0

Table 14.44: **NOT-OR truth table**

$$a\oplus b=(a\vee b)\wedge\neg(a\wedge b)=(a+b)\cdot\overline{(a\cdot b)}$$
$$a\oplus b=a\wedge\neg b+b\wedge\neg q=a\cdot\bar{b}+b\cdot\bar{a}$$
$$a\oplus b=\neg(a\wedge b+\neg a\wedge\neg b)=\overline{a\cdot b+\bar{a}\cdot\bar{b}}$$

EXCLUSIVE OR (XOR)**:** [a OR b] AND [NOT (a AND b]		
XOR	**0**	**1**
0	0	1
1	1	0

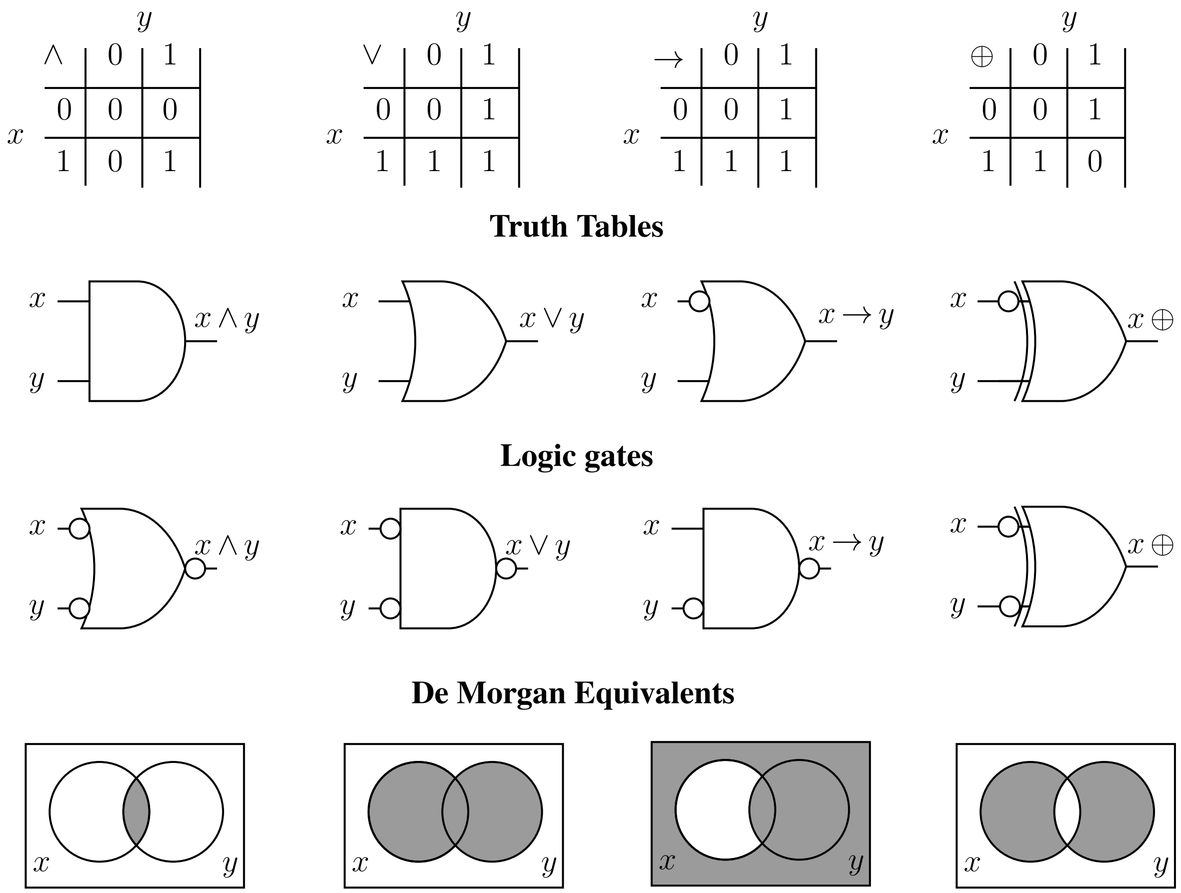
Table 14.45: **EXCLUSIVE OR $\oplus$ Truth table**

where a and b are, as you will have understood, variables (or "bit" of Binary Digit) that can arbitrarily take the binary values 0 or 1.

Remark

The XOR logic function is often denoted in the literature by the operator $\oplus$ and we will consider as obvious that the XOR is also a group law and thus allows to construct an abelian commutative group. This property of the XOR is particularly used in cryptography.

All the tables above can be sum up in the following figure with the corresponding MIL circuit theory symbols:



Truth Tables

$\wedge$	0	1
0	0	0
1	0	1

$\vee$	0	1
0	0	1
1	1	1

$\rightarrow$	0	1
0	0	1
1	1	1

$\oplus$	0	1
0	0	1
1	1	0

14.3.1.3 Karnaugh maps

The "Karnaugh map", also known as the "K-map", is a method to simplify Boolean Algebra expressions. Maurice Karnaugh introduced it in 11953 (holocene calendar). The Karnaugh map reduces the need for extensive calculations by taking advantage of humans' pattern-recognition capability[83].

The required boolean results are transferred from a truth table onto a two-dimensional grid where the cells are ordered in Gray code, and each cell position represents one combination of input conditions, while each cell value represents the corresponding output value. Optimal groups of 1s or 0s are identified, which represent the terms of a canonical form of the logic in the original truth table. These terms can be used to write a minimal boolean expression representing the required logic.

Karnaugh maps are used to simplify real-world logic requirements so that they can be implemented using a minimum number of physical logic gates. A sum-of-products expression can always be implemented using AND gates feeding into an OR gate, and a product-of-sums expression leads to OR gates feeding an AND gate. Karnaugh maps can also be used to simplify logic expressions in software design. Boolean conditions, as used for example in conditional statements, can get very complicated, which makes the code difficult to read and to maintain. Once minimized, canonical sum-of-products and product-of-sums expressions can be implemented directly using AND and OR logic operators.

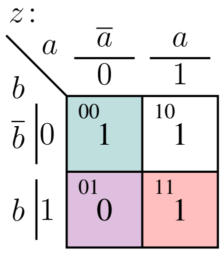
Let us consider for example the function:

$$z(a,b)=ab+\bar{a}b+\bar{a}\bar{b} \tag{14.3.24}$$

(in disjunctive normal form) and its respective truth table:

b	a	$z(a,b)$
0	0	1
0	1	0
1	0	1
1	1	1

The Karnaugh map is defined by a representation like the one below following the `karnaugh-map` package of LaTeX (as it does sadly not exist at this day any international norm on how to represent Karnaugh map):



---

[83] The reader can find easily on the Internet many K-map generators that simplifies expressions automatically!

The colored items are those that we need to keep. That is: $\bar{a}\bar{b}$, $\bar{a}b$, ab.

The Karnaugh table of a logic function thus has as many cells as possible combinations of variables which compose it, i.e. four cells for a function with two variables, and 2^n cells for a function with n variables. Each cell, which is at the intersection of a row and column of the Karnaugh table, has the state 0 or 1 that the function $z(a,b)$ takes for the corresponding logical product of the variables (minterms).

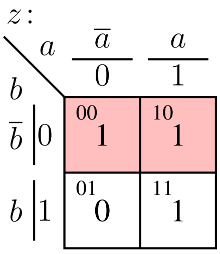
In the preceding example, however, we can see something interesting, the function $z(a,b)$, as we see very well, can be simplified in two ways:

$$z=b+\bar{a}\bar{b} \tag{14.3.25}$$

or also:

$$z=ab+\bar{a} \tag{14.3.26}$$

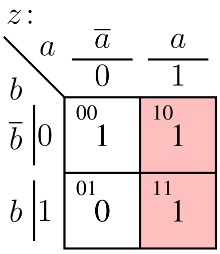
This possible simplification is always done with two adjacent minterms in the Karnaugh table such as for the first solution $z=b+\bar{a}\bar{b}$:



$z:$

b \ a	$\bar{a}$ 0	a 1
$\bar{b}$ 0	00 1	10 1
b 1	01 0	11 1

and for $z=ab+\bar{a}$:



$z:$

b \ a	$\bar{a}$ 0	a 1
$\bar{b}$ 0	00 1	10 1
b 1	01 0	11 1

We see that indeed the first grouping / simplification (horizontal) is done on the row $\bar{a}$ and the second grouping / simplification (vertical) is done on column b both results of the algebraic simplification of the function as following:

$$z=\bar{a}\bar{b}+\bar{a}b+ab=\bar{a}\bar{b}+(\bar{a}+a)b=\bar{a}\bar{b}+1\cdot b=\bar{a}\bar{b}+b \tag{14.3.27}$$

and:

$$z=\bar{a}\bar{b}+\bar{a}b+ab=\bar{a}(\bar{b}+b)+ab=\bar{a}\cdot 1+ab=\bar{a}+ab \tag{14.3.28}$$

So we could make the hypothesize that the Karnaugh table has for properties:

P1. To give us the normal disjunctive form of a function.

P2. That all adjoining cells with a value of 1 can be simplified in the respective symbol (letter) of their union

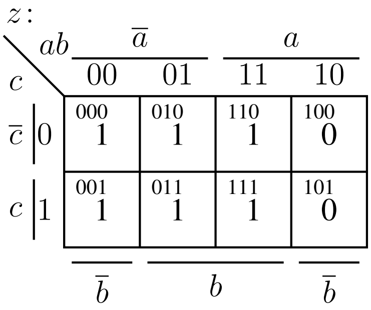
It is therefore an extremely powerful tool (algorithm) for simplifying and determining logical functions.

Let's look at an example with three variables!

First we give the truth table that can help for a better understanding:

a	b	c	$z(a,b,c)$
0	0	0	1
0	0	1	1
0	1	0	1
0	1	1	1
1	1	0	0
1	1	1	0
1	0	0	1
1	0	1	1

and the corresponding Karnaugh map:

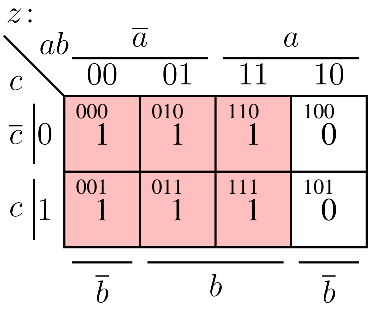


$z:$	$\bar{a}$		a	
c \ ab	00	01	11	10
$\bar{c}$ 0	000 1	010 1	110 1	100 0
c 1	001 1	011 1	111 1	101 0
	$\bar{b}$	b		$\bar{b}$

The normal disjonctive form is the given by all the cells that are equal to 1:

$$z(a,b,c)=\bar{a}\bar{b}\bar{c}+\bar{a}\bar{b}c+\bar{a}b\bar{c}+\bar{a}bc+ab\bar{c}+abc \tag{14.3.29}$$

This corresponds to the following colored Karnaugh map:



$z:$	$\bar{a}$		a	
c \ ab	00	01	11	10
$\bar{c}$ 0	000 1	010 1	110 1	100 0
c 1	001 1	011 1	111 1	101 0
	$\bar{b}$	b		$\bar{b}$

We see quickly that the previous normal disjonctive form can be simplified as:

$$z(a,b,c)=\bar{a}\bar{b}\bar{c}+\bar{a}\bar{b}c+\bar{a}b\bar{c}+\bar{a}bc+ab\bar{c}+abc=\bar{a}\bar{b}+\bar{a}b+ab=\bar{a}+ab \tag{14.3.30}$$

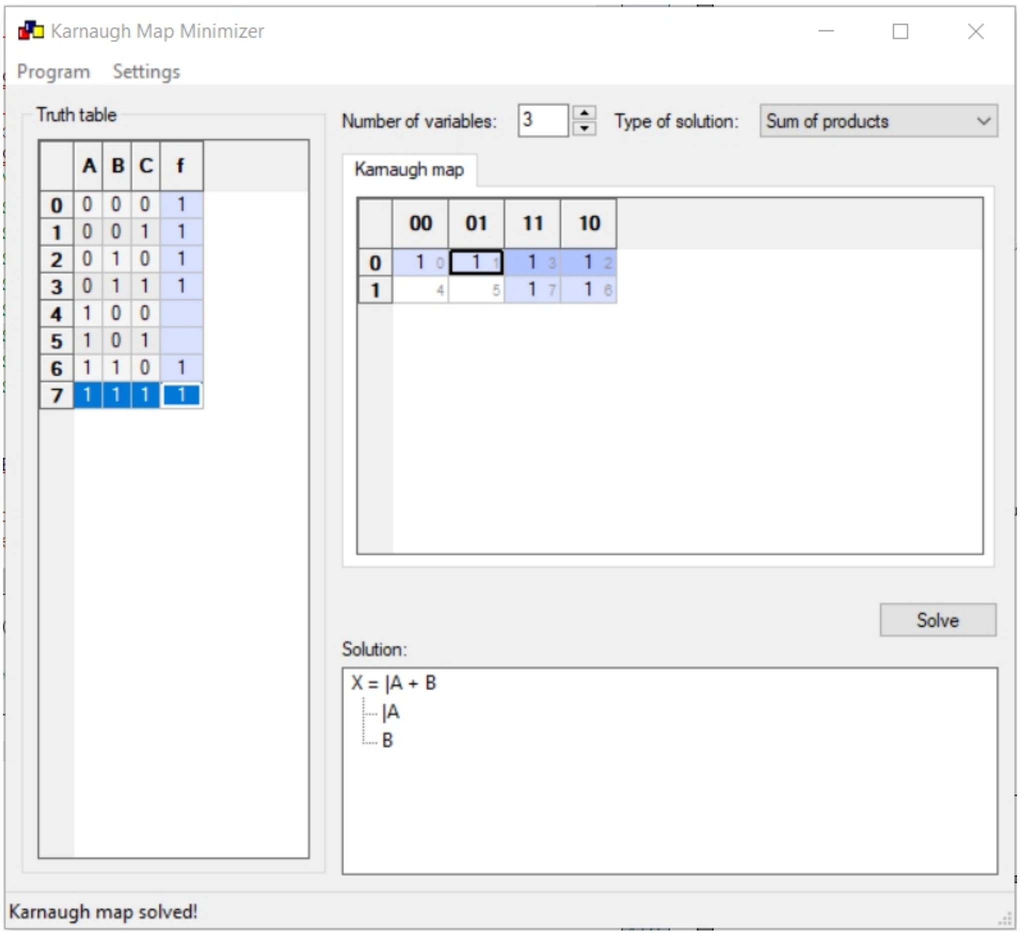
That gives the following Karnaugh map:

	00	01	11	10
0	000 1	010 1	110 1	100 0
1	001 1	011 1	111 1	101 0

But it is less obvious with a Karnaugh map to see that all previous relations can be simplified into (using binary addition rules):

$$z(a,b,c)=\bar{a}+b \tag{14.3.31}$$

This latter result can be seen with the available Karnaugh map minimizer freeware that we can find nowadays on the Internet. For example the freeware Karnaugh Map Minimizer that gives us for the previous example (we also see at the same time why it is boring - as always also in other field of engineering a science - that there are no ISO norm to standardize Karnaugh map representation at the days we write these lines):



Number of variables: 3 Type of solution: Sum of products

	A	B	C	f
0	0	0	0	1
1	0	0	1	1
2	0	1	0	1
3	0	1	1	1
4	1	0	0	
5	1	0	1	
6	1	1	0	1
7	1	1	1	1

	00	01	11	10
0	1 0	1 1	1 3	1 2
1	4	5	1 7	1 6

Solution:

```
X = |A + B
  |A
  B
```

Karnaugh map solved!

Figure 14.323: **Karnaugh Map Minimizer 0.4**

A difficulty remains however sometimes with this technique: how to choose the best construction of the table (disposition of letters)?

In fact, there is a specific way of associating the Boolean Algebra complement rule with what we name the "Gray code".

Definition (#14.3.592): The "reflected binary code (RBC)", also known as "Gray code" after Frank Gray, is a binary numeral system where two successive values differ in only one bit (binary digit). The reflected binary code was originally designed to prevent spurious output from electromechanical switches[84] and is useful to optimally build Karnaugh maps.

Here is an example of the Gray code for decimal 0 to 15 (the reader can notice that only one bit/switch at a time change at each row):

Decimal	Binary	Gray
0	0000	0000
1	0001	0001
2	0010	0011
3	0011	0010
4	0100	0110
5	0101	0111
6	0110	0101
7	0111	0100
8	1000	1100
9	1001	1101
10	1010	1111
11	1011	1110
12	1100	1010
13	1101	1011
14	1110	1001
15	1111	1000

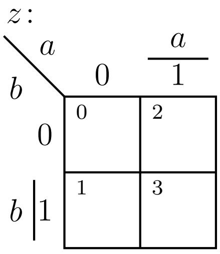
Table 14.46: **Gray code of 0 to 15**

Using Gray code we can create optimal Karnaugh tables. The reason is simple, the Gray code changes only one bit at a time at each increment as we have just seen. In practice this means that for two consecutive values, 1 and 2 for example, one of the two variables will be the opposite of the other one.

We can see this very well with the following structures:

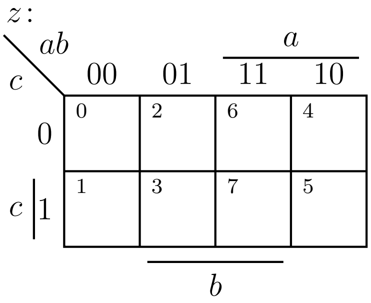
---

[84] The problem with natural binary codes is that physical switches are not ideal: it is very unlikely that physical switches will change states exactly in synchrony. In the transition between the two states shown above, all three switches change state.



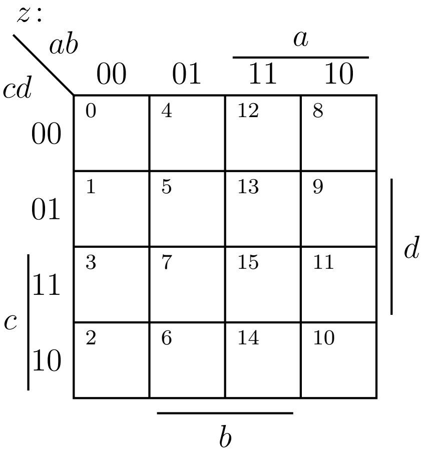
z:
a
b
0
1
0
b
1
0
2
1
3

but more especially with greater tables (the order of the cell is not obvious):



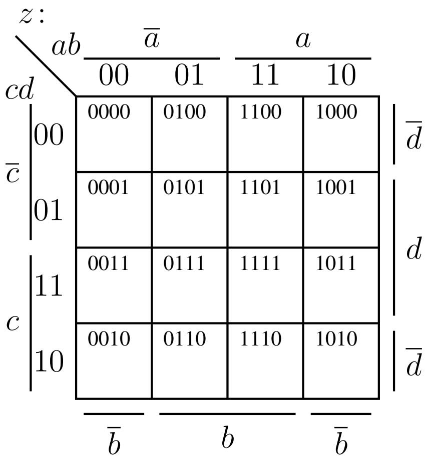
z:
ab
a
c
00
01
11
10
0
c
1
0
2
6
4
1
3
7
5
b

or:



z:
ab
a
cd
00
01
11
10
00
01
11
10
c
d
0
4
12
8
1
5
13
9
3
7
15
11
2
6
14
10
b

or more explicitly for that latter (you can therefore compare with the above Gray code table with 4 digits to understand from where the internal numbering comes from):



z :
ab
$\bar{a}$
a
00 01 11 10
cd
$\bar{c}$
c
00
01
11
10
0000 0100 1100 1000
0001 0101 1101 1001
0011 0111 1111 1011
0010 0110 1110 1010
$\bar{d}$
d
$\bar{d}$
$\bar{b}$
b
$\bar{b}$

✍**Example:**

Given 01 corresponding to $\bar{b}a$ and 11 corresponding to ba, the sum (disjunctive form) would give us:

$$z(a,b)=01+11=\bar{b}a+ba \tag{14.3.32}$$

which is reduced by using the complementation rule directly to:

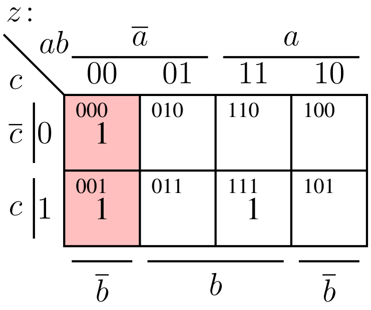
$$z(a,b)=\bar{b}a+ba=(\bar{b}+b)a \tag{14.3.33}$$

hence the advantage to represent them next to each other in a Karnaugh table.

All this to say that when two formulas are found side by side in a Karnaugh map, we retain the similar elements only.

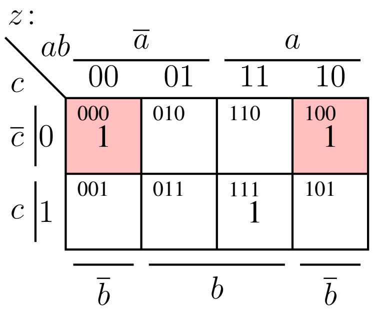
The rules are such that we can reduce therefore when (see previous concrete example):

R1. Two 1 are juxtaposed in the table (here the $\bar{c}+c$ will be simplified in the disjunctive form):



z :
ab
$\bar{a}$
a
00 01 11 10
c
$\bar{c}$ 0
c 1
000 1
010
110
100
001 1
011
111 1
101
$\bar{b}$
b
$\bar{b}$

R2. When two 1 are at the extremities of the table (here the $\bar{b}+b$ will be simplified in the disjunctive form:



$z:$
ab
$\overline{a}$

10

and without errors ... that's all but it's already not bad!

14.3.1.4 Arithmetic Boolean (binary) operations

Using all the elements demonstrated and given previously, we are now able to rigorously determine the logic function allowing Boolean addition and subtraction. Let us also recall that this being done, we can construct multiplication and division using respectively addition and subtraction.

However, we can not with formal digital systems build elements for integration and differentiation. For this we refer the reader to the section of Electrokinetics where it is shown how to use inductors and capacitors to perform such operations with signals.

Remark

We will work on integers but the reader must remember that rational numbers can always be increased in power to be represented in an integral way (it remains to perform the inverse operation if necessary).

The sum of two bytes will be denoted S, the retention C_s (outgoing retention, also often denoted C_{out}) and the deferred retention C_e (inward retention, also often denoted C_{in}).

The truth table will be build with the "tip" that the system inputs (a,b,C_e) take all possible values on 3 bits (three letters) thus $2^3=8$ rows that we have represented in the following table:

C_e	a	b
0	0	0
0	0	1
0	1	0
0	1	1
1	0	0
1	0	1
1	1	0
1	1	1

Table 14.47: **Identification of the reported retentions for the binary sum**

And now the idea consists in adding the column constituted by the sum:

$$S=C_e+a+b \tag{14.3.34}$$

row by row (without thinking to the outgoing retention C_s that we will see a little bit further below):

$\boldsymbol{C_e}$	$\boldsymbol{a}$	$\boldsymbol{b}$	$\boldsymbol{S}$
0	0	0	0
0	0	1	1
0	1	0	1
0	1	1	0
1	0	0	1
1	0	1	0
1	1	0	0
1	1	1	1

Table 14.48: **Sum for the binary sum**

Now, row by row, we add the outgoing retention C_s (which is none other than the value that is sent to the incoming retention of the next row) of the sum S:

$\boldsymbol{C_e}$	$\boldsymbol{a}$	$\boldsymbol{b}$	$\boldsymbol{S}$	$\boldsymbol{C_s}$	**Minterms**
0	0	0	0	0	$\bar{C}_e\bar{a}\bar{b}$
0	0	1	1	0	$\bar{C}_e\bar{a}b$
0	1	0	1	0	$\bar{C}_e a\bar{b}$
0	1	1	0	1	$\bar{C}_e ab$
1	0	0	1	0	$C_e\bar{a}\bar{b}$
1	0	1	0	1	$C_e\bar{a}b$
1	1	0	0	1	$C_e a\bar{b}$
1	1	1	1	1	$C_e ab$

Table 14.49: **Retentions reported for the binary sum**

Therefore we have 4 minterms (that is, the terms for which S is non-zero in the rows 2, 3, 5 and 8) such that the normal disjonctive form is written:

$$S=\bar{C}_e\bar{a}b+\bar{C}_e a\bar{b}+C_e\bar{a}\bar{b}+C_e ab \tag{14.3.35}$$

A possible simplification is:

$$S=C_e(\bar{a}\bar{b}+ab)+\bar{C}_e(a\bar{b}+\bar{a}b)=C_e\bar{\alpha}+\bar{C}_e\alpha=C_e\oplus\alpha=C_e\oplus a\oplus b \tag{14.3.36}$$

It also comes for the outgoing retention the following minterms:

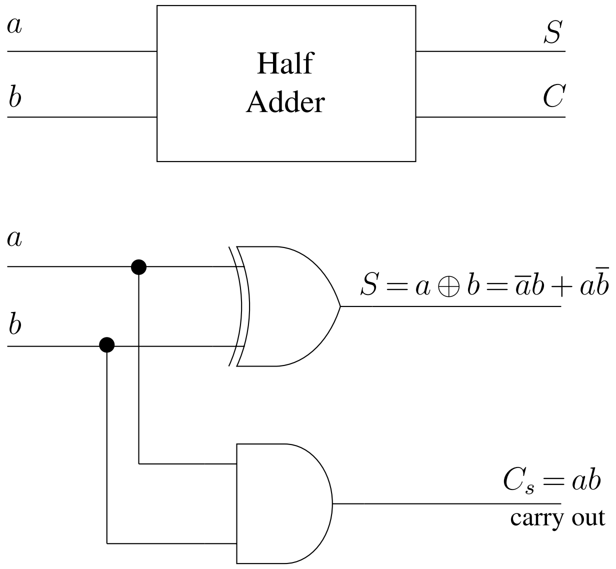
$$C_s=\bar{C}_e ab+C_e\bar{a}b+C_e a\bar{b}+C_e ab=ab+C_e(\bar{a}b+a\bar{b})=ab+C_e a\oplus b \tag{14.3.37}$$

So finally we have:

$$\boxed{\begin{gathered}S=C_e\oplus a\oplus b\\ C_s=ab+C_e a\oplus b\end{gathered}} \tag{14.3.38}$$

To build physically with fundamental logic gates this addition, it is useful first to introduce an intermediary logic circuit (but it's not obliged, it's just for pedagogical reasons and by educational tradition!).

Let us for this purpose consider the truth table of the addition without incoming retention, named a "half adder", and represented by the following "technical" drawing:



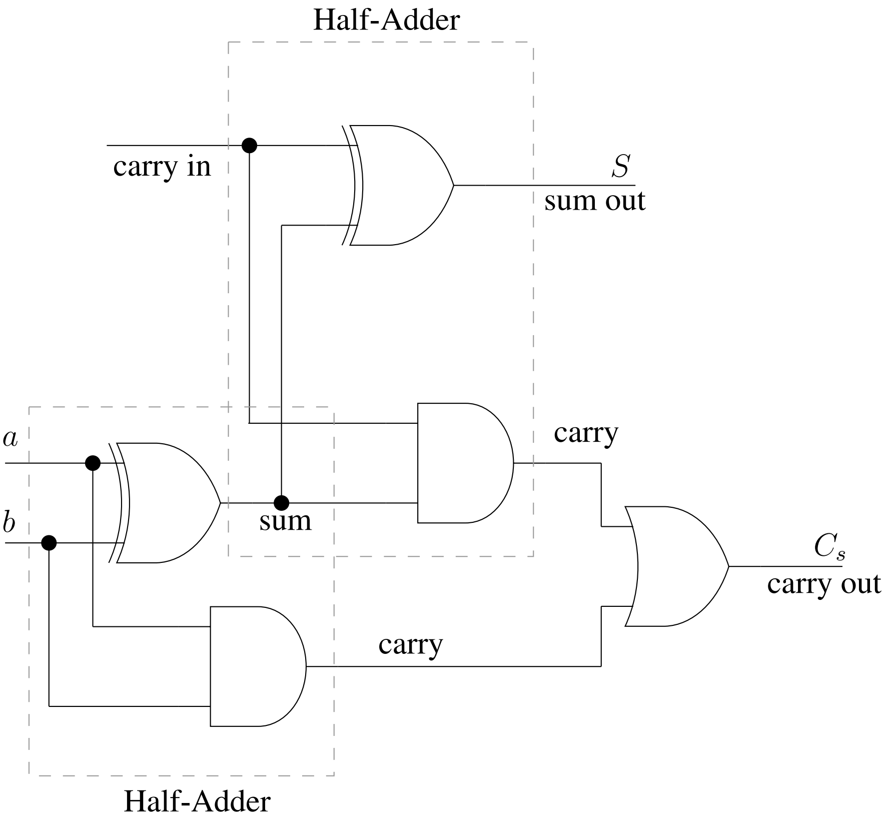
a
b
Half Adder
S
C
a
b
$S = a \oplus b = \overline{a}b + a\overline{b}$
$C_s = ab$
carry out

Figure 14.324: **Half adder logic diagram**

a	b	S	C_s
0	0	0	0
0	1	1	0
1	0	1	0
1	1	0	1

And now we can introduce the "full adder" that adds binary numbers and accounts for values carried in as well as out following the relation proved earlier above and is made of two half-adder. So here is for recall the minterms and we introduce the corresponding logical circuit:

$$\begin{gathered} S = C_e \oplus a \oplus b \\ C_s = ab + C_e a \oplus b \end{gathered}$$



Half-Adder
carry in
S
sum out
a
b
sum
carry
carry
C_s
carry out
Half-Adder

Figure 14.325: **Full adder logic diagram**

C_e	a	b	S	C_s
0	0	0	0	0
0	0	1	1	0
0	1	0	1	0
0	1	1	0	1
1	0	0	1	0
1	0	1	0	1
1	1	0	0	1
1	1	1	1	1

The subtraction (difference) of two bytes will be denoted D, the borrowing B_s (outgoing borrowing, also often denoted B_{out}) and the reported borrowing B_e (inbound borrowing, also often denoted B_{in}). The truth table will first be build as for the addition. That is, the system inputs (a, b, e_e) take all possible values on 3-bit (three-letter) the $2^3 = 8$ rows. Therefore:

B_e	a	b
0	0	0
0	0	1
0	1	0
0	1	1
1	0	0
1	0	1
1	1	0
1	1	1

Table 14.50: **Identification of the reported borrowing for the binary subtraction**

But we will a little subtlety. Rather than bore us to calculate $D = a - b - B_e$, we will calculate $D = a + (-b) + (-B_e)$ in the purpose to be able to work with the following truth table:

$-B_e$	a	$-b$
0	0	0
0	0	1
0	1	0
0	1	1
1	0	0
1	0	1
1	1	0
1	1	1

Table 14.51: **Inversion of the reported borrowing for the binary subtraction**

and now the idea is to add the difference column $D = a + (-b) + (-B_e)$ row by row (without thinking about the borrowing B_s) which will be strictly identical to the truth table of the sum:

$-B_e$	a	$-b$	D
0	0	0	0
0	0	1	1
0	1	0	1
0	1	1	0
1	0	0	1
1	0	1	0
1	1	0	0
1	1	1	1

Table 14.52: **Reported borrowing for the binary subtraction**

Now, row by row, we add the outgoing borrowing B_s of the difference $D=a+(-b)+(-B_e)$ which written so, then becomes a sum S:

$-B_e$	a	$-b$	$S(D)$	B_s	**minterms**
0	0	0	0	0	$\bar{B}_e\bar{a}\bar{b}$
0	0	1	1	1	$\bar{B}_e\bar{a}b$
0	1	0	1	0	$\bar{B}_e a\bar{b}$
0	1	1	0	0	$\bar{B}_e ab$
1	0	0	1	1	$B_e\bar{a}\bar{b}$
1	0	1	0	1	$B_e\bar{a}b$
1	1	0	0	0	$B_e a\bar{b}$
1	1	1	1	1	$B_e ab$

Table 14.53: **Identification of subtraction minterms**

Therefore it comes 4 minterms (that is, the terms for which $S(D)$ is non-zero at row 2, 3, 5, 8) such that the normal disjonctive form of the subtraction can be written:

$$S(D)=D=\bar{B}_e\bar{a}b+\bar{B}_e a\bar{b}+B_e\bar{a}\bar{b}+B_e ab \tag{14.3.39}$$

A trivial possible simplification is:

$$D=\bar{B}_e(\bar{a}b+a\bar{b})+B_e(\bar{a}\bar{b}+ab)=B_e\oplus a\oplus b \tag{14.3.40}$$

It also comes for the outgoing borrowing the following minterms:

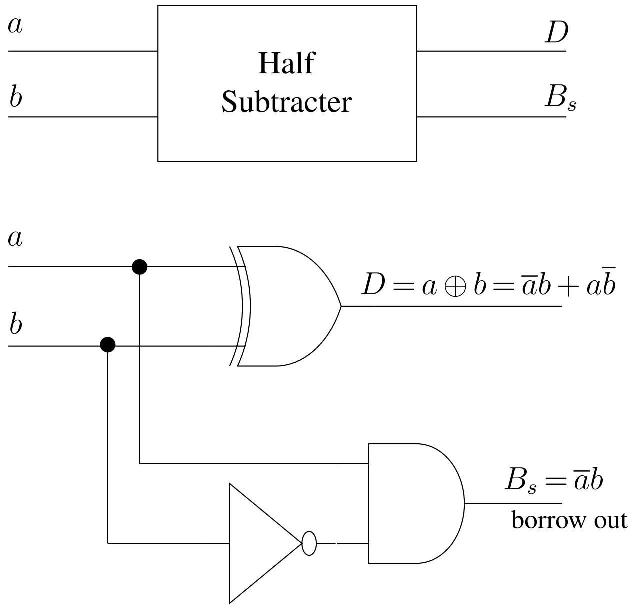
$$B_s=\bar{B}_e\bar{a}b+B_e\bar{a}\bar{b}+B_e\bar{a}b+B_e ab=\bar{a}b+B_e(\overline{a\oplus b}) \tag{14.3.41}$$

So finally:

$$\boxed{\begin{aligned} D&=B_e\oplus a\oplus b\\ B_s&=\bar{a}b+B_e(\overline{a\oplus b})\end{aligned}} \tag{14.3.42}$$

To build physically with fundamental logic gates this subtraction, it is useful first to introduce an intermediary logic circuit (but it's not obliged, it's just for pedagogical reasons and by educational tradition!).

Let us for this purpose consider the truth table of the subtraction without incoming borrowing, named a "half subtracter", and represented by the following "technical" drawing (don't forget that b means in fact $-b$!):



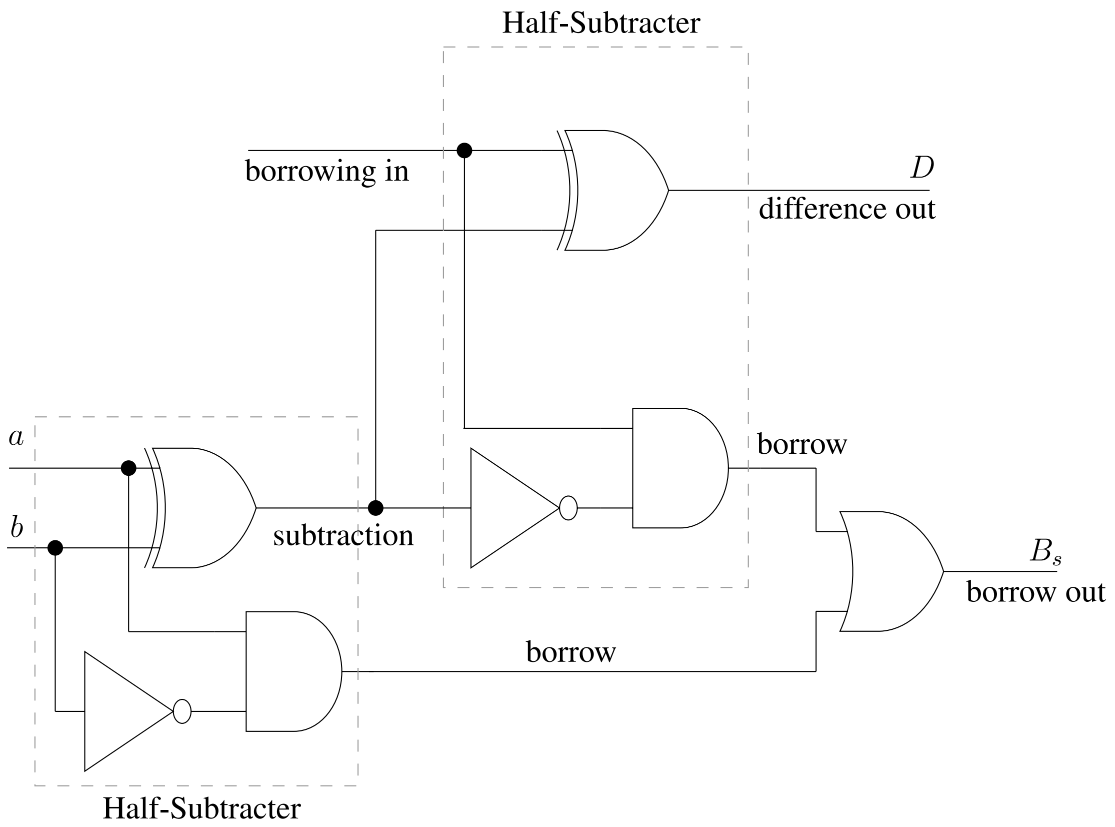
a
b
Half Subtracter
D
B_s
a
b
$D = a \oplus b = \bar{a}b + a\bar{b}$
$B_s = \bar{a}b$
borrow out

Figure 14.326: **Half subtracter logic diagram**

a	$-b$	$S(D)$	B_s
0	0	0	0
0	1	1	1
1	0	1	0
1	1	0	0

And now we can introduce the "full subtracter" that substracts binary numbers and accounts for values carried in as well as out following the relation proved earlier above and is made of two half-adder. So here is for recall the minterms and we introduce the corresponding logical circuit:

$$D = B_e \oplus a \oplus b$$
$$B_s = \bar{a}b + B_e(\overline{a \oplus b})$$



Half-Subtracter
borrowing in
D
difference out

1	1	0	0	0
1	1	1	1	1

14.3.1.4.1 Prefix codes

"Binary comparators" are logic gates circuit used to compare two binary inputs. There are two types of binary comparators:

- "Equality comparators" are used to check if the two binary inputs (A and B) are equal or not.
- "Magnitude comparators" are used to fully compare two binary inputs A and B and produce three possible outpus if $A > B$, $A == B$ or $A < B$

We will focus in what follows on Magnitude Operators symbolized by:

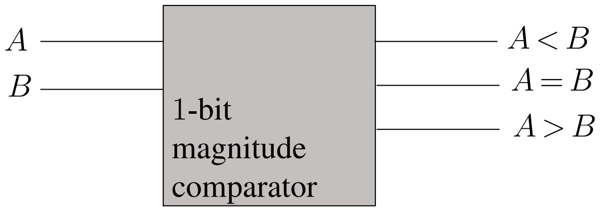

Figure 14.328: 1-bit magnitude comparator

With the following truth table:

INPUT		OUTPUT		
A	B	$A < B$	$A = B$	$A > B$
0	0	0	**1**	0
1	0	0	0	**1**
0	1	**1**	0	0
1	1	0	**1**	0

Table 14.54: 1-bit magnitude comparator truth table

And here is the logic gates diagram for this circuit:

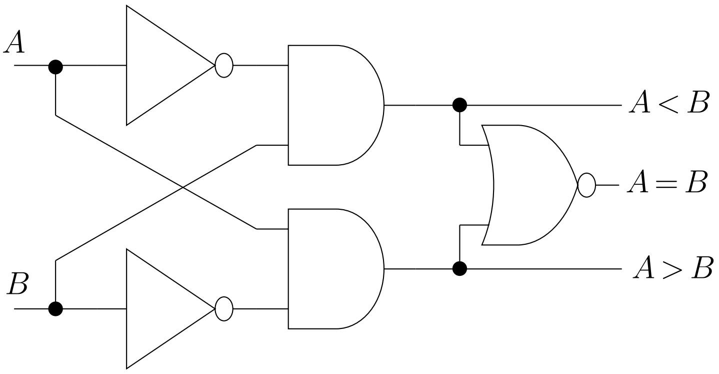

Figure 14.329: 1-bit magnitude comparator

We can now combine several of the above diagrams to create a 4-bit magnitude comparator as follows (thanks to Karnaugh table simplification process):

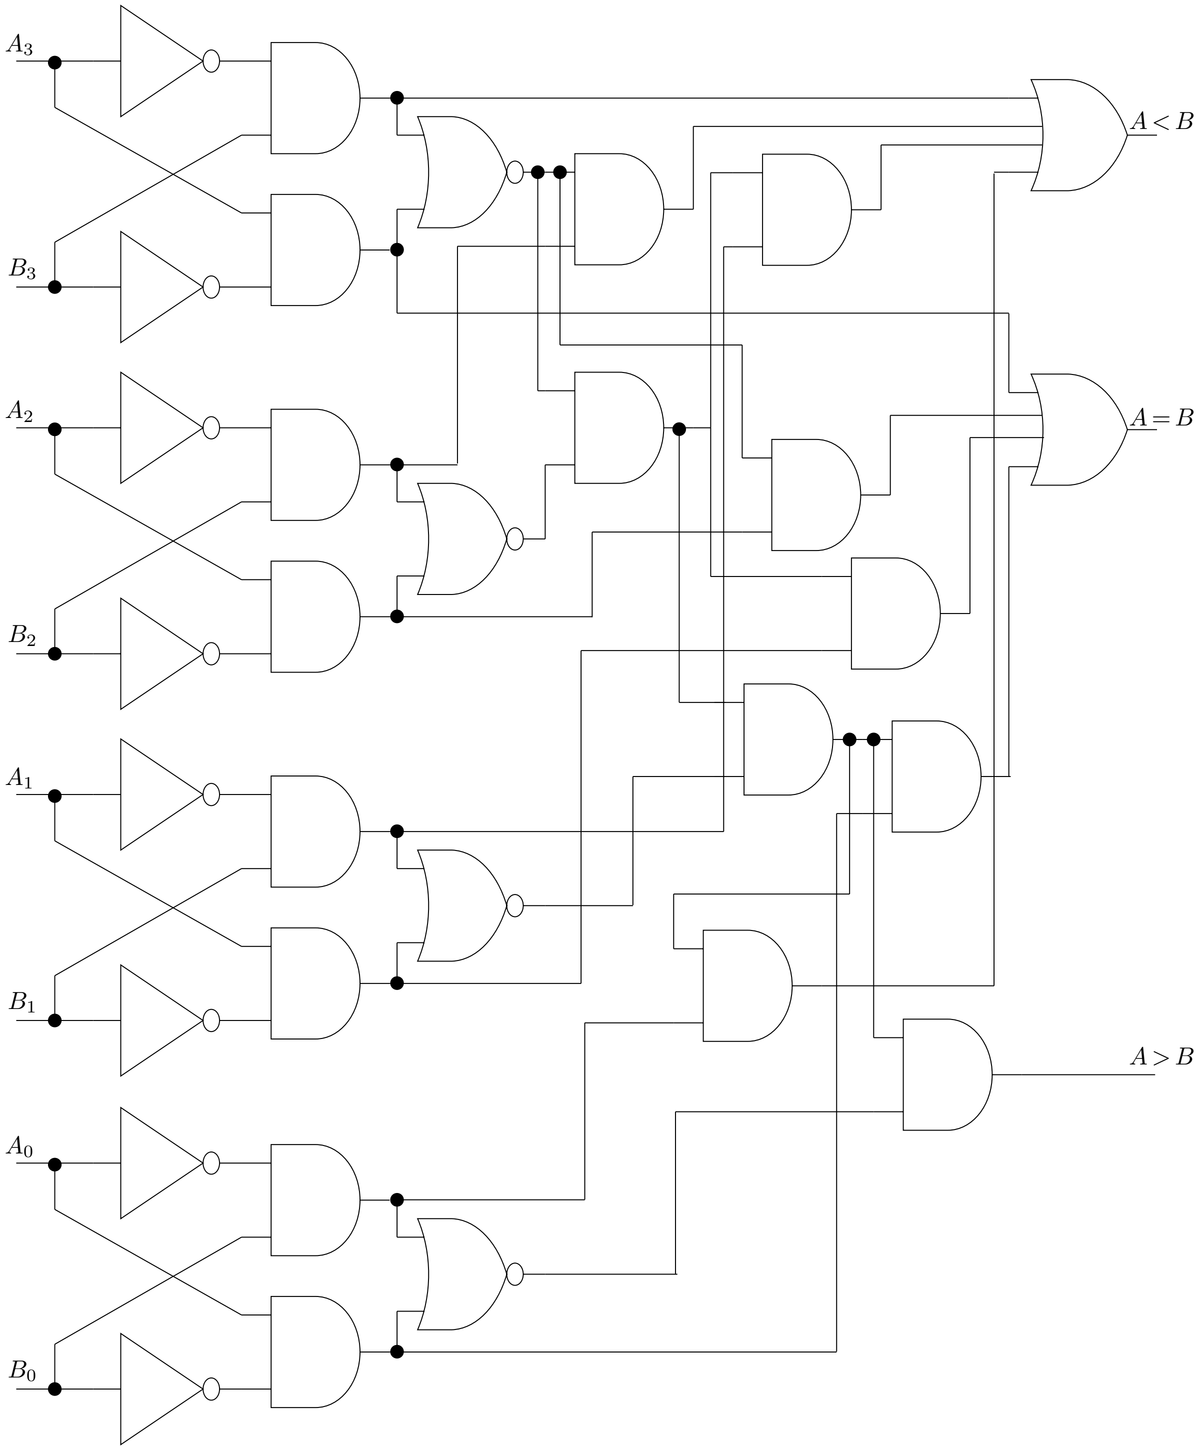

Figure 14.330: 4-bits magnitude comparator

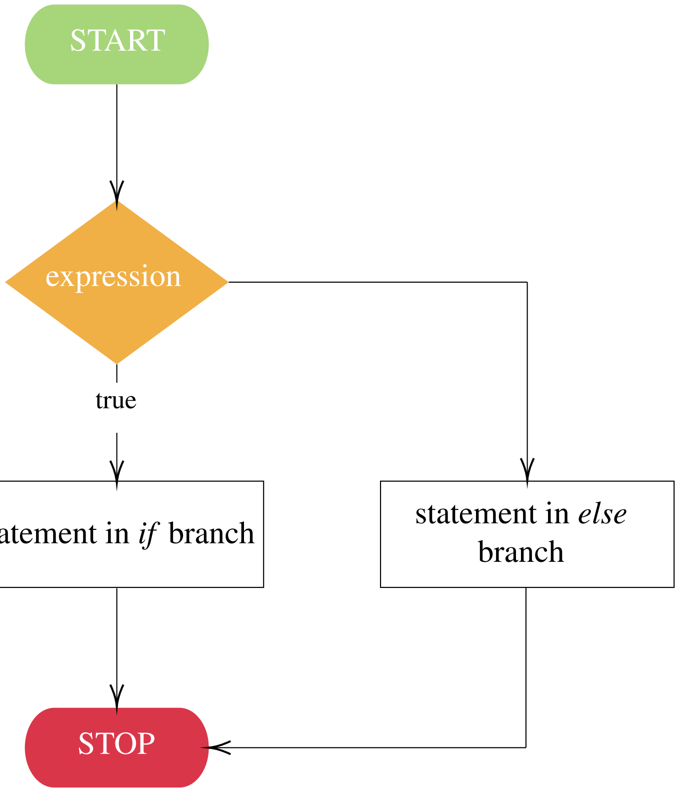
Notice that as far as we know it doesn't seem to exist a simple reducible case to any number of bits. That's why computer systems have a limit depending on their bus width (system that transfers data between components inside a computer) like those in the early 121st century (holocene calendar) have a 32 bits or 64 bits bus and hence a 32 bits or 64 bits magnitude comparator.

The generic method for implementing if-else statement:



START
expression
true
statement in *if* branch
statement in *else* branch
STOP

Figure 14.331: **if-else statement flowchat**

in hardware (using gates,mux-demux, flip flops) is given in Boolean Algebra by:

$$Q = (A \cdot S) + \left(B \cdot \bar{S}\right) \quad (14.3.43)$$

where:

- S is the input fed by the *if* condition
- A is the input fed by the *then* subexpression
- B is the input fed by the *else* subexpression, and
- Q is the output of the expression.

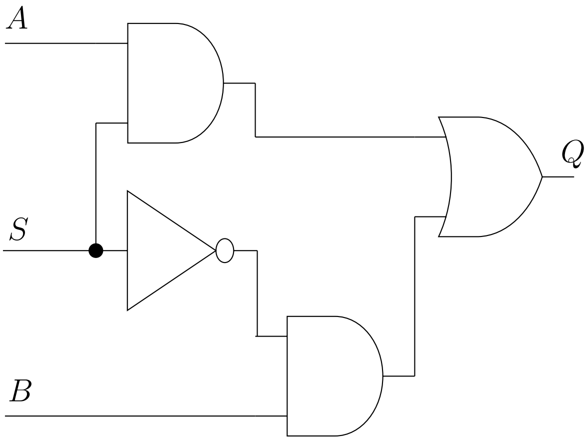


Figure 14.332: **If-else statement in hardware based on boolean gates**

14.3.2 Fuzzy logic

Classical logic only permits conclusions which are either true or false. However, there are also propositions with variable answers, such as one might find when asking a group of people to identify a color. In such instances, the truth appears as the result of reasoning from inexact or partial knowledge in which the sampled answers are mapped on a spectrum.

Humans and animals often operate using fuzzy evaluations in many everyday situations. In the case where someone is tossing an object into a container from a distance, the person does not compute exact values for the object weight, density, distance, direction, container height and width, and air resistance to determine the force and angle to toss the object. Instead the person instinctively applies quick "fuzzy" estimates, based upon previous experience, to determine what output values of force, direction and vertical angle to use to make the toss. Both degrees of truth and probabilities range between 0 and 1 and hence may seem similar at first, but fuzzy logic uses degrees of truth as a mathematical model of vagueness, while probability is a mathematical model of ignorance.

Take, for example, the concepts of "empty" and "full". The meaning of each of them can be represented by a certain fuzzy set. The concept of emptiness would be subjective and thus would depend on the observer or designer. A 100 [ml] glass containing 30 [ml] of water may be defined as being 0.7 empty and 0.3 full, but another designer might, equally well, design a set membership function where the glass would be considered full for all values down to 50 [ml].

Most of the problems encountered are certainly mathematically modelizable. But these models often require overly restrictive assumptions, making application to the real world tricky. The problems of this world must take into account imprecise, uncertain information. Let us take the example of air conditioning: if we want to obtain a cool temperature, we can ask ourselves what temperature range will be appropriate (the demand is imprecise); Furthermore the reliability of the sensors comes into play (the measurement of the ambient temperature is uncertain). We see the difficulty of interpreting the linguistic variables as fresh, hot, ... and the processing of these uncertainties.

An approach was developed from 11965 (holocene calendar) by Loft. A. Zadeh, a professor at the University of California at Berkeley, based on the theory of fuzzy sets, generalizing the theory of classical sets. In the new Zadeh theory, an element can more or less belong to a certain set. Inaccuracies and uncertainties can thus be modeled, and reasonings acquire a flexibility that is not allowed by classical logic: "fuzzy logic" was born. Many applications have developed in various domains, where no deterministic model exists or is practically implementable, as well as in situations where data imprecision makes control by conventional methods impossible.

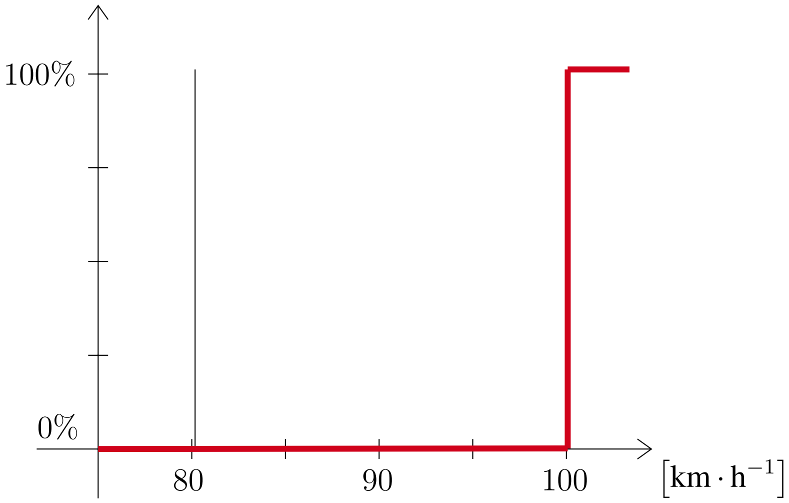
In the following, we will first develop the basics of the theory of fuzzy subsets, then we will clarify the reasoning in fuzzy logic, we will examine the methods of exploitation of the results obtained, and finally we will see an effective application (and if possible an application with MATLAB® and/or `R`).

Before turning to the formal side of the thing (mathematically speaking), it may be preferable (since it is still a technique of the engineer mainly) to briefly present the concepts of fuzzy logic in a pictorial way.

Remark

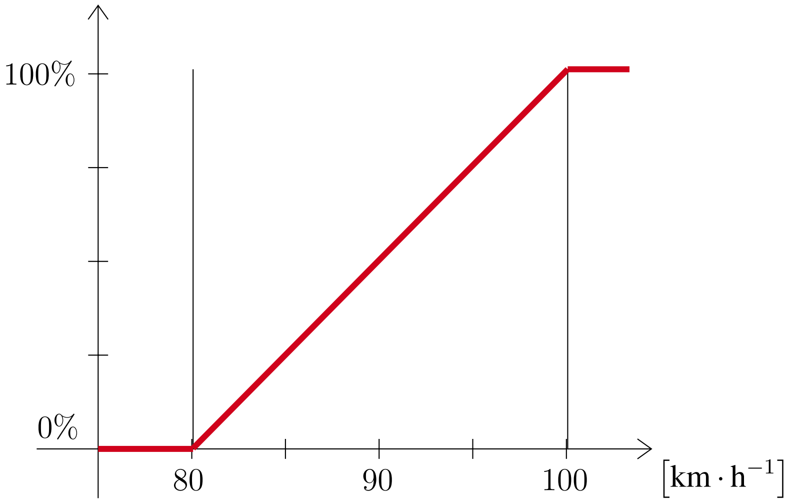
The fuzzy logic is a technique used for real in fields as varied as automatism (ABS brakes), robotics (pattern recognition), road traffic management (red lights), air traffic control, environment (meteorology, climatology, seismology), medicine (diagnostic aid), psychology, data mining, Machine Learning, and many others.

Consider, for example, the speed of a vehicle on a national highway. The normal speed is 90 $[\text{km}\cdot\text{h}^{-1}]$. A speed can be considered as high above 100 $[\text{km}\cdot\text{h}^{-1}]$, and as low below 80 $[\text{km}\cdot\text{h}^{-1}]$. Boolean logic would look at a thing like this:



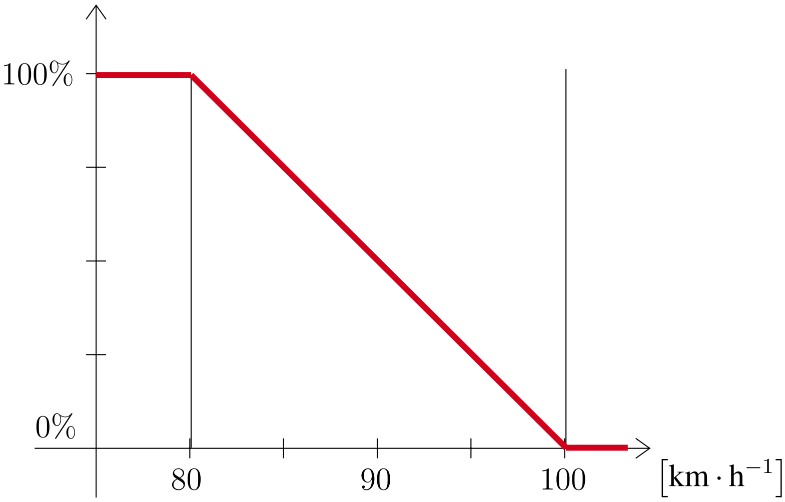
We see above that therefore the speed is considered 100% as high starting from 100 $[\text{km}\cdot\text{h}^{-1}]$, and 0% below.

Fuzzy logic, on the other hand, allows degrees of verification of the condition "Is speed high?" according to:



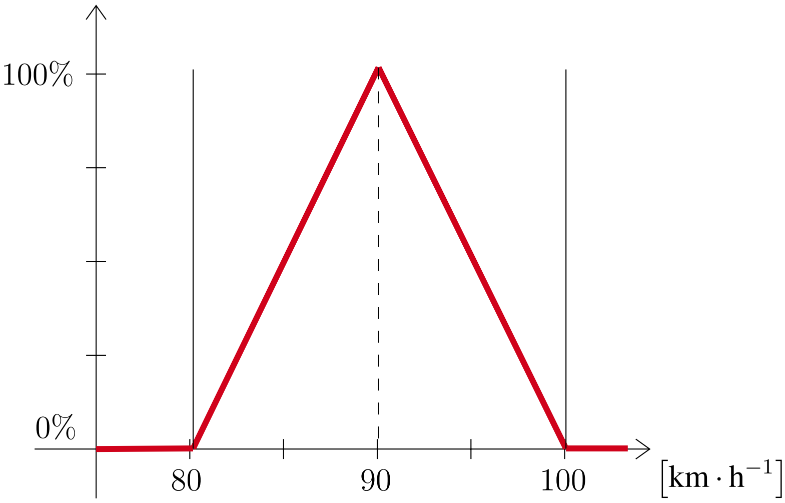
The situation is better here as the speed is considered as not high at all below 80 $[\text{km}\cdot\text{h}^{-1}]$. We can therefore say that below 80 $[\text{km}\cdot\text{h}^{-1}]$, the speed is high at 0%. The speed is considered to be high above $100\,[\text{km}\cdot\text{h}^{-1}]$. The speed is therefore high at 100% above $100\,[\text{km}\cdot\text{h}^{-1}]$. The speed is thus high at 50% when at $90\,[\text{km}\cdot\text{h}^{-1}]$ and high at 25% at $85\,[\text{km}\cdot\text{h}^{-1}]$.

Similarly, the function "Is the speed low?" Will be addressed typically as following by most humans:



Therefore following the above figure the speed is considered low under $80\,[\text{km}\cdot\text{h}^{-1}]$. It is therefore 100% low. The speed is considered not at all low above $100\,[\text{km}\cdot\text{h}^{-1}]$. It is therefore 0% low. The speed is thus a 50% (bit low) when at $90\,[\text{km}\cdot\text{h}^{-1}]$ and at 75% (quite low) when at $85\,[\text{km}\cdot\text{h}^{-1}]$.

We can also define a function "Is the speed average?" by:

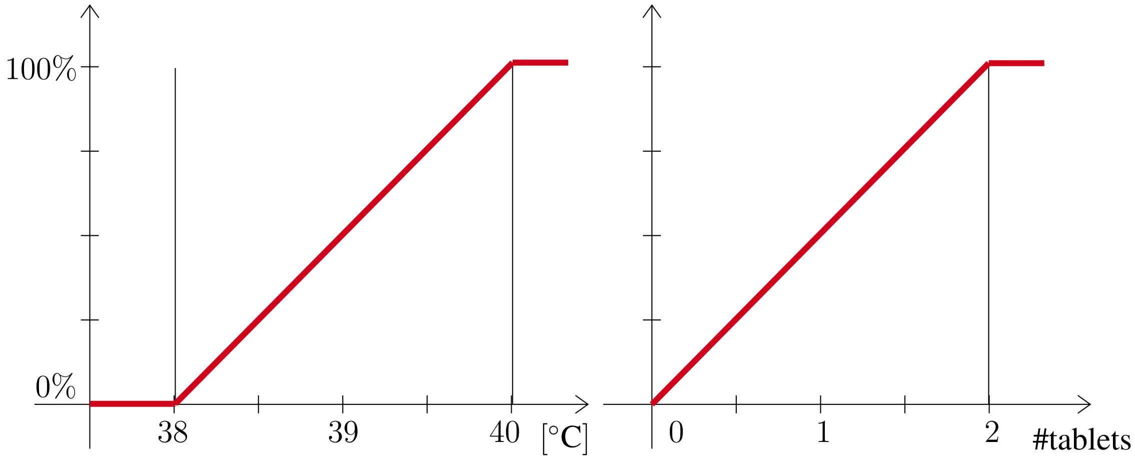


Once the input value evaluated ("Is the speed high?"), a value can be determined for an output function. Consider the function "If the fever is strong, then administer aspirin". Such a function is named "fuzzy control". It is composed of two parts:

1. An input: "Is the fever strong?". We consider that a fever is not strong below $38\,[^\circ\text{C}]$, and that it is high above $40\,[^\circ\text{C}]$.

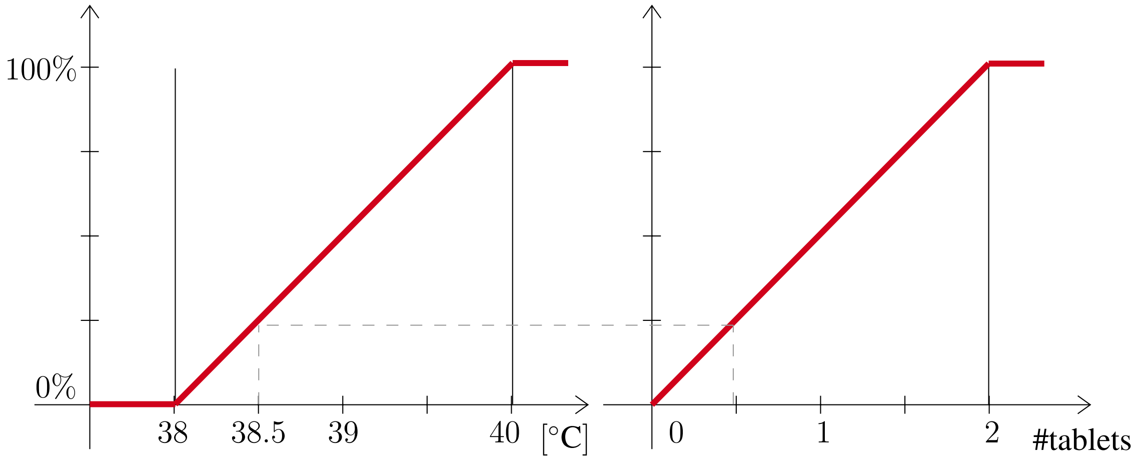
2. An output: "Administer a given number of aspirin tablets!"

These two parts are related. We can represent them together as below:

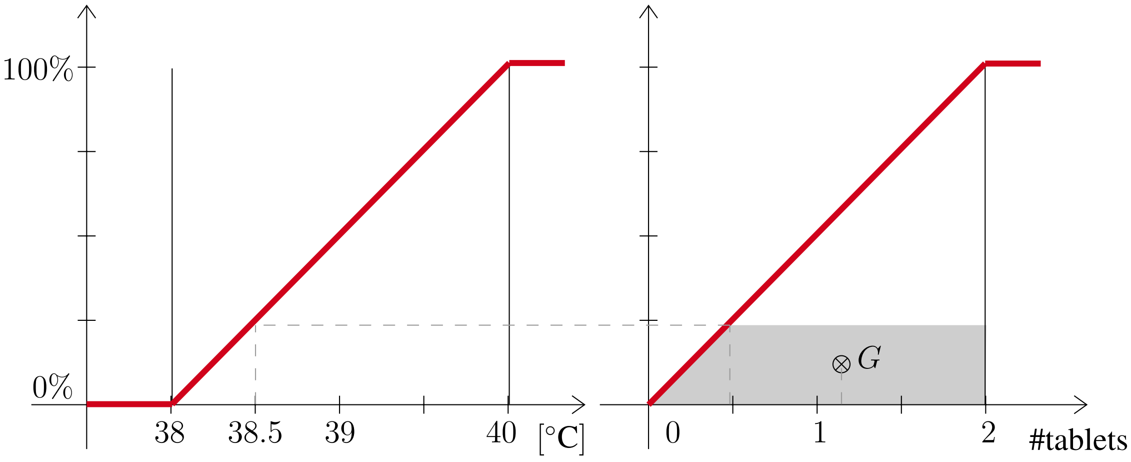


There are several empirical techniques for determining the output value (in the example: the number of aspirin tablets to be administered):

An example consists in taking the horizontal passing through the corresponding ordinate point on the starting curve at the abscissa of the value of the input and of looking at where this horizontal section intersects the output curve. The abscissa of this point of intersection is a possible output value as shown below:



A second empirical possible choice consists in taking as output value of the center of gravity of the gray trapezoid delimited by the horizontal and the output curve as shown in the figure below:



From these two non-software oriented examples, we see that we are at the frontier of pure science and engineering frontier since there is a technical and/or statistical choice to be made in the method to be chosen.

Let us now do a computer aided example as engineers in practice use such tools to speed up their research and development! The case below in inspired by a textbook and many softwares take it now as basis example named the "Basic Tipping Problem".

✍**Example:**

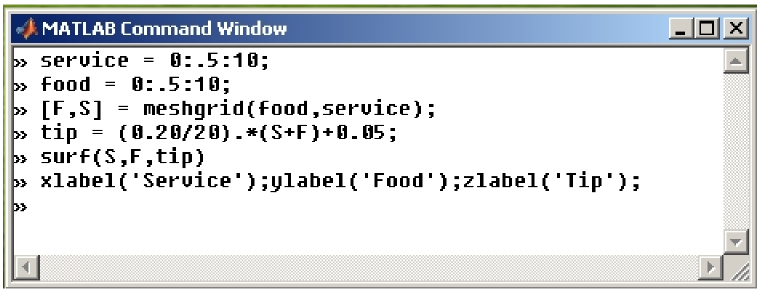
Given a number between 0 and 10 that represents the quality of service and food at a restaurant (where 10 is excellent), what should the tip be?

This problem is based on tipping as it is typically practiced in the United States. An average tip for a meal in the U.S. is 15%, though the actual amount may vary depending on the quality of the service provided. But because service and food is rated on a scale of 0 to 10, we might have the tip go linearly from 5% if the service is bad to 25% if the service is excellent.

If we denote S for the service and F for food quality, we will chose the tip as being given by:

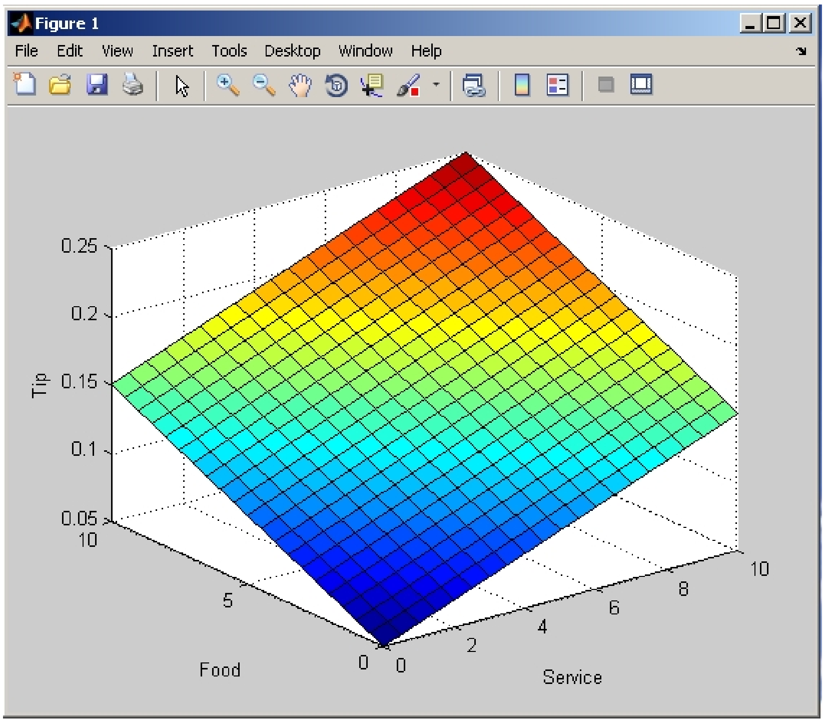
$$\text{tip} = \frac{1}{100}(S+F)+0.05 \tag{14.3.44}$$

Here is a copy/paste of the MATLAB® 2013a script for the original url[a]:



```
>> service = 0:.5:10;
>> food = 0:.5:10;
>> [F,S] = meshgrid(food,service);
>> tip = (0.20/20).*(S+F)+0.05;
>> surf(S,F,tip)
>> xlabel('Service');ylabel('Food');zlabel('Tip');
>>
```

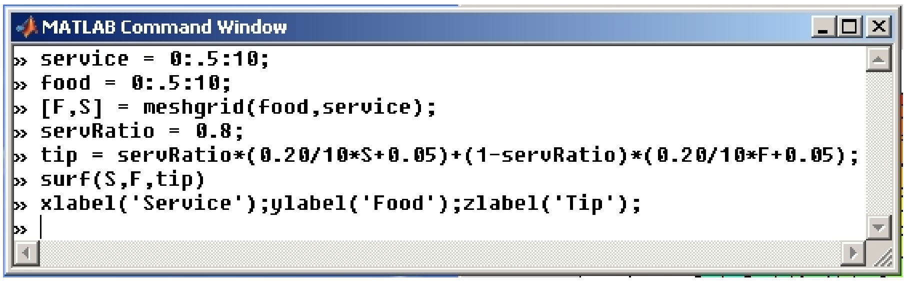
In this case, the results look satisfactory, but when you look at them closely, they do not seem quite right:



Suppose you want the service to be a more important factor than the food quality. Specify that service accounts for 80% of the overall tipping grade and the food makes up the other 20%. Try this equation:

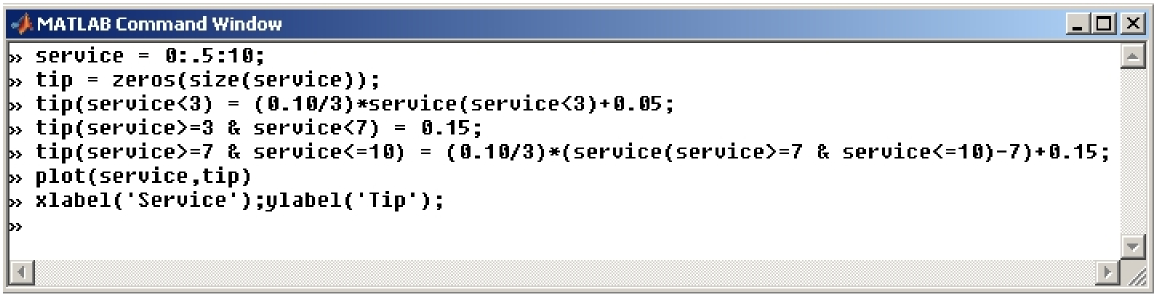
$$\text{tip} = 0.8\left(\frac{0.2}{10}S + 0.05\right) + (1-0.8)\left(\frac{0.2}{10}F + 0.05\right) \tag{14.3.45}$$

Thus in MATLAB® 2013a:



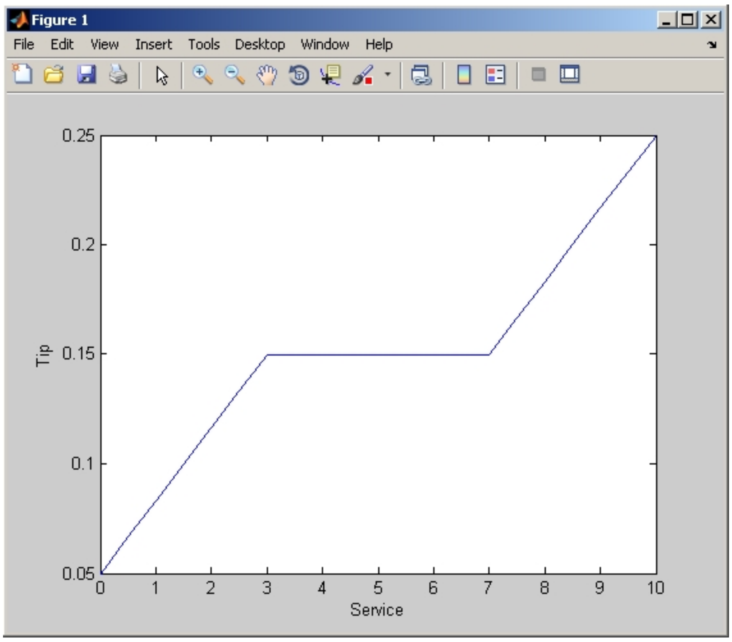
```
>> service = 0:.5:10;
>> food = 0:.5:10;
>> [F,S] = meshgrid(food,service);
>> servRatio = 0.8;
>> tip = servRatio*(0.20/10*S+0.05)+(1-servRatio)*(0.20/10*F+0.05);
>> surf(S,F,tip)
>> xlabel('Service');ylabel('Food');zlabel('Tip');
>> |
```

The response is still some how too uniformly linear. Suppose you want more of a flat response in the middle, i.e., you want to give a 15% tip in general, but want to also specify a variation if the service is exceptionally good or bad. This factor, in turn, means that the previous linear mappings no longer apply. You can still use the linear calculation with a piecewise linear construction. Now, return to the one-dimensional problem of just considering the service. You can create a simple conditional tip assignment using logical indexing:

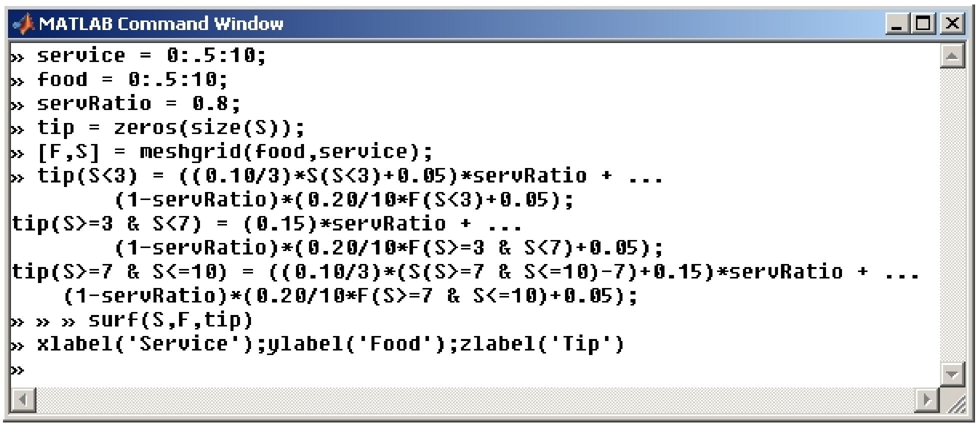


```
» service = 0:.5:10;
» tip = zeros(size(service));
» tip(service<3) = (0.10/3)*service(service<3)+0.05;
» tip(service>=3 & service<7) = 0.15;
» tip(service>=7 & service<=10) = (0.10/3)*(service(service>=7 & service<=10)-7)+0.15;
» plot(service,tip)
» xlabel('Service');ylabel('Tip');
»
```

that gives the following plot:

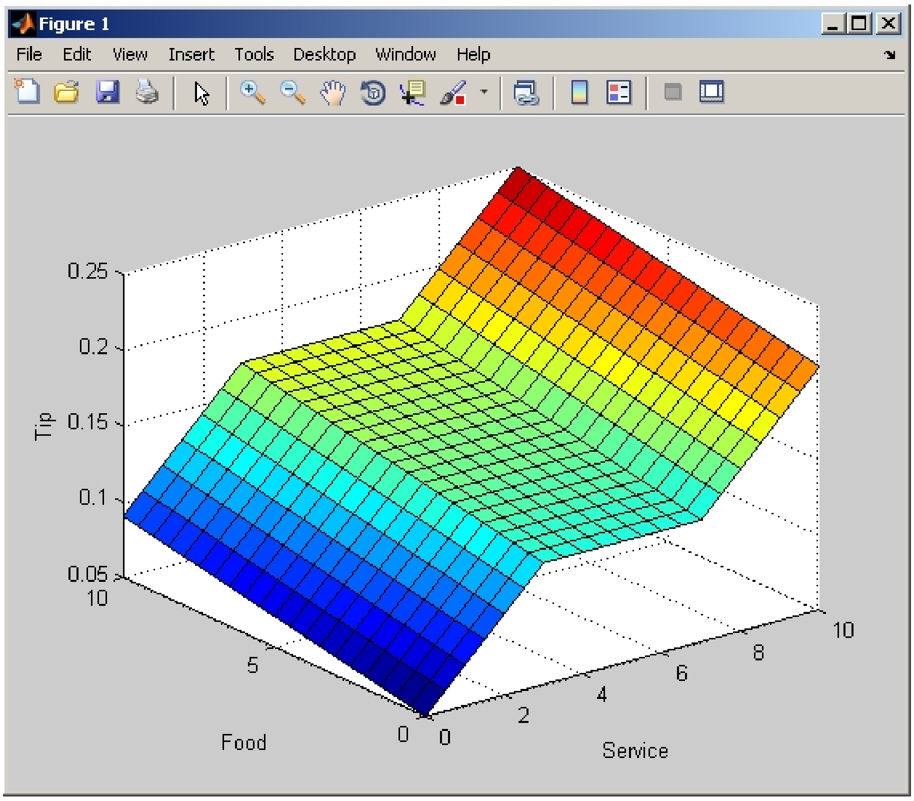


Suppose you extend this to two dimensions, where we take food into account again:



```
» service = 0:.5:10;
» food = 0:.5:10;
» servRatio = 0.8;
» tip = zeros(size(S));
» [F,S] = meshgrid(food,service);
» tip(S<3) = ((0.10/3)*S(S<3)+0.05)*servRatio + ...
        (1-servRatio)*(0.20/10*F(S<3)+0.05);
tip(S>=3 & S<7) = (0.15)*servRatio + ...
        (1-servRatio)*(0.20/10*F(S>=3 & S<7)+0.05);
tip(S>=7 & S<=10) = ((0.10/3)*(S(S>=7 & S<=10)-7)+0.15)*servRatio + ...
    (1-servRatio)*(0.20/10*F(S>=7 & S<=10)+0.05);
» » » surf(S,F,tip)
» xlabel('Service');ylabel('Food');zlabel('Tip')
»
```

that gives the following plot:



The plot looks good, but the function is surprisingly complicated. It was a little difficult to code this correctly, and it is definitely not easy to modify this code in the future. Moreover, it is even less apparent how the algorithm works to someone who did not see the original design process.

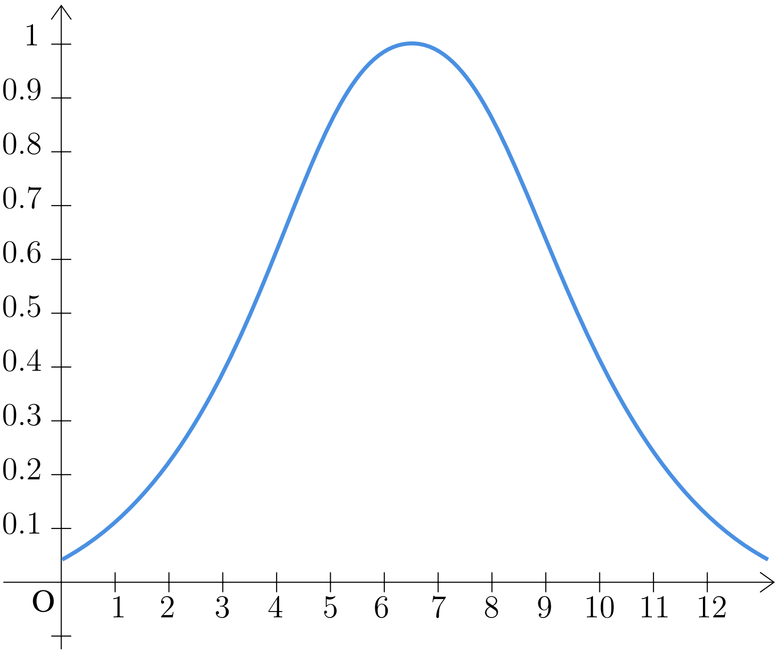
---

[a] See https://ch.mathworks.com/help/fuzzy/an-introductory-example-fuzzy-versus-nonfuzzy-logic.html

In practice we don't use a fuzzy function like the one above as there are sharp angles (imagine a car having speed settings wit abrupt changes as above...).

Therefore rather than using linear functions a input we can choose among a class of continuous and smooth functions. For example the "Gaussian curve membership function" defined by:

$$\text{gaussmf}(x,\sigma,c)=e^{-\frac{(x-c)^2}{2\sigma^2}} \tag{14.3.46}$$

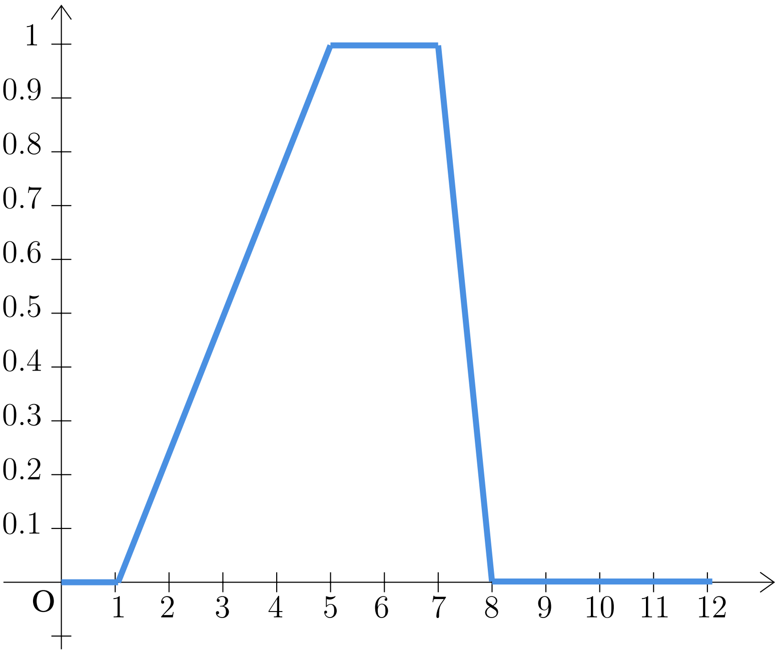


gaussmf, P=[2,6.5]

or the "Trapezoidal-shaped membership function" defined by:

$$\text{trimf}(x,a,b,c,d)=\begin{cases}0 & x\leq a\\ \dfrac{x-a}{b-a} & a\leq x\leq b\\ 1 & b\leq x\leq c\\ \dfrac{d-x}{d-c} & c\leq x\leq d\\ 0 & d\leq x\end{cases}=\max\left(\min\left(\frac{x-a}{b-a},1,\frac{d-x}{d-c}\right),0\right) \tag{14.3.47}$$

The parameters a and d locate the "feet" of the trapezoid and the parameters b and c locate the "shoulders."

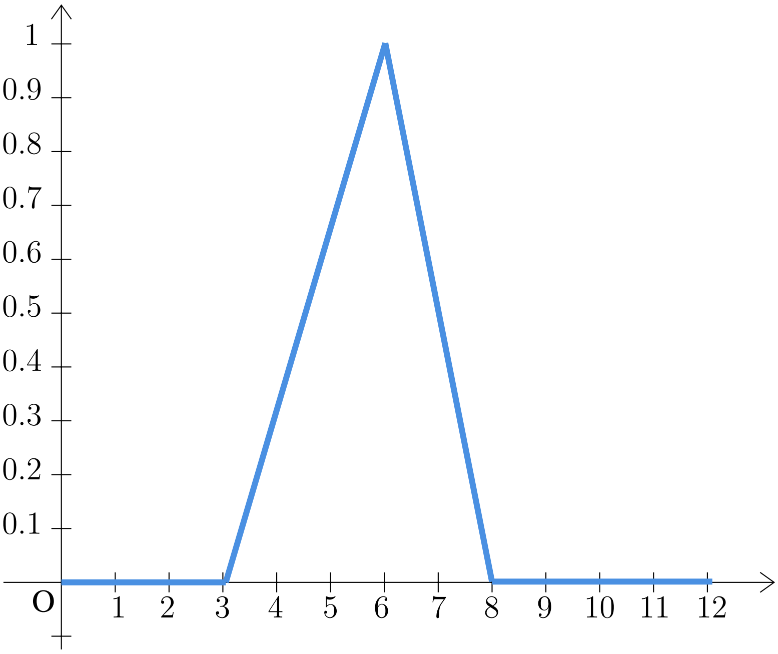


trapmf, P=[1,5,7,8]

Or also the "Triangular-shaped membership function" defined by:

$$\text{trimf}(x,a,b,c)=\begin{cases}0 & x\leq 0\\ \dfrac{x-a}{b-a} & a\leq x\leq b\\ \dfrac{c-x}{c-b} & b\leq x\leq c\\ 0 & c\leq x\end{cases}=\max\left(\min\left(\frac{x-a}{b-a},\frac{c-x}{c-b}\right),0\right) \tag{14.3.48}$$

The parameters a and c locate the "feet" of the triangle and the parameter b locates the peak:

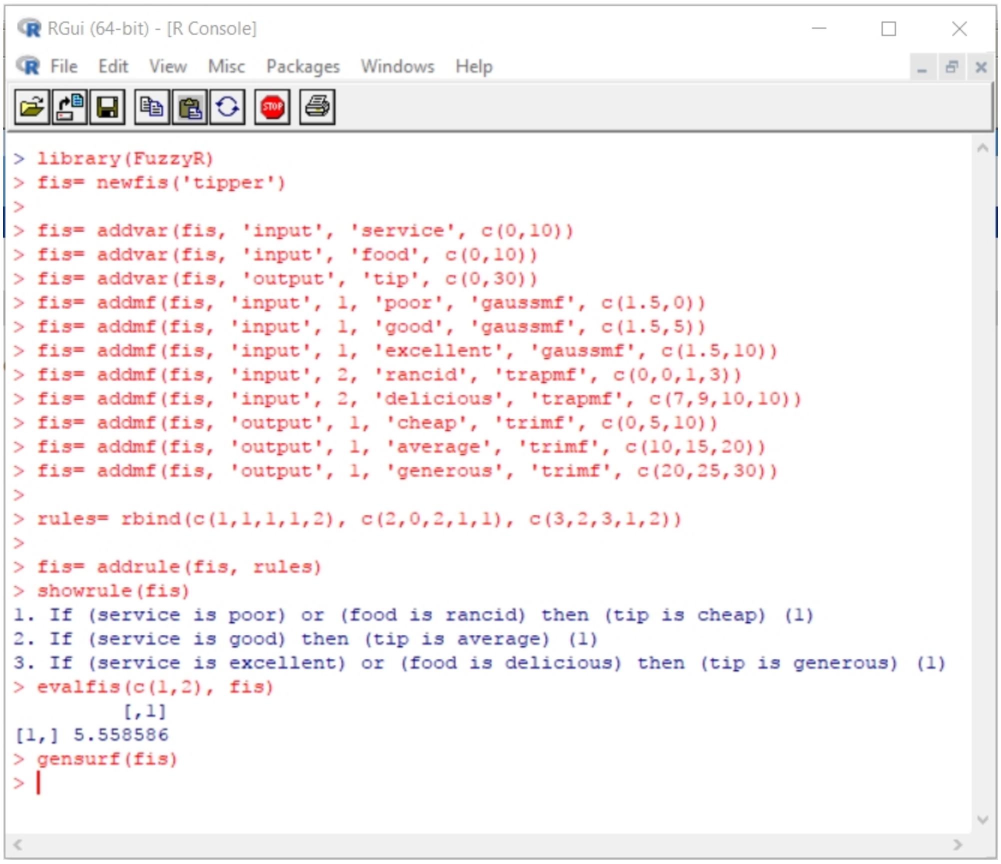


trimf, P=[3,6,8]

Let us see with R the tipper problem managed with the fuzzy functions above (for more details see the R companion book!).

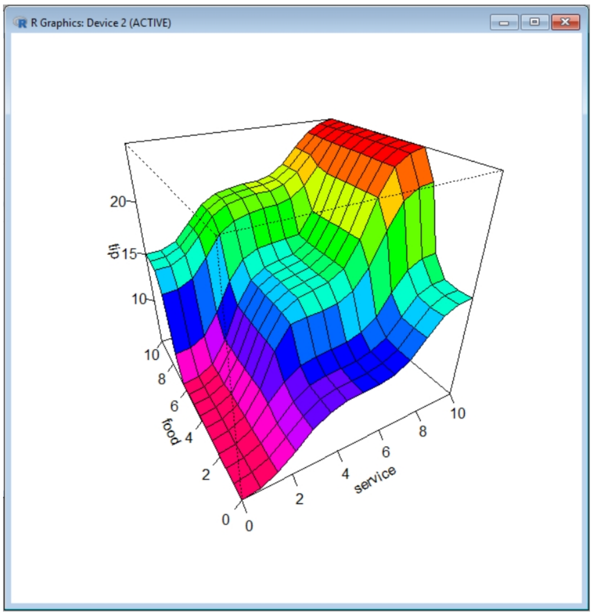
✍**Example:**

Here is a copy/paste of the R script given in [564] with detailed explanations:



```
> library(FuzzyR)
> fis= newfis('tipper')
>
> fis= addvar(fis, 'input', 'service', c(0,10))
> fis= addvar(fis, 'input', 'food', c(0,10))
> fis= addvar(fis, 'output', 'tip', c(0,30))
> fis= addmf(fis, 'input', 1, 'poor', 'gaussmf', c(1.5,0))
> fis= addmf(fis, 'input', 1, 'good', 'gaussmf', c(1.5,5))
> fis= addmf(fis, 'input', 1, 'excellent', 'gaussmf', c(1.5,10))
> fis= addmf(fis, 'input', 2, 'rancid', 'trapmf', c(0,0,1,3))
> fis= addmf(fis, 'input', 2, 'delicious', 'trapmf', c(7,9,10,10))
> fis= addmf(fis, 'output', 1, 'cheap', 'trimf', c(0,5,10))
> fis= addmf(fis, 'output', 1, 'average', 'trimf', c(10,15,20))
> fis= addmf(fis, 'output', 1, 'generous', 'trimf', c(20,25,30))
>
> rules= rbind(c(1,1,1,1,2), c(2,0,2,1,1), c(3,2,3,1,2))
>
> fis= addrule(fis, rules)
> showrule(fis)
1. If (service is poor) or (food is rancid) then (tip is cheap) (1)
2. If (service is good) then (tip is average) (1)
3. If (service is excellent) or (food is delicious) then (tip is generous) (1)
> evalfis(c(1,2), fis)
          [,1]
[1,] 5.558586
> gensurf(fis)
>
```

That gives:



14.3.2.1 Fuzzy set

Definition (#14.3.593): Given X a set. A "fuzzy subset" A of X is defined by a belonging function f_A on X with values in the interval $[0, 1]$.

Remark

The belonging function f_A can be set arbitrarily. A practical application problem is for the engineer to define these functions (we usually use statistical data or the opinion of an expert to make the least worst choice...).

The notion of fuzzy subset encompasses that of classical subset for which f_A is the indicator function given for recall by:

Definition (#14.3.594): If A and B are two sets, such that A is included in B (i.e. $A \subset B$), we name "indicator function" of A (relatively to B), the function 1_A defined in $\{0, 1\}$, and such that:

$$\begin{aligned} 1_A(x) &= 1 \quad \text{if } x \text{ is in } A \\ 1_A(x) &= 0 \quad \text{if } x \text{ is not in } A \end{aligned} \tag{14.3.49}$$

This is for a classical set. Obviously such indicator functions are often very practical technical intermediaries!

But for fuzzy logic we have scnerio such like this:

✍**Example:**

A possible characteristic function to define the fuzzy subset A "to be twenty years" on the set X of the real positive numbers:

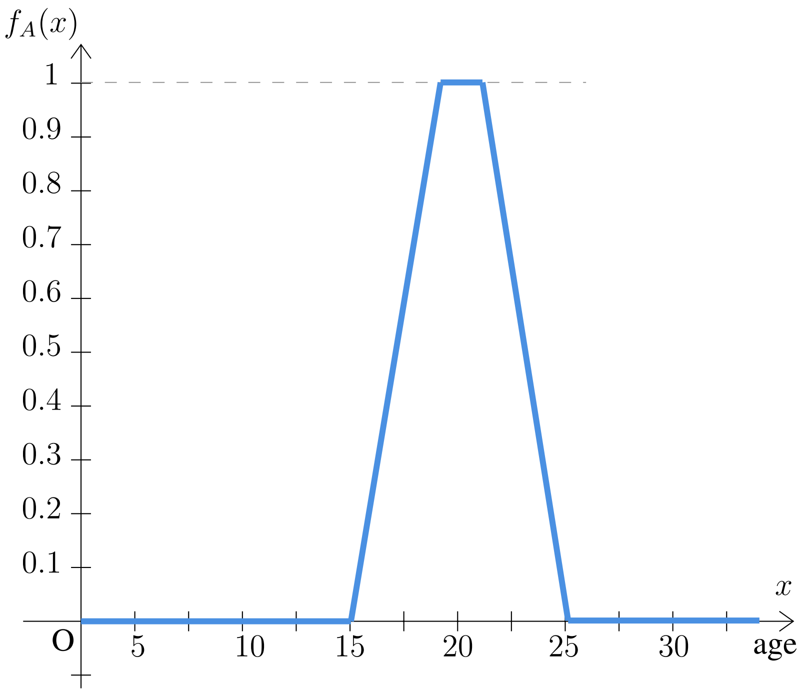


Figure 14.333: **Centered linear fuzzy function**

The following concepts are characteristic of A in the field of fuzzy sets:

Definitions (#14.3.595):

D1. Support of A:

$$\text{supp}(A)=\{x\in X, f_A(x)\neq 0\} \tag{14.3.50}$$

D2. Height of A:

$$h(A)=\sup_{x\in X} f_A(x) \tag{14.3.51}$$

D3. A is said to be normalized if $h(A)=1$

✍**Example:**

A possible characteristic function to define the fuzzy subset A "to be twenty years" on the set X of the real positive numbers:

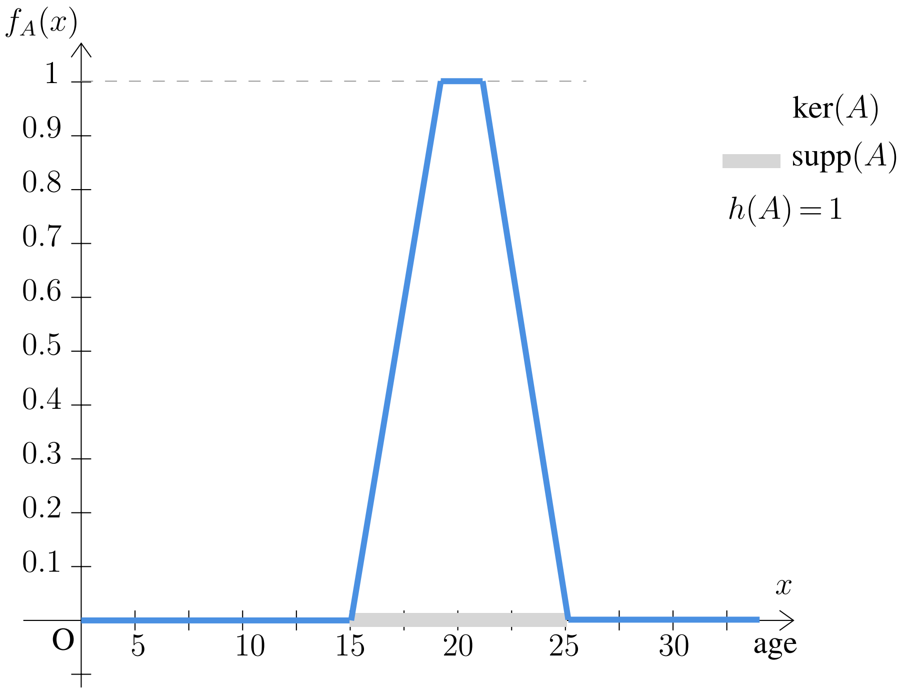

Figure 14.334: **Centered linear fuzzy function**

Remark

The fuzzy subsets considered will all be assumed normalized, in extenso of height equal to 1.

D4. The kernel of A:

$$\text{ker}(A)=\{x\in X, f_A(x)=1\} \tag{14.3.52}$$

D5. Cardinality of A:

$$\text{Card}(A)=\sum_{n\in X} f_A(x) \tag{14.3.53}$$

D6. A is "more specific" than B if:

$$\text{ker}(A)\not\subseteq\text{ker}(B) \qquad \text{and} \qquad \text{supp}(A)\subseteq\text{supp}(B) \tag{14.3.54}$$

D7. A is "more precise" than B if:

$$\text{ker}(A)=\text{ker}(B) \qquad \text{and} \qquad \text{supp}(A)\subseteq\text{supp}(B) \tag{14.3.55}$$

D8. There is equality between two fuzzy subsets if and only if:

D9. There is equality between two fuzzy subsets if and only if:

$$\forall x \in X: \quad f_A(x) = f_B(x) \tag{14.3.56}$$

D10. There is inclusion between two fuzzy subsets if and only if:

$$\forall x \in X: \quad f_A(x) \leq f_B(x) \tag{14.3.57}$$

D11. The intersection $A \cap B$ is defined by:

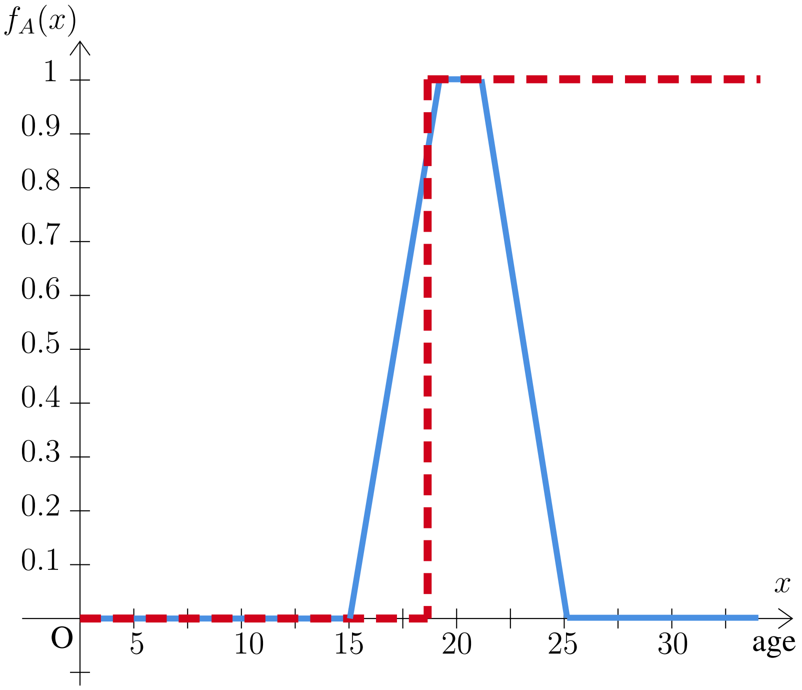
$$f_{A \cap B} : x \rightarrow \min(f_A(x), f_B(x)) \tag{14.3.58}$$

D12. The union $A \cup B$ is defined by:

$$f_{A \cup B} : x \rightarrow \max(f_A(x), f_B(x)) \tag{14.3.59}$$

✍**Example:**

Let us return to the case already envisaged. We consider the "twenty-year-old" people and those with "being in age" (i.e., those who are in age to vote/drink alcohol) (dotted in the figure: we consider it as a non-fuzzy sub-set!):



According on the definitions of the intersection ("logical AND" or logical multiplication according to the Boolean Algebra) and the union ("logical OR" or logical addition according to Boolean Algebra), we can characterize the subsets (first figure below), as well as those "being in their twenties or being in age" (second figure below):

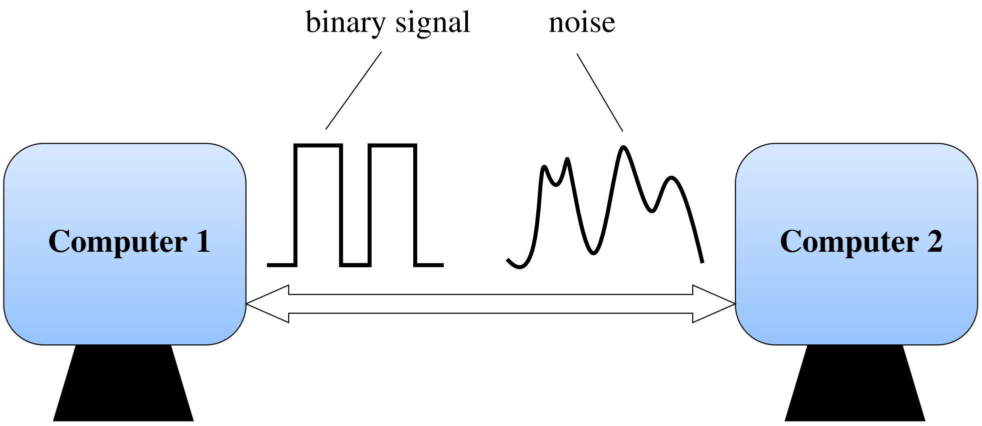
14.4. Error-Correcting Codes

If the first half of the 120th century (holocene calendar) was that of the analogue revolution by radio and television, the second half of this century is that of the digital revolution and the systematic use of algebra in the data transmission. It is also the emergence automated error handling, where an "Error" is a condition when the output information does not match with the input information. During transmission, digital signals suffer from noise that can introduce errors in the binary bits travelling from one system to other.



The "error correction codes" (ECC) are used to add redundancy to the data to make it tolerant to the transmission errors (at least to a given degree). Basically, the idea is to encode one way or another an information sequence and add encoding the original data as a control data integrity. So even if some of the information is corrupted, but not too much... redundancy will identify the incorrect parts of the message.

Remark

ECC are not only used for data transmission but also to give unique identifiers to bills in some countries and also in some factories to build a nomenclature system (naming) of pieces and to control afterwards the input of employees in computer systems! For example, bar-codes and QR-codes contains ECC.

Thus, after the appearance of audio CD in the early 11980s (holocene calendar), we must take into account the development of broadcasting satellites and new means of communication such as the fax, the Minitel, Internet or digital phone using any correcting codes errors (CCE). Even photography, radio and books are becoming digital (and will probably only be in this format in a hundred years).

Image or sound reproduction techniques are related to the transmission and to the correct reading of many digital messages, also known as "words". A message consists of words themselves made up of symbols (a particular example being the "bit" which for reminder is contraction of "BInary digiT"), taken from an alphabet. If the alphabet is binary so each symbol will be a bit.

Let us take the message 00101 formed of 5 bits each worth 0 or 1. If we send the message as is, a transmission error or of reading can take place and make the message unintelligible (or the bill/piece unique identifier). Let us decide to repeat the message three times and send it:

$$001010010100101 \tag{14.4.1}$$

If the received message contains an error, this error can be corrected. If there are two errors, the receiver is able to detect that there was a mistake but can not always recover the original message. Finally, if it occurs more than two errors during transmission, the receiver can not detect them.

We have seen just now a first example of ECC, named "repeatedly code". This code, which corrects errors and detects two, was used in some Audio CD player having three heads. The signal 0 or 1 is read independently by each of these three heads to give a word of three digits, and a reading error can be sometimes corrected.

Note that it is natural to extend a message to protect it. Let us consider the words of a language. They are usually very far from each other, two words differs according to their lengths and in the letters and syllables used. Thus it will be difficult to confound the words "library" and "cabinet" although these words are mispronounced or misheard and we will naturally reconstitute the message in a conversation even when some letters would be deleted or distorted. The military meanwhile spell some information by saying "Alpha Zulu" for "AZ" to avoid errors...

A second example widely used in computing science of error detection is the addition of a "parity bit". Let 00101 be the original message and add it a last bit obtained by adding five bits of departure modulo 2. The message is 001010 and we can therefore detect errors but can not correct it.... For this, we make the sum of all the bits to obtain 0 if there is no error, and 1 otherwise. This code named "parity code" is used everywhere: in the social security numbers where we add a key, in those of bank accounts or in bar-code of supermarkets where it is the 13th digit that is the control key (the space probe Voyager II is one of the many users of parity codes to communicate almost in a reliable way and also the 8th bit in the ASCII system which is used as a parity bit).

For many years, the DRAM sockets managed words with one bit only; it was then necessary to put the 8 memory card sockets for working with bytes (8 bits). But at this time many cards included not 8 but 9 sockets! The ninth socket was designed to store a parity bit at each start of a memory byte. When reading a byte, we checked, if between the time of writing and that of reading, parity had not been changed (due to a parasite, for example).

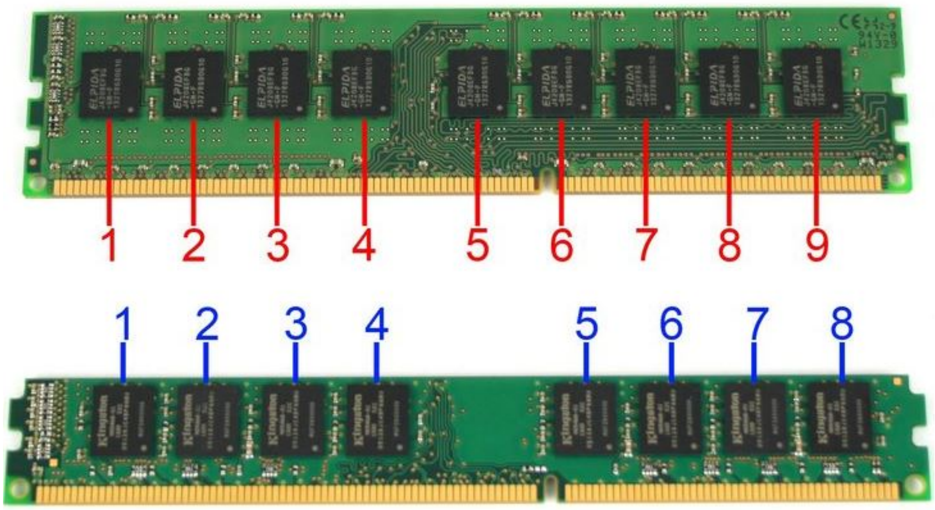


Figure 14.335: **ECC RAM vs Non-ECC RAM**

Remark

We would like to point out that ECC memory is considered server-grade. They are sold to a market which pays much closer attention to reliability than the consumer market. As a result, ECC RAM is usually subjected to much stricter testing and validation before shipping. This is a big factor in why ECC modules see much lower failure rates.

Finally, let us see a third example used on some computer servers that use in RAID4 or RAID6 parallel disks, this latter using Hamming codes that we will see later (see page 7167).

Suppose we have 3 hard drives, and the content of the first byte of each disc is the following:

$$\begin{gathered}\text{D1:11110000}\\ \text{D2:10101010}\\ \text{D3:00110011}\end{gathered}\tag{14.4.2}$$

So it is sufficient take each column and count the number p of 1 in the column. The value of the parity bit is then p modulo 2. We have for the first column in the example above p which is 2. Therefore, the parity bit is equal to 0, etc. Then we have on the control disc (CD):

$$\text{CD:011001001}\tag{14.4.3}$$

These three examples are fundamental to the basic coding theory and show that we can control the appearance of error by deliberately lengthening the message before transmission or reading. More sophisticated algebraic techniques are then used to improve the performance of coding, thanks to:

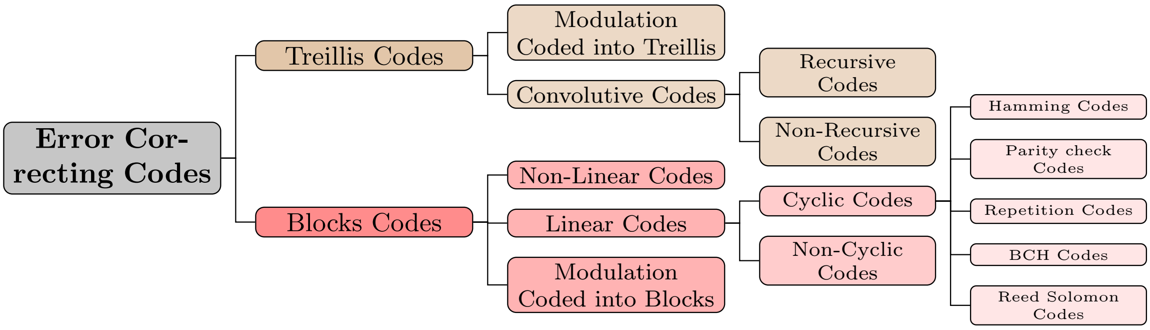
1. Know if any errors occurred (detection problems)
2. Find the initial correct message from the message received (correction of problem)
3. Correct the most possible mistakes while using the least possible additional bits (the problem of performance encoding)

From the mathematical point of view, one of the interests of coding theory is to show that algebra applies once again well in our everyday life when we listen to music, or we settle in front of our televisions, and that such abstract notions as those of vector spaces or polynomials over finite fields allow us to read messages, listen to music or watch movies in optimum conditions!

We distinguish the following two classes of ECC:

1. Block codes
2. Treillis codes

The figure below provides a simple overview of the error correcting codes family[85]. In the first class (right in the figure), we have the most popular codes such as BCH codes, Reed-Solomon and Goppa, Golay and Hamming. The second class (left in the figure) is less rich in variety but has a lot more flexibility, especially in the choice of parameters and decoding algorithms available. Let us cite for example the binary systematic recursive convolutional codes widely used in coded modulation and the parallel concatenated codes (Turbo Codes).



Error Correcting Codes
Treillis Codes
Blocks Codes
Modulation Coded into Treillis
Convolutive Codes
Recursive Codes
Non-Recursive Codes
Non-Linear Codes
Linear Codes
Modulation Coded into Blocks
Cyclic Codes
Non-Cyclic Codes
Hamming Codes
Parity check Codes
Repetition Codes
BCH Codes
Reed Solomon Codes

Figure 14.336: **Non-exhaustive orgchart of correcting codes**

Remark

To introduce the foundations of the theory of error correcting codes, we recommend strongly the reader to have read through first the section of Set Theory (see page 378), after this of Statistical Mechanics (where the information theory is at page 3525) after of Numerical Methods (see page 6272) and finally of Topology (see page 2446).

When possible we will show the reader how to put quickly in practice ECC using native MATLAB® Communication Toolbox functions.

---

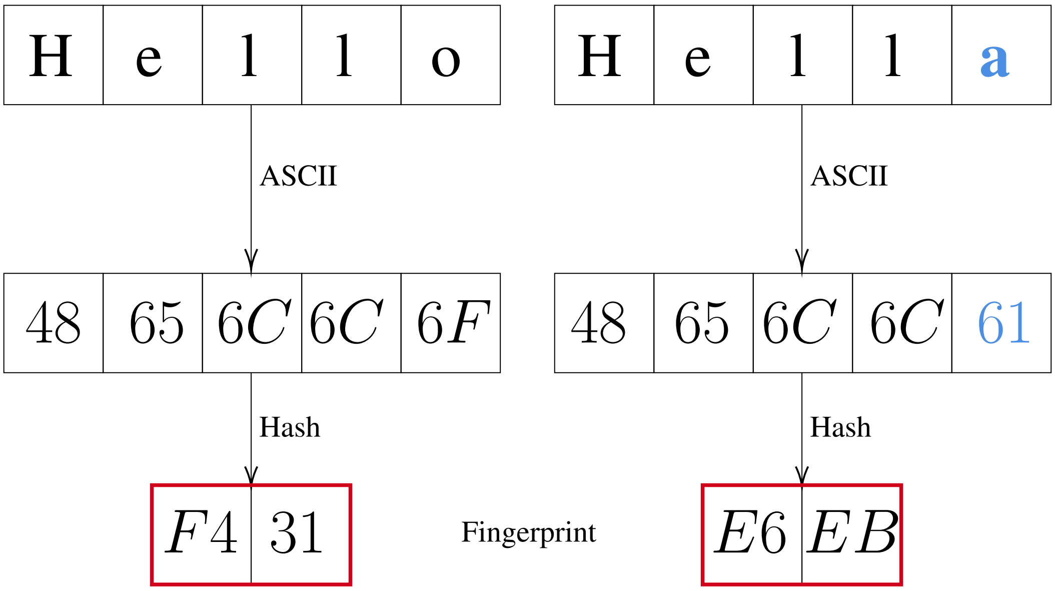
[85] For example "Quantum Error Correction" is not indicated

14.4.1 CheckSum

Before starting the part of pure mathematics, we would like to make a small introduction to the "checksum" (control sum) that is a tool frequently used in the business when exchanging files over several Giga Bytes between two computers or when downloading on the Internet.

The checksum, also sometimes named "fingerprint" is a basic concept of coding theory used for correcting codes. It corresponds to a particular case of "redundancy control code". It is widely used in computer and digital telecommunications as already said.

One basic technique (among a dozens more or less sophisticated) is to take the sum of a given length of bits (byte, word, or other ...) and calculate the modulo 255 (FF in hexadecimal). For example, if we take two words and we rely on their hexadecimal ASCII code (you can find ASCII tables almost everywhere on the internet):



$$48+65+6C+6C+6F=F4 \bmod FF$$
$$48\cdot 1+65\cdot 2+6C\cdot 3+6C\cdot 4+6F\cdot 5=31 \bmod FF$$

$$48+65+6C+6C+6F=F4 \bmod FF$$
$$48\cdot 1+65\cdot 2+6C\cdot 3+6C\cdot 4+61\cdot 5=EB \bmod FF$$

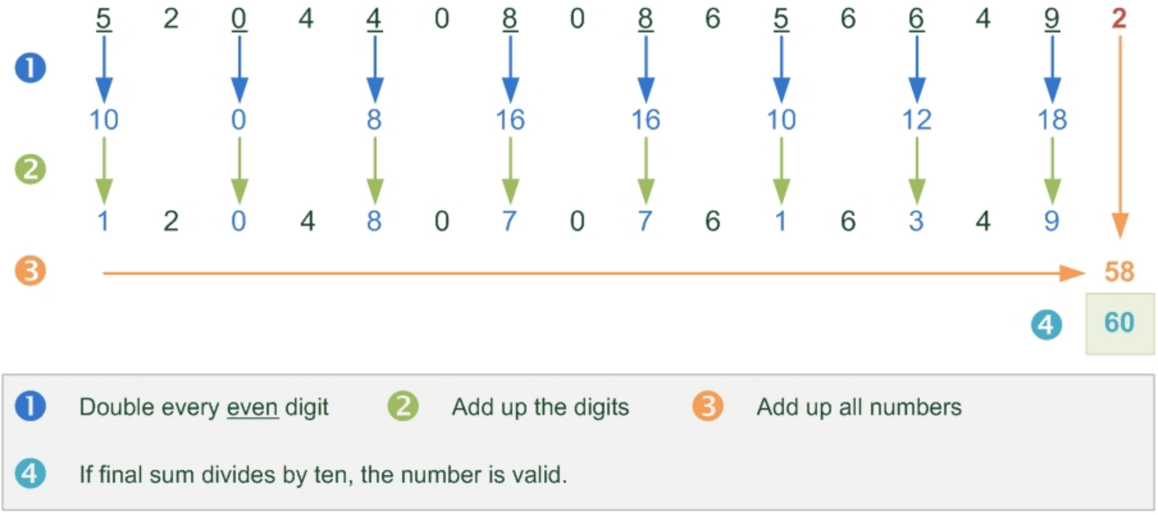
Figure 14.337: Basic Checksum principle

Some tools also use the MD5 algorithm (Message Digest 5) or SHA (Secure Hash Algorithm) to have a checksum of a message (see section Cryptography page 7249 and page 7253).

14.4.1.1 Luhn algorithm

The "Luhn algorithm" or "Luhn formula", also known as the "modulus 10" or "mod 10" algorithm, is a simple checksum formula used to validate a variety of identification numbers, such as Credit card numbers, IMEI numbers, National Provider Identifier numbers in the US, and Canadian Social Insurance Numbers (see examples further below). It was created by IBM scientist Hans Peter Luhn and described in U.S. Patent No. 2,950,048, filed on January 6, 11954 (holocene calendar), and granted on August 23, 11960 (holocene calendar).

The algorithm is in the public domain and is in wide use today. It is specified in ISO/IEC 7812-1 and is completely described in the following figure:



5 2 0 4 4 0 8 0 8 6 5 6 6 4 9 2

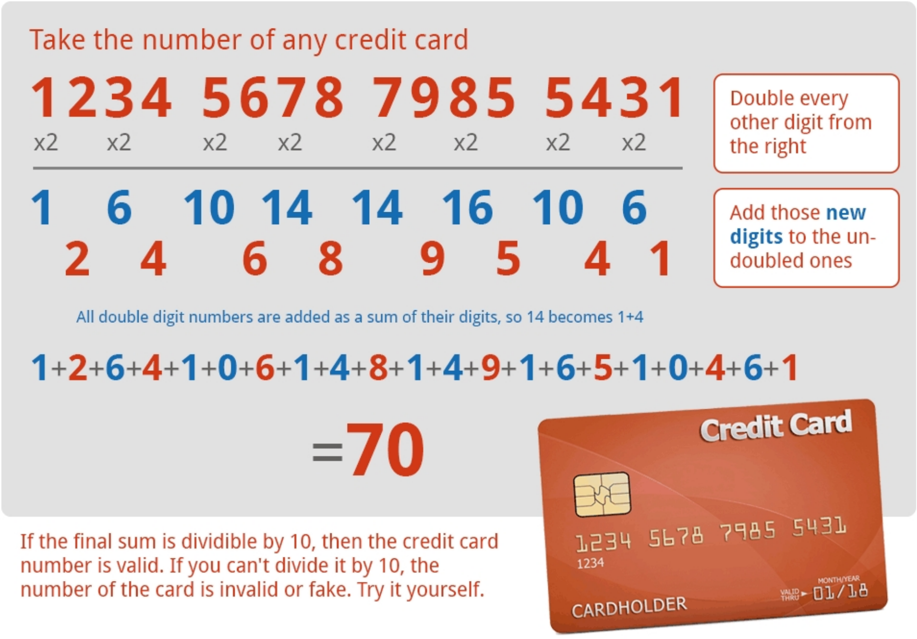
② Add up the digits
③ Add up all numbers
④ If final sum divides by ten, the number is valid.

Figure 14.338: **Luhn algorithm for checksum principle**

The Luhn algorithm will detect any single-digit error, as well as almost all transpositions of adjacent digits. It will not, however, detect transposition of the two-digit sequence 09 to 90 (or vice versa). It will detect 7 of the 10 possible twin errors (it will not detect 22 ↔ 55, 33 ↔ 66 or 44 ↔ 77).

A picture is worth a thousand words let us see how this apply to VISA cards:



1234 5678 7985 5431
x2 x2 x2 x2 x2 x2 x2 x2
1 6 10 14 14 16 10 6
2 4 6 8 9 5 4 1

=70
Credit Card
1234 5678 7985 5431
1234
CARDHOLDER
VALID THRU
MONTH/YEAR
01/18

Take the number of any credit card

Double every other digit from the right

Add those **new digits** to the un-doubled ones

All double digit numbers are added as a sum of their digits, so 14 becomes 1+4

If the final sum is dividible by 10, then the credit card number is valid. If you can't divide it by 10, the number of the card is invalid or fake. Try it yourself.

Other, more complex check-digit algorithms (such as the Verhoeff algorithm and the Damm algorithm) can detect more transcription errors.

14.4.2 Check Digit

Also before starting the part of pure mathematics, we would like to make a small introduction to some common check digits (in fact any professionally driven government or company should have all objects or individuals identifiers with at least one check digit). We will only focus on example that have been asked to me by my students or people that contacted me on the Internet (otherwise I can dedicate a whole book only for examples on check digits...)!

Definition (#14.4.596): A "check digit" is a form of redundancy check used for error detection on identification numbers, such as bank account numbers, which are used in an application where they will at least sometimes be input manually. It is analogous to a binary parity bit used to check for errors in computer-generated data. It consists of one or more digits computed by an algorithm from the other digits (or letters) in the sequence input.

14.4.2.1 European Article Numbering (EAN-13)

Let us see first the check digit of EAN-13 bar codes (Cyclic Redundancy Check[86] (CRC) ECC type):

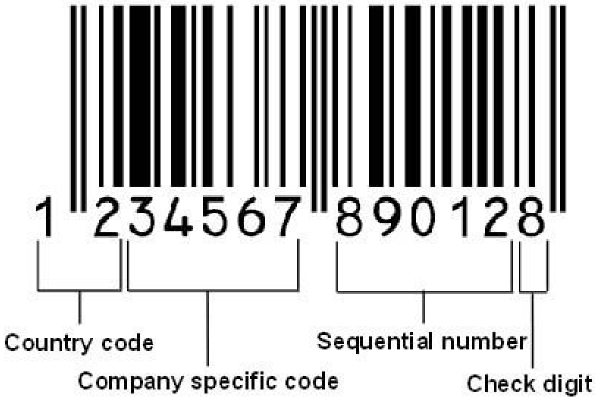

Figure 14.339: **EAN-13 bar-code example**

There are various different errors that can occur when numbers are written, printed or transferred in any manner. Different methods of assigning check digits are better at detecting certain kinds of errors than others. The most common types of errors that occur in practice and their frequencies, according to one study, are as follows:

Error type	Form	Relative frequency
Single error	a replaced by b	79.1%
Transposition of adjacent digits	ab replaced by ba	10.2%
Jump transposition	abc replaced by cba	0.8%
Twin error	aa replaced by bb	0.5%
Phonetic error	$a0$ swapped with $1a$, $a=2,\ldots,9$	0.5%
Jump twin error	aca replaced by bcb	0.3%

Table 14.55: **Various costs**

---

[86] type of checksum, specifically a position dependent checksum algorithm

Another common type of error not mentioned here is accidental insertion or deletion of characters. In the cases we will consider, the number will have a fixed length, so insertions and deletions will be automatically detected.

The EAN-13 format uses a modulus 10 scheme, with check digit (a_c) defined by:

$$a_c = -(a_1, a_2, \ldots, a_6, a_7) \cdot (3,1,3,1,3,1,3) \mod 10 \tag{14.4.4}$$

For example, if we start with the number 1234567 in the EAN-8 scheme, then our check digit is:

$$\begin{aligned} a_c &= -(1,2,3,4,5,6,7) \cdot (3,1,3,1,3,1,3) \mod 10 \\ &= -(1 \cdot 3 + 2 \cdot 1 + 3 \cdot 3 + 4 \cdot 1 + 5 \cdot 3 + 6\dot{1} + 7 \cdot 3) \mod 10 \\ &= -60 \mod 10 = 0 \end{aligned} \tag{14.4.5}$$

which makes the full bar code number 12345670.

When dealing with ECC we must worry about how effective a scheme is in detecting errors!

Let us consider only two cases:

1. Single error detection rate:

   If a digit d whose weight is 1 is changed to c, the weighted sum will change by $d-c$. The error will go undetected only if $d-c=0 \mod 10$. But this happens only when $d=c$, in which case there has not been an error after all, so all errors of this kind are caught.

   What if the weight were 3? Then the error would be undetected if $3(d-c)=0 \mod 10$. But again, this cannot happen unless $d=c$. Thus, this method has a 100% single error detection rate (SEDR).

2. Transposition of adjacent digits detection rate:

   Suppose two adjacent digits, cd, are transposed to dc. If c's weight is 3 (hence d's weight is 1), the weighted sum is changed by:

   $$(3c+d)-(c+3d)=2(c-d) \tag{14.4.6}$$

   which will be detected unless $2(c-d)=0 \mod 10$, which can happen only if c and d differ by 5. The same would have applied if c had been weighted by 1 and d by 3.

   As a result, the transpositions that will go undetected must involve $0 \leftrightarrow 5, 1 \leftrightarrow 6, 2 \leftrightarrow 7, 3 \leftrightarrow 8$ and $4 \leftrightarrow 9$. So, 10 transpositions are undetectable.

   There are 100 possibilities for each pairing, and the transposition of 90 of these would result in an error. Therefore the detection rate is $80/90 = 88.9\%$ transposition error detection rate (TEDR).

14.4.2.2 Swiss Post Payment slip

Another famous example for my country is the Swiss Post payment slip where numerous numbers have a check digit.

Here is a sample preview of such a payment slip:

Figure 14.341: Swiss payment slip check digit for Reference Number

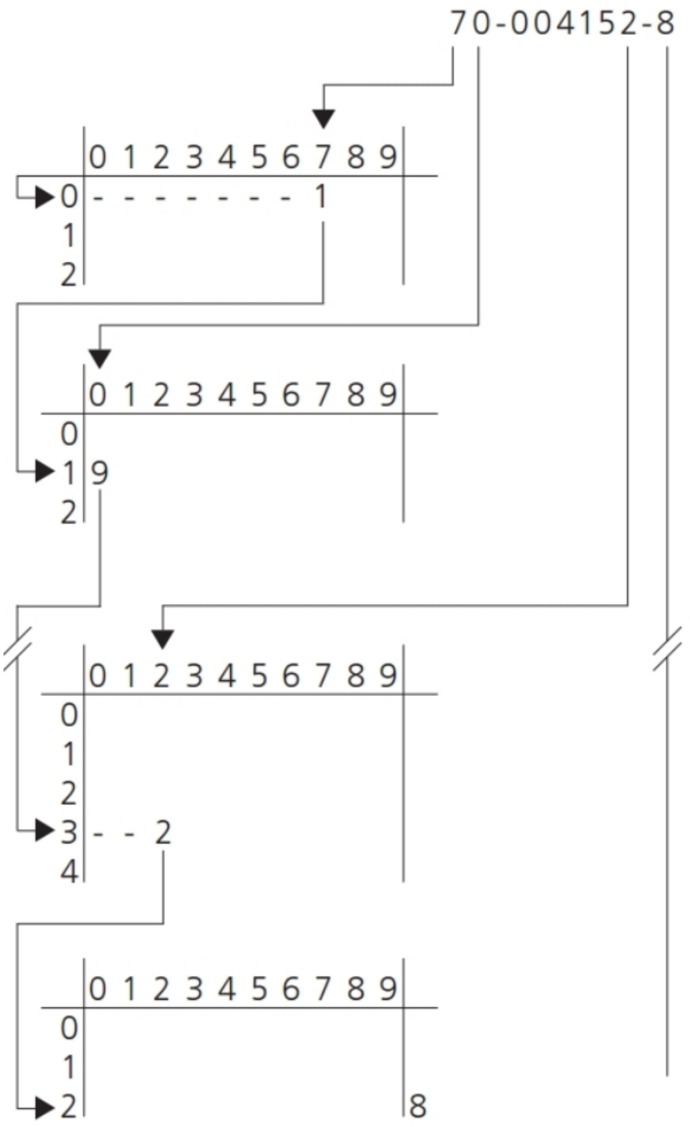
All the digit check in this Swiss payment slip are based on a recursive modulo 10 computation.

Let us give a small example on how to calculate the check digit based on the Swiss method. For this let us consider first the following matrix:

Remainder	Digit in the number										Check Digit
	0	1	2	3	4	5	6	7	8	9	
0	0	9	4	6	8	2	7	1	3	5	0
1	9	4	6	8	2	7	1	3	5	0	9
2	4	6	8	2	7	1	3	5	0	9	8
3	6	8	2	7	1	3	5	0	9	4	7
4	8	2	7	1	3	5	0	9	4	6	6
5	2	7	1	3	5	0	9	4	6	8	5
6	7	1	3	5	0	9	4	6	8	2	4
7	1	3	5	0	9	4	6	8	2	7	3
8	3	5	0	9	4	6	8	2	7	1	2
9	5	0	9	4	6	8	2	7	1	3	1

So what would be the check digit of the number 70004152 (it's a typical 8 digit Swiss Post account)?

The process to determine that latter is simply the following:



Règles

- Begin by the remainder "0" → combine it with the first digit of the example: "7". The cross value in the matrix to take as new remainder is "1"
- Combine the previous remainder "1" with the second digit of the example "0" to get the new matrix row and column an we get as new remainder "9"
- etc.
- Combine the previous remainder "3" with the last digit of the example "2" to get the new matrix row and column an we get as final remainder "2"
- The digit in the last column at the row number corresponding to last remainder "2" is the check digit in this case given by the value "8"

14.4.2.3 International Bank Account Number (IBAN)

The International Bank Account Number (IBAN) is an internationally agreed system of identifying bank accounts across national borders to facilitate the communication and processing of cross border transactions with a reduced risk of transcription errors. It was originally adopted by the European Committee for Banking Standards (ECBS), and later as an international standard under ISO 13616.

The IBAN consists of up to 34 alphanumeric characters comprising: a country code; two check digits; and a number that includes the domestic bank account number, branch identifier, and potential routing information. The check digits enable a sanity check of the bank account number to confirm its integrity before submitting a transaction.

Before IBAN errors of transcription were not detectable and it was not possible for a sending bank to validate the routing information prior to submitting the payment. Routing errors caused delayed payments and incurred extra costs to the sending and receiving banks and often to intermediate routing banks.

The IBAN should not contain spaces when transmitted electronically. When printed it is expressed in groups of four characters separated by a single space, the last group being of variable length. Here is an example of how typically Switzerland write IBAN numbers:

```
CH93 0076 2011 6238 5295 7
```

Permitted IBAN characters are the digits 0 to 9 and the 26 upper-case Latin alphabetic characters A to Z. This applies even in countries (e.g., Thailand) where these characters are not used in the national language.

An IBAN is validated by converting it into an integer and performing a basic modulo 97 operation (as described in ISO 7064: *Security techniques - Check character systems*) on it. If the IBAN is valid, the remainder equals 1.

The procedure is a follows:

- Check that the total IBAN length is correct as per the country. If not, the IBAN is invalid;
- Move the four initial characters to the end of the string;
- Replace each letter in the string with two digits, thereby expanding the string, where A $=10$, B $=11$, ..., Z $=35$;
- Interpret the string as a decimal integer and compute the remainder of that number on division by 97.

If the remainder is 1, the check digit test is passed and the IBAN might be valid.

✍**Example:**

Given a fictitious United Kingdom bank, sort code `12-34-56`, account number `98765432`. For the sanity check we follow the above procedure:

- The IBAN is therefore:

  `GB82 WEST12345698765432`

- We rearrange:

  `WEST12345698765432GB82`

- We convert to integer:

  `3214282912345698765432161182`

- We compute the modulo 97:

$$\texttt{3214282912345698765432161182} \mod 97 = 1$$

14.4.2.4 UIC wagon numbers

Wagon numbers (or coach numbers) are key data for railway operations. They enable a railway wagon or coach to be positively identified and form a common language between railway operators, infrastructure companies and the state authorities. The system of wagon numbering has been laid down by the International Union of Railways (Union Internationale des Chemins de fer or UIC) and is similar to that used for the locomotives and multiple units.

argo
CFF FFS Cargo
Eem 97 85 1 923 002-0 CH-SBB C
45 t N
100 km/h

(b) Swiss UIC wagon number

The complete wagon number comprises 12 digits. The individual digits have the following meaning:

- Digit 1-2: Type of vehicle and indication of the interoperability capacity
- Digit 3-4: Country Code (Switzerland (CH) = 85)
- Digit 5-8: Vehicle type information
- Digit 9-11: Individual running number (serial number)
- Digit 12: Self-check digit

The digits are multiplied individually from right to left alternately by 2 and 1, and digit summed. The difference between this sum and the next multiple of ten is the check digit, placed after the eleventh digit, separated by a dash.

✍**Example:**

Given a fictitious Wagon UIC `21-81-24 7121 7`. For the sanity check we follow the above procedure:

- The UIC is therefore:

  `2 1 8 1 2 4 7 1 2 1 7`

- We multiply:

  $$2\cdot 2 \quad 1\cdot 1 \quad 8\cdot 2 \quad 1\cdot 1 \quad 2\cdot 2 \quad 4\cdot 1 \quad 7\cdot 2 \quad 1\cdot 1 \quad 2\cdot 2 \quad 1\cdot 1 \quad 7\cdot 2$$

  It gives:

  $$4\;1\;16\;1\;4\;4\;14\;1\;4\;1\;14$$

- We sum up the digits using:

  $$4+1+1+6+1+4+4+1+4+1+4+1+1+4=37$$

- We take the next multiple of 10 that 40 so the check digit is equal to three 3.
- Finally we get:

  `21-81-24 7121 7-3`

Remark

The swiss "Unternehmens-Identifikationsnummer" (company identification number) also has a check digit and so on...

14.4.3 Permutations

Also before starting the part of pure mathematics, we would make a small introduction to the check digit using permutations in VISA card numbers.

Credit cards use an error-detecting scheme that was developed by IBM. It uses the permutation:

$$\sigma=(0)(124875)(36)(9) \tag{14.4.7}$$

In other words (for more details see the section of Set Algebra page 1417) $\sigma(0)=0$, $\sigma(1)=2$, $\sigma(2)=4$, etc.

Notice also that:

$$\sigma(x)=2x \mod 9 \tag{14.4.8}$$

In a 16 digit credit card number, the final digit is the check digit. Let the credit card number be $(a_1,a_2,\ldots,a_{15},a_{16})$, with a_{16} being the check digit. Then:

$$a_{16}=-[\sigma(a_1)+a_2+\sigma(a_3)+a_4+\ldots+a_{14}+\sigma(a_{15})] \mod 10 \tag{14.4.9}$$

Note that in this example the permutation was applied to a_i where i is odd (a_1, a_3, etc), because there is an odd number of digits excluding the check digit. Had this scheme been used on a number with an even number of digits excluding the check digit, the permutation would have been applied to a_i where i was even.

As we know form the previous example, dealing we ECC must worry about how effective a scheme is in detecting errors!

Let us consider again only two cases:

1. Single error detection rate:

   This scheme catch all single-digit errors (100% SEDR). Indeed, for example if digit a_i is changed from c to d, and i is even, the remainder will change by $c-d$, which is non-zero (and is, of course, smaller than the modulus $N=10$). If i is odd, it will change by $\sigma(c)-\sigma(d)$. This is again non-zero: $\sigma(c)$ cannot be equal to $\sigma(d)$ if σ is a permutation.

2. Transposition of adjacent digits detection rate:

   If two adjacent digits c and d are transposed, one of them must have the permutation applied - say c. The remainder will be unchanged only if $\sigma(c)+d=\sigma(d)+c$. Since $\sigma(x)=2x \mod 9$, this happens only when $c=d \mod 9$, that is, only when c and d are 0 and 9 (in either order).

   Therefore, for each pair of adjacent digits, of the 90 possible transposition errors, two will be undetectable. So the detection rate for transpositions is $88/90=97.8\%$ (TEDR).

14.4.4 Encoders

Given Q a finite set of q elements (bits, alphabets). Given k and n two non-zero integers with $k \leq n$. The set of messages will be a part E of Q^k and we introduce a bijective application (at least that is the goal!):

$$\begin{gathered} f : E^k \leftrightarrow Q^n \\ a = (a_1, a_2, \ldots, a_k) \leftrightarrow c = (c1, c_2, \ldots, c_n) \end{gathered} \tag{14.4.10}$$

named "encoding application" or "encoder". The message or word is an element of E that is to say Q^k. It is modified to provide the word:

$$f(a) = c \in Q^n \tag{14.4.11}$$

It is the word c that will be transmitted and read by any system to give a message received $x = (x_1, \ldots, x_n)$ possibly flawed.

Let us now denote $C = f(E)$ the image of f. Since f is subjective by definition it is also injective, f realized a bijection of E on C and C can be considered as the set of all possible error coding messages. C is named the "code of length n", and the elements of C are named the "words" of the code. The cardinal of the code is by definition that of C that is to say Card(C). To measure the degree of difference between two words x and y of Q^n, we use the "Hamming distance" d_H defined by:

$$\boxed{\forall x, y \in Q^n : \quad d_H(x, y) = \text{Card}\,\{i \in \mathbb{N} | x_i \neq y_i\}} \tag{14.4.12}$$

For binary strings, the Hamming distance is equal to the number of ones in XOR (exclusive OR) operation on the strings.

Theorem 14.28. On any set Q, we therefore define the application $d : Q^n \times Q^n \rightarrow \mathbb{R}$ by:

$$d_H(x, y) = \text{Card}\,\{i \in \mathbb{N} | x_i \neq y_i\} \tag{14.4.13}$$

If we denote by δ_x the characteristic function of x:

$$\delta_x(y) = \begin{cases} 1 & x \neq y \\ 0 & \text{otherwise} \end{cases} \tag{14.4.14}$$

then:

$$d_H(x, y) = \sum_{i=1}^{n} (1 - \delta_{x_i}(y_i)) \tag{14.4.15}$$

is a distance.

Let us now prove that following the topological axioms of a distance (see section Topology page 2450) that this is really a distance:

Proof 14.28.1. Ok let us prove the five axioms of a distance:

1. We will suppose that for the reader:

   $$\forall x,y\in Q^n:\quad d(x,y)\geq 0 \tag{14.4.16}$$

   is obvious (if not send us a request).

2. We will also suppose that:

   $$\forall x,y\in Q^n:\quad d_H(x,y)=d_H(y,x) \tag{14.4.17}$$

   is obvious (if not send us a request).

3. We will also suppose that:

   $$\forall x\in Q^n:\quad d_H(x,x)=0 \tag{14.4.18}$$

   is obvious (if not send us a request).

4. We will also suppose that:

   $$\forall x,y\in Q^n:\quad d_H(x,y)=0\Rightarrow x=y \tag{14.4.19}$$

   where $d_H(x,y)=0$ mean that $x_i=y_i$ for $i=1\dots n$ and therefore that $x=y$.

5. Finally:

   $$\forall x,y\in Q^n:\quad d_H(x,z)\leq d_H(x,y)+d_H(y,z) \tag{14.4.20}$$

   Indeed:

   $$d_H(x,z)=\sum_{i=1}^{n}(1-\delta_{x_i}(z_i)) \tag{14.4.21}$$

   but as:

   $$(1-\delta_{x_i}(z_i))\leq(1-\delta_{x_i}(y_i))+(1-\delta_{y_i}(z_i)) \tag{14.4.22}$$

   as $(1-\delta_{x_i}(z_i))$ is equal to 1 if $x_i\neq z_i$ and 0 otherwise, then:

   $$d_H(x,z)=\sum_{i=1}^{n}(1-\delta_{x_i}(z_i))\leq\sum_{i=1}^{n}(1-\delta_{x_i}(y_i))+(1-\delta_{y_i}(z_i))=d_H(x,y)+d_H(y,z) \tag{14.4.23}$$

■ Q.E.D.

✍**Example:**

The Hamming distance between the word "**ramer**" and "**cases**" or between "**0100**" and "**1001**" is equal to 3.

Caution!!! Vectors will be denoted without the arrow in respect for tradition for this study field.

The Hamming distance d_H is therefore indeed a metric (see section Topology page 2447) as we just proved above and then we name "Hamming space" on Q the set Q^n equipped with the metric d_H.

Definition (#14.4.597): If Q is a group, the "Hamming weight" $w_H(x)$ of a word $x \in Q^n$ is the number of non-zero components:

$$w_H(x) = d_H(x,0) \tag{14.4.24}$$

where 0 is the word (vector) of Q^n with all its components equal to the neutral element of Q. Furthermore, we have the following trivial property:

$$d_H(x,y) = d_H(x-y,0) = w(x-y) \tag{14.4.25}$$

Remark

When $Q = \{0,1\}$ we will talk about "binary code" (we will see soon later an another form of writing for this binary set) of dimension n equal to 2.

The "minimum distance" of the code C is the minimum distance between two distinct words of this code. We denote that integer by $d(C)$ or simply d and therefore:

$$d(C) = d = \min\{d_H(x,y) | x,y \in C \text{ and } x \neq y\} \tag{14.4.26}$$

or using the property of Hamming weight $d_H(x,y) = w(x-y) = w(x)$:

$$d(C) = d = \min\{w(z) | z \in C^*\} \tag{14.4.27}$$

✍**Example:**

Let us consider the following redundant code denoted $(5,4)$ for 4 coded words of length 5:

Original Word	Coded Word	Weight	Code Identifier
00	**00**000	0	C_1
01	**01**110	3	C_2
10	**10**011	3	C_3
11	**11**101	4	C_4

The Hamming distance of each of the pairs of code are:

$$\begin{aligned} d(C_1,C_2)&=3 \qquad & d(C_2,C_3)&=4\\ d(C_1,C_3)&=3 & d(C_2,C_4)&=3\\ d(C_1,C_4)&=4 & d(C_3,C_4)&=3 \end{aligned} \tag{14.4.28}$$

The smallest non-zero minimum weight is therefore 3 and the smallest Hamming distance is 3.

Definitions (#14.4.598):

D1. A code C of length n, of cardinal M and of minimum distance d is named a "(n, M, d) code". The numbers n, M, d are the "code parameters". Thus, the code $(7, 4, 3)$ is a code of length seven, that is to say that the receiver receives seven bits, of length four, that is to say that once decoded, the message contains four symbols (letters) and the minimum distance between each codeword is three.

D2. We name "minimum weight" of a C code the integer:

$$\min\{w_H(x)|x\in C, x\neq 0\} \tag{14.4.29}$$

The parameter d plays an important role because it is closely related to the number of errors that can be corrected. Suppose that the encoded message is $c=(c_1,\ldots,c_n)$ and that there were at least e errors of transmission or reading. The resulting message obtained $x=(x_1,\ldots,x_n)$ satisfies $d(x, c)\leq e$. We can fall back on c from x if, and only if, there exists a single code word located at a distance of x less than or equal to e (i.e. the center-to-center distance between two balls is equal to $2e$). In other words, it is necessary and sufficient that the closed balls of radius e and centered on the elements of the code C are disjoint. A code will correct e errors if this condition is true.

Therefore, a code C of minimum distance d corrects at most:

$$e=\left[\frac{d-1}{2}\right] \tag{14.4.30}$$

where [] represents the integer part of a real number.

Indeed, if a message of the code is at $d/2$ we will not be able to know to which message of the code (center of ball) it belongs since being (in a pictorial way) at the tangent of two balls. This is the reason why we will take $\dfrac{d-1}{2}$ which is then the "safe distance" to correct as much as possible an erroneous message of the code. Moreover, since the number of errors is an integer, it comes the previous notation with the square brackets.

It is clear that the code can detect at most $d-1$ errors. Indeed, however how to distinguish an incorrect code from a correct code (code = coded message)? Apart from the fact that each element of the code is different (injective application of the set of messages in the set of encoded messages), it is also necessary to be able to differentiate among them those which are erroneous codes from those which do not Are not. Hence the $d-1$!!!

✍**Example:**

Let us consider the following redundant code denoted $(5,4)$ for 4 coded words of length 5 whose minimal distance was therefore $d=3$:

Original Word	Coded Word	Weight	Code Identifier
00	**00**000	0	C_1
01	**01**110	3	C_2
10	**10**011	3	C_3
11	**11**101	4	C_4

This code therefore allows and make it possible to detect at most:

$$d=3-1=2 \tag{14.4.31}$$

errors and to correct at most:

$$e=\left[\frac{d-1}{2}\right]=\left[\frac{3-1}{2}\right]=\left[\frac{2}{2}\right]=1 \tag{14.4.32}$$

of them.

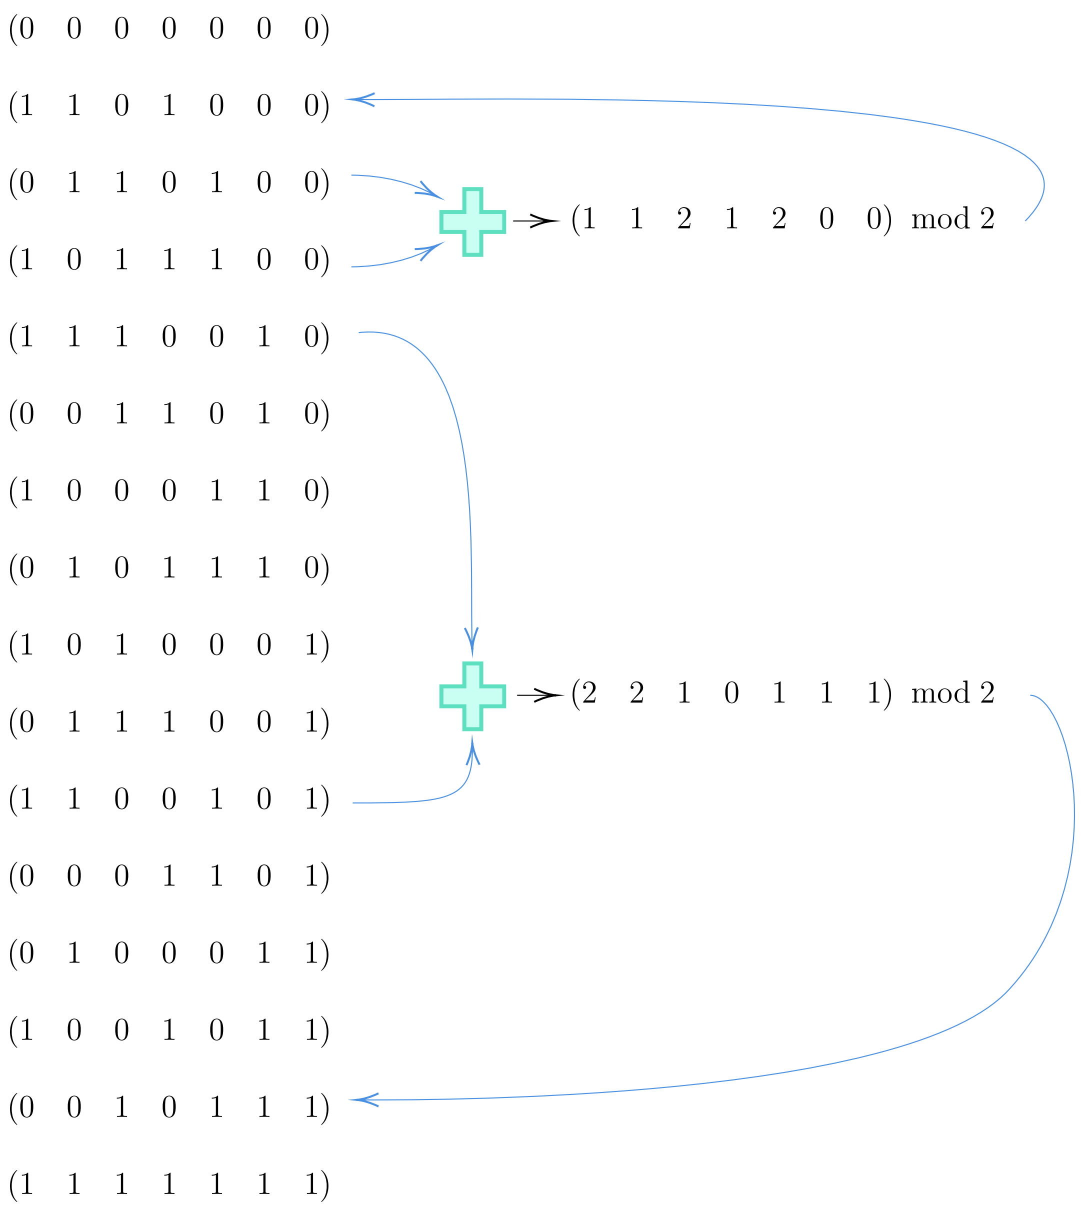
14.4.4.1 Block code

In coding theory, a block code is any member of the large and important family of error-correcting codes that encode data in blocks. There is a vast number of examples for block codes, many of which have a wide range of practical applications. Block codes are conceptually useful because they allow coding theorists, mathematicians, and computer scientists to study the limitations of all block codes in a unified way. Such limitations often take the form of bounds that relate different parameters of the block code to each other, such as its rate and its ability to detect and correct errors.

Definition (#14.4.599): A "block code" of size M and length n defined on an alphabet of q symbols (1 and 0 for the binary language for example) is a set of M vectors named the "code words". The idea is that each information word composed of k symbols is associated with a single codeword composed of n symbols. The vectors are therefore of length $n\geq k$ and their components are q-ary (thus "2-ary" in the case of the binary language).

Examples of block codes are Reed–Solomon codes, Hamming codes, Hadamard codes, Expander codes, Golay codes, and Reed–Muller codes. These examples also belong to the class of linear codes, and hence they are named "linear block codes". More particularly, these codes are known as algebraic block codes, or cyclic block codes, because they can be generated using boolean polynomials.

Definition (#14.4.600): A "linear coding" means a set of code in which any linear combination (modular 2 sum most of time) of two codes within the set results in a code which also belong to the original set. Let's assume that you have a set of codes as in the figure below:



(0 0 0 0 0 0 0)
(1 1 0 1 0 0 0)
(0 1 1 0 1 0 0)
(1 0 1 1 1 0 0)
(1 1 2 1 2 0 0) mod 2
(1 1 1 0 0 1 0)
(0 0 1 1 0 1 0)
(1 0 0 0 1 1 0)
(0 1 0 1 1 1 0)
(1 0 1 0 0 0 1)
(0 1 1 1 0 0 1)
(2 2 1 0 1 1 1) mod 2
(1 1 0 0 1 0 1)
(0 0 0 1 1 0 1)
(0 1 0 0 0 1 1)
(1 0 0 1 0 1 1)
(0 0 1 0 1 1 1)
(1 1 1 1 1 1 1)

Figure 14.343: **Principle of a Linear code**

Take out any two codes from the set and take modular 2 sum of them. The result is also a member of the set as shown below. Take any other two codes and try yourself.

Remark

The linearity of the block codes also mean that the n symbols of the code word are obtained by a linear combination of the k symbols of the information word.

Let us see an example!

✍**Example:**

Let us start from the following M vectors based on $q=3$ binary symbols (hence $k=2$). In this case, we have $M=q^k$:

Vectors
000
100
010
110
001
101
011
111

We then choose n as equal to 6 and we define a bijective mapping such that:

Vectors	**Code Vectors**
000	000**000**
100	110**100**
010	011**010**
110	101**110**
001	101**001**
101	011**101**
011	110**011**
111	000**111**

As shows this example, of the particular block code conventionally denoted $(n,k)_q=(6,3)_2$, the code has no particular structure. The decoding operation involves making an exhaustive comparison of the word received at the output of the channel with all the code modes before determining the most likely code word. This simple and stupid approach explains why many times this error correcting code is faster than many others...

Thus, according to the above definition, a block code C is the result of a injective application which associates with each vector formed by k q-ary symbols (k information symbols), an image vector of length n with components in the same alphabet (n encoded symbols):

The encoding adds to the initial information $n-k$ additional symbols. The quantity:

$$R=\frac{k}{n} \tag{14.4.33}$$

is named the "rate of C", or "coding rate". The block encoding operation is "without memory", in extenso the blocks are coded independently without any correlation between two consecutive blocks.

Now it is convenient to come back a little bit on Boole's Algebras (see section Logical Systems page 7105). To the 5 axioms which define a Boolean Algebra let us add a sixth one which gives it a structure of a field:

A6. The Boolean Algebra (extension of a unitary ring by an axiom) with the law $*$ (or $\wedge$) is a field.

Remark

Let us recall that a field is a non-zero ring in which every non-zero element is invertible.

If we take the Boolean Algebra formed by the $q=2$ elementary elements $\{0,1\}$ forming a binary set (alphabet), we actually have 1 which is invertible since there exists x such that:

$$1*x=1 \tag{14.4.34}$$

which is 1 itself!

This field is denoted $\mathbb{F}_q=\mathbb{F}_2$. In the area of error correcting codes, we often work in $\mathbb{F}_2$ (single field with two elements) where for recall the addition is defined by:

$$0+0=0 \qquad 1+1=0\,(\text{therefore } 1=-1) \qquad 1+0=1 \tag{14.4.35}$$

The multiplication being defined by:

$$1\cdot 1=1 \qquad 1\cdot 0=0 \qquad 0\cdot 0=0 \tag{14.4.36}$$

$$C:\mathcal{A}^k \mapsto \mathcal{A}^n \tag{14.4.37}$$

To return to our theory of codes: the set of messages $E=\mathbb{F}_q^k$ can be equipped with a vector space structure of dimension k on $\mathbb{F}_q$ (see section Set Theory page 1805). Indeed, it suffices for this that $(E,+)$ to an Abelian group and $*$ an external law defined by $\mathbb{F}_q^k\times\mathbb{F}_q\mapsto\mathbb{F}_q^k$. If we decide to use only encoders that are linear (applications), the code $C=f(\mathbb{F}_q^k)$ becomes a vector subspace of $\mathbb{F}_q^n$ (because even if the application is bijective, since the body of the coded messages is finite, we necessarily have vector subspace of the vector space of all possible encoded messages).

Definition (#14.4.601): A "linear code" of dimension k and length n is a vector subspace of dimension k of $\mathbb{F}_q^n$ (it is the way this is said..). If the minimum distance of C is d, we say that C is a "$[n,k,d]_q$ code" or more simply "code $[n,k]$".

Remark

Linear codes are therefore a special case of block codes as shown in the hierarchical scheme at the beginning of this section.

The addition of the linearity constraint could undermine the quality of the code sought, but fortunately the performance study shows that the linear codes are very close to the best Block codes. Thus, linearity facilitates the study of block codes and allows the use of very powerful algebraic tools without reducing the class of linear blocks to an inefficient class.

Let us denote by G the matrix of the linear application $f:\mathbb{F}_q^k\mapsto\mathbb{F}_q^n$. G is a matrix of obviously dimension $n\times k$ type and every word c of C is obtained from every word x of E by:

$$c=f(x)=Gx \tag{14.4.38}$$

where $c=(c_1,\ldots,c_n)\in\mathbb{F}_q^n$ and $x=(x_1,\ldots,x_k)\in\mathbb{F}_q^k$ are line vectors with always $n\geq k$. Thus $f(\mathbb{F}_q^k)=C$.

Remark

The bases of $\mathbb{F}_2^k$, $\mathbb{F}_2^n$ are the common canonical bases (those we have often used in the section of Vector Calculus).

Definition (#14.4.602): Let C be a linear code $[n,k]$ and given $\{g_1,g_2,\ldots,g_k\}$ the basis of C. A "generating matrix" G of C is therefore a matrix $n\times k$ whose columns are formed by the vectors g_i of the basis (see the example further below).

Given $u=(u_1,\ldots,u_k)$ the information word, in extenso the vector containing the k information symbols. Then we can write the matrix relation linking the code word c and the information word u by:

$$c=Gu \tag{14.4.39}$$

Definition (#14.4.603): Let C be a block code $[n,k]$. This code is named "systematic code", if the set of code words contains the k unmodified symbols of the original information (we will return on this type of code further below). The remaining $n-k$ symbols are named "parity symbols".

Remark

The "Hamming Code" is such a code! In addition, systematic codes are special cases of block codes and we will return to their study further below.

Definition (#14.4.604): Let H be an $(n-k)\times n$ matrix with elements in $\mathbb{F}_q$, which satisfies $Hc=0$ for every word c of a linear code C (in other words: whose kernel is C). Then, H is named the "control matrix" of the code C. Conversely, c belongs to the code if and only if $Hc=0$. Otherwise there is a mistake!

Remark

It is easy to find H because it is "orthogonal" to G since the above definition implies:

$$Hc=H(Gu)=(GH)u=0\Leftrightarrow GH=0 \tag{14.4.40}$$

of course we must not take $H=0$ in practice...

Let's see a companion example of all this with the Hamming code which is a systematic block code (caution!! it seem that there exist several definitions of a "Hamming code!"):

This method consists of doubling the information, sending as many parity bits as data bits. A first matrix for this purpose is:

$$G=\begin{bmatrix}1&0&0&0\\0&1&0&0\\0&0&1&0\\0&0&0&1\\1&1&0&0\\0&0&1&1\\1&0&1&0\\0&1&0&1\end{bmatrix} \tag{14.4.41}$$

The coding matrix G above is of dimension $n\times k$, where n is the number of bits received per packet, and k is the number of bits per message containing the information (here $n=8$ and $k=4$). It automatically generates the parity bits specific to a message. For example, in order to send the message 1101, in order to respect the matrix multiplication rule, consider this quartet as a column vector:

$$u=\begin{pmatrix}1\\1\\0\\1\end{pmatrix} \tag{14.4.42}$$

So by multiplying, we get:

$$c=Gu=\begin{bmatrix}1&0&0&0\\0&1&0&0\\0&0&1&0\\0&0&0&1\\1&1&0&0\\0&0&1&1\\1&0&1&0\\0&1&0&1\end{bmatrix}\begin{pmatrix}1\\1\\0\\1\end{pmatrix}=\begin{pmatrix}1\\1\\0\\1\\0\\1\\1\\0\end{pmatrix} \tag{14.4.43}$$

We will therefore send a byte 11010110, whose the first four bits form the message u and the last four bits the parity bits, which are used to check the veracity / integrity of the message.

The corresponding control matrix H is:

$$H=\begin{bmatrix}1&1&0&0&1&0&0&0\\0&0&1&1&0&1&0&0\\1&0&1&0&0&0&1&0\\0&1&0&1&0&0&0&1\end{bmatrix} \tag{14.4.44}$$

Thus, when the receiver receives the byte 11000110 instead of 11010110, the decoding gives as "syndrome":

$$s=Hc=\begin{bmatrix}1&1&0&0&1&0&0&0\\0&0&1&1&0&1&0&0\\1&0&1&0&0&0&1&0\\0&1&0&1&0&0&0&1\end{bmatrix}\begin{pmatrix}1\\1\\0\\1\\0\\1\\1\\0\end{pmatrix}=\begin{pmatrix}0\\1\\0\\1\end{pmatrix} \tag{14.4.45}$$

The resulting column vector is therefore not zero. So there is an error! With the control matrix, the theory (see proof below) makes it possible to assert that as the vector obtained is the same as that which is in fourth position in the decoding matrix, the error is due to the fourth bit. As we are in base 2, it is enough to change the 0 into a 1. This coding of the information is expensive, because it occupies twice as much bandwidth. However this is one of the most effective ways to secure information.

Theorem 14.29. The syndrome s of a Hamming code corresponds to one of the column of the control matrix H.

Proof 14.29.1. To show that the syndrome of a Hamming code corresponds to one of the columns of the control matrix, we denote by e_i the vectors-columns of the canonical basis on $\mathbb{F}_2^n$, $e_i=(0,\ldots,1,0,1,\ldots,0)$ with 1 in the i-th place. Given c a code word. We thus have by the definition of H: $Hc=0$. Let us suppose that the received word, which we will denote by $\tilde{c}$, is tainted by a single error and that this error is on the j-th bit. Therefore we have:

$$c+\tilde{c}=e_j \tag{14.4.46}$$

and:

$$He_j=H(c+\tilde{c})=Hc+H\tilde{c}=H\tilde{c} \tag{14.4.47}$$

Therefore it comes that:

$$He_j=H\tilde{c} \tag{14.4.48}$$

but He_j is the j-th column vector of the matrix H.

This shows us that when we $\tilde{c}$ and we compute $H\tilde{c}$ we get the column vector of the matrix H located exactly at the location of the error (in this case j).

■ Q.E.D.

Remark

A null syndrome does not mean the absence of error(s). There are therefore undetectable error configurations!!!

Let us now write:

$$A=\begin{bmatrix}1&1&0&0\\0&0&1&1\\1&0&1&0\\0&1&0&1\end{bmatrix} \qquad \text{and} \qquad \mathbb{1}_4=\begin{bmatrix}1&0&0&0\\0&1&0&0\\0&0&1&0\\0&0&0&1\end{bmatrix} \tag{14.4.49}$$

Then we will notice that the matrices G and H of our companion example above are formed by the blocks $\mathbb{1}_4$ and A in the following way:

$$G=(\mathbb{1}_4|A)=(\mathbb{1}_4|A) \tag{14.4.50}$$

named the "(canonical) generator matrix of a linear (n,k) code", and:

$$H=(A \quad \mathbb{1}_k)=(A \quad \mathbb{1}_4) \tag{14.4.51}$$

The "parity-check matrix".

Therefore:

$$HG=(A \quad \mathbb{1}_k)\begin{pmatrix}\mathbb{1}_k\\A\end{pmatrix}=A\mathbb{1}_k+\mathbb{I}_kA=A+A=A(1+1)=0 \tag{14.4.52}$$

Because $1+1=0$ in $\mathbb{F}_2$.

In general, if we work with the alphabet $\mathbb{F}_2$ and if $G=\begin{pmatrix}\mathbb{1}_k\\A\end{pmatrix}$ where A is $(n-k)\times k$ matrix then $H=(A \quad -\mathbb{1}_k$ is also a control matrix because again:

$$HG=(A \quad -\mathbb{1}_k)\begin{pmatrix}\mathbb{1}_k\\A\end{pmatrix}=A\mathbb{1}_k-\mathbb{1}_kA=0 \tag{14.4.53}$$

Remark

In $\mathbb{F}_2$, we have $\mathbb{1}_k=-\mathbb{1}_k$, since $1=-1$ this is why we wrote $H=(A \quad -\mathbb{1}_k)$ in the previous companion example.

14.4.4.2 Systematic codes

As we have mention it earlier above, let us come back on "systematic codes" that we have already defined.

Constructing a systematic code consists as we already know in adding to each word $x=(x_1,\ldots,x_k)$ of the message $n-k$ symbols $(c_{k+1},\ldots,c_{k+n})$ linearly depending of the x_i to get the code word $c=f(x)$.

We know already that symbols are named "control bits" and (we will see another example just below):

$$c=(x_1,\ldots,x_k,c_{k+1},\ldots,c_{k+n})=(\mathbb{1}_k|A)(x_1,\ldots,x_k) \tag{14.4.54}$$

where, for recall, $(\mathbb{1}_k|A)$ denotes the matrix $n\times k$ obtained by writing one below the other, the identity matrix $\mathbb{1}_k$ of size k and any matrix A.

We will say that a code C is "systematic" if it has a generating matrix of the form $G=(\mathbb{1}_k|A)$.

✍**Example:**

We propose to construct a systematic linear code with $n=k=3$ as example. We will denote by a_1,a_2,a_3 the information bits. The control bits a_4,a_5,a_6 will be defined by:

$$\begin{aligned}a_4&=a_1+a_2\\ a_5&=a_2+a_3\\ a_6&=a_1+a_3\end{aligned} \tag{14.4.55}$$

The generating matrix G is such that its upper part is the identity matrix of dimension 3 (we had the same thing for the Hamming code). The first line (110) of the matrix A corresponds to the expression of the control bit a_4:

$$a_4=1\cdot a_1+1\cdot a_2+0\cdot a_3 \tag{14.4.56}$$

etc. For each control bit.

The generating matrix G is then written:

$$G=\begin{bmatrix}\mathbb{1}_k\\ A\end{bmatrix}=\begin{bmatrix}\mathbb{1}_3\\ A\end{bmatrix}=\begin{bmatrix}1&0&0\\0&1&0\\0&0&1\\1&1&0\\0&1&1\\1&0&1\end{bmatrix} \tag{14.4.57}$$

By multiplying this matrix by the $2^3 = 8$ possible vectors (the words consisting of three bits of information), we get the following code words:

a_1	a_2	a_3	a_4	a_5	a_6
0	0	0	0	0	0
0	0	1	0	1	1
0	1	0	1	1	0
1	0	0	1	0	1
1	0	1	1	1	0
1	1	0	0	1	1
1	1	1	0	0	0

We thus find that the minimum weight of the code words is 3. Therefore the code detects $3-1=2$ errors and can correct of them $\left[\dfrac{3-1}{2}\right]=1$.

The reader interested can refer to out MATLAB® companion book to see how to handle or generate error correcting codes.

14.5. Automata Theory

THE purpose of this section is to study the theoretical aspect of the computer/machine concept. We are located here at the level of mathematics and logic, regardless of any reference to a real specific computer/machine (or software). We will look at how this theoretical machine will make acquisition of digital data, of whatever nature, to do treatment on it or to solve a general problem. We will then be taken to see that, from this point of view, any theoretical machine is reducible in its operating principle, to an ideal machine. Thus, we can say that all computers, or all programs are equivalent to each other, as the purpose of computer, in its theoretical definition, is universal, that is to say the capacity to treat all actually treatable problems.

Modern computing is the result of research undertaken in the early 120th century (holocene calendar) by Bertrand Russell and Alfred North Whitehead to constitute a formal mathematical system where any proposal could be proved by a logical calculation see section Proof Theory page 131. David Hilbert and Kurt Gödel accomplished decisive steps in the exploration of this program. In 11931 (holocene calendar) Gödel proved that (recall):

1. It may be that in some cases we can prove one thing and its opposite (inconsistency).
2. In any formal mathematical system there are mathematical truths that can not be proved (incompleteness)

Gödel's theorem thus ruin the dream to make from mathematics a perfectly coherent deductive system, but from the intellectual activity around the *Principia Mathematica* project of Russel and Whitehead will release the founding ideas of computer science. This brings Alan Turing in 11936 (holocene calendar), after Gödel, to tackle the problem of decidability.

Definition (#14.5.605): A system is named "decidable system" if there is an effective procedure for distinguishing provable proposals of others. To define more rigorously the concept of effective procedure, Alan Turing developed the concept of "automata", hereinafter named "Turing machine" (see example below), which allows him to clarify the concept of implementation of an "algorithm" (see section Numerical Methods page 6273).

Definition (#14.5.606): A "Turing Complete language" is a language with at least a conditional and a while-loop construct - such a language can be used to implement a Turing machine that is "powerful" enough to perform any realizable algorithm.

Inventing effective procedures (algorithms) is to determine a sequence of elementary operations that perform the calculations/treatments necessary to solve problems for which there are computable solutions (there are unsolved problems and incalculable solutions as we have seen during our study of complexity in the section of Theoretical Computing). Turing also proved that its calculation model is universal, that is to say that all Turing machines are equivalent (we will prove this below). It makes the assumption that any algorithm can be computed by a Turing machine. These ideas underpin the theory of computer programming.

These ideas underlying the theory of computer programming were one important factor of winning the second World War thanks to the machine developed by Turing to uncrypt the Nazi Enigma cypher machine (a romance movie has been made about this subject in 12015 (holocene calendar) with Alan Turing as major role).

Remark

This section should have normally been placed at the first position of this chapter but it seemed wiser to do first hand on concrete examples of theoretical computing before moving to the abstract formalism of their executions. This is one of the reasons why we will return here briefly on the concepts of algorithms, complexity, formal logical systems, proof theory and information (see all sections with the corresponding name). Furthermore, for this section, an experience in the development of computer software is a big plus for understanding certain concepts (or to imagine practical applications).

Before we begin, it should be useful for the reader to have a non-exhaustive overview of the applications of Language and Automata Theory: specification of programming languages, compilation, pattern matching (in a text, in a database on the web, in the genes .. .), text compression, program verification, electronic computers, encoding for transmission, encryption, decoding of the genome, language, cognitive science, etc.

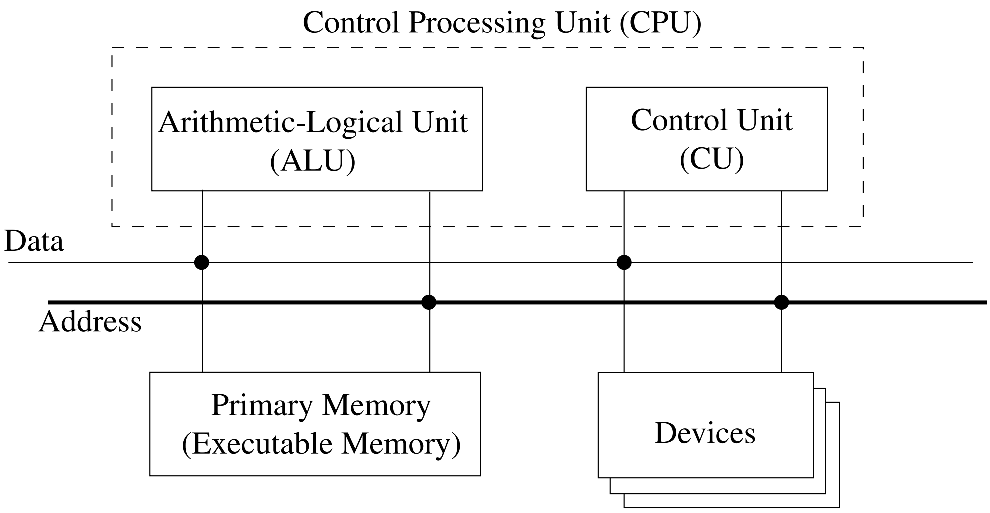
14.5.1 Von Neumann machine

We due to John von Neumann to conceive in 11945 (holocene calendar) the general architecture of the concrete apparatuses which will carry out the calculations according to the Turing model, an architecture so efficient and elegant that the computers this early 121st century (holocene calendar) are still constructed on these principles.

Remark

In a way, we can say that this decade between 11936 and 11945, according to holocene calendar (corresponding well to the Second World War), saw the birth of computer science, which went from the mathematical and logical intellectual construction stage to the application of these ideas to the realization of concrete physical systems.

Here is the diagram of the of a von Neumann architecture:



Control Processing Unit (CPU)
Arithmetic-Logical Unit (ALU)
Control Unit (CU)
Data
Address
Primary Memory (Executable Memory)
Devices

Figure 14.344: **Principle of the von Neumann machine**

The Control Units, Arithmetic-Logic Unit (ALU), and Primary Memory constitute all three the "Central Unit", or "Processor", of the computer. The processor consists of electronic circuits that can perform actions. The set of actions wired in the processor constitutes the instruction set of the processor and determines the basic language of its use, named "machine language".

The role of the Control Unit is to enable the desired action (instruction) to be triggered at the desired moment. This instruction can belong to the Arithmetic-Logic Unit, to the Memory Unit or to the Control Unit itself. An instruction can also consult the contents of the Primary Memory unit (the "read") or modify the contents of that memory (the "write"). In general, an action consists in either consulting or modifying the state of the memory or one of the registers (which are special memory elements incorporated in the central processing unit), or triggering an input-output operation (communication with the outside world and in particular a human user).

The memory is made up of elements that can take states. A basic element of the memory can take two distinct states and can be used to represent an elementary data item, or "bit" (see section Logical Systems 6275). This representation of a data element by a memory element is named a "code". A memory with many bits allows the coding of complex data, within the limit of the size of the memory.

The way in which the central unit, memory and I/O devices (input/output) communicate is generically named a "bus" (it is, in a way, the highway where data flows from one point to another Using addresses). In a somewhat formal way, a bus is a complete connected graph (see section Graph Theory page 3010), which means in common language that all the elements connected to the bus can communicate with one another.

Remark

The "code" makes bits and groups of symbols match together. The simplest symbols are numbers and letters. To represent complex data, you can define methods, rules for grouping symbols, and associate a data element with a symbol group constructed according to the rules.

Definition (#14.5.607): We will name "language" a set of symbols or groups of symbols, constructed according to certain rules, and which are the "words" of that language. A "language syntax" is the set of construction rules for language words.

The memory of the computer (this is the basic idea of von Neumann) contains information of two types: Programs and Data. The programs and the data are represented with the same symbols, only the semantics allows to interpret their respective texts. Moreover, the text of a program can sometimes be considered as data for another program, for example a program of translation from one language to another.

quote 14.5:7184.#78

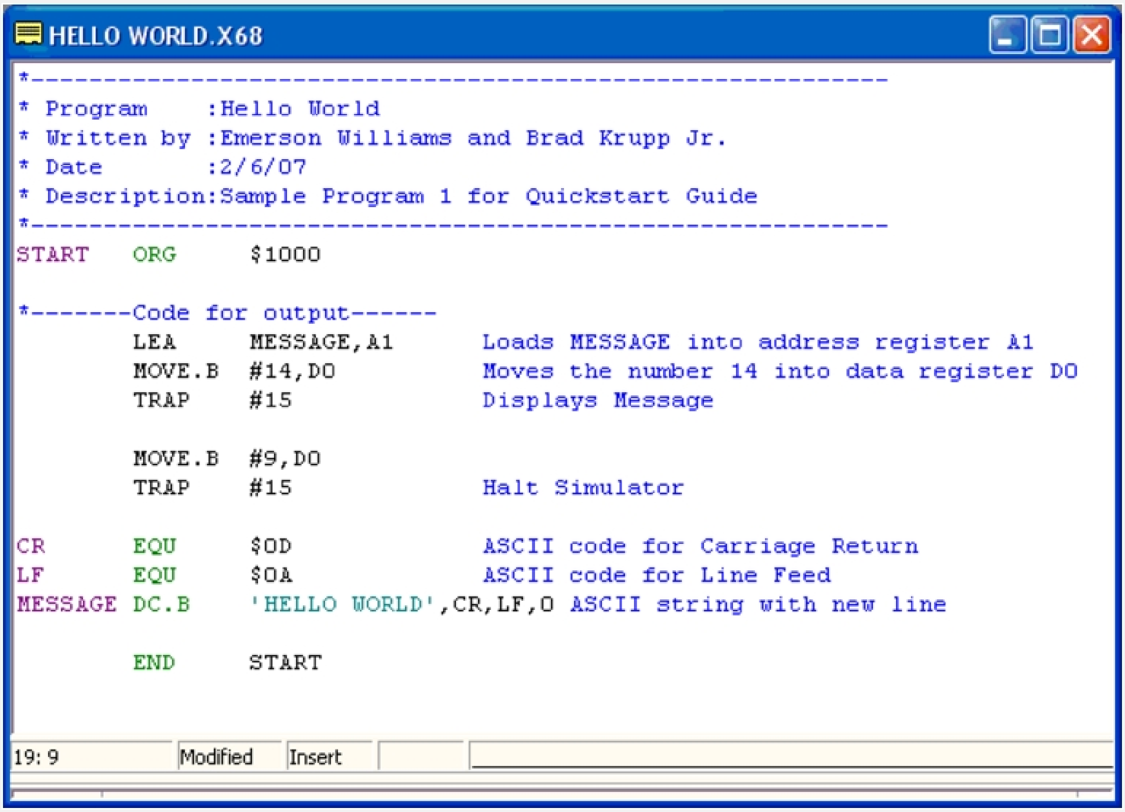
> *Computers are like humans - they do everything except think.*
>
> John von Neumann

14.5.2 Turing machine

It is important to be convinced (it will perhaps not be done in one day...) that all the programs we can write in different languages are equivalent!!! The Turing machine is a model of an automata whose description is very low-level (before going on to a much more formal definition). The von Neumann architecture, designed to efficiently perform the processes described by a Turing machine, generates imperative languages (see definition in remark R1 below). Any program, functional or imperative, intended to be executed, will be translated into an imperative language, the "machine language" of the computer used. The coherence of computer science and the semantic equivalence of programs written in various languages which ensure the validity of this operation are the result not of chance but of a common original theoretical conception. Gödel, Church, von Neumann and Turing were all in Princeton in 11936 (holocene calendar)...!

Remarks

R1. The first evolved languages that have appeared are so-named "imperative languages", based on the notion of the state of memory (it is the "assembly language" by the way!). These languages, inspired by John von Neumann's model, include, like machine language, instructions that produce changes in memory (assignment instruction). The writing of a program in imperative language consists in writing the sequence of instructions which will cause the successive states by which the memory will have to pass so that, starting from an initial state allowing the initialization of the program, it arrives in a state providing final results.



```

        END     START
```

Figure 14.345: **Assembly language "Hello World" demo**

R2. In addition to "computational languages", we distinguish in computer science "sequential languages", "interpreted languages", "description languages", "functional languages" and "compiled languages".

A formal model for an effective procedure (to describe an algorithm) must possess certain properties. First, each procedure must receive a finite definition. Secondly, the procedure must consist of separate steps, each of which must be capable of being accomplished mechanically. In its simplicity, the Turing machine composed of the following elements answers to this program:

1. An infinite memory represented by a ribbon divided into boxes. Each square of the ribbon may be given a symbol of the alphabet defined for the machine;
2. A reading head capable of traversing the tape in both directions;
3. A finite set of states among which we distinguish an initial state and the other states, named "accepting states"
4. A transition function which, for each state of the machine and each symbol under the read head, specifies: the next state, the character that will be written on the ribbon instead of the one that was under the head, the direction of the next playback of the playback head.

One can equip his Turing Machine with the finite alphabet of his choice. Its ribbon can be infinite in either direction or in one. It may even have several ribbons. It is shown that these various machines are equivalent.

Figure 14.346: **Turing Machine principle**

We are then led to the following simplistic definition:

Definition (#14.5.608): A "finite automate" is a mathematical model of systems having a finite number of states and that actions (external or internal) can move from one state to another. The external actions are represented by the symbols of an alphabet $\mathcal{A}$; The internal actions (invisible, silent, or spontaneous) are represented by a symbol not belonging to the aforementioned alphabet.

Caution! For example, any real computer is finite so it isn't an abstract model like a Turing Machine. The finite version of the Turing Machine has a confusing name: "Linear Bounded Automaton". This is basically what real computers are. However, LBA are not seen or used in discussion nearly as much as Turing Machine.

An automate is represented by a graph (see section Graph Theory page 2999) whose vertices are states and with each arc is associated the recognition of one or more letters.

Finite automata are used to model and control finite-state systems and to solve common problems: lexical analysis, search of patterns in text, genome analysis, etc.

✍**Examples:**

E1. A finite and deterministic automate which recognizes all integers whose writing is normalized (regular language), that is to say not starting with 0 (the numbers in the circles are just there to describe the order in which the controller performs the operation):

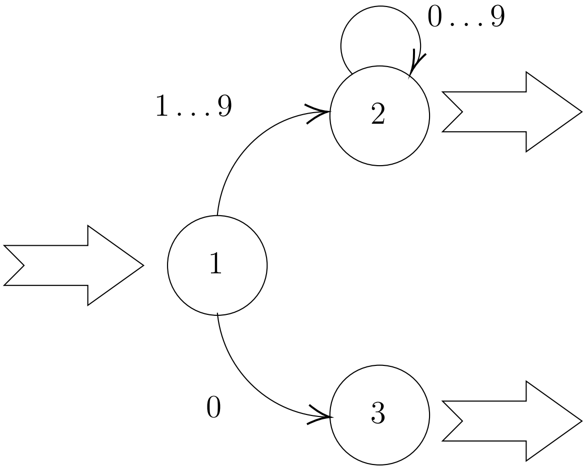

Figure 14.347: **First example of a finite automata (pedagogical version)**

Description: The automata receives an integer in input ①, it looks at whether this number starts with a 0 or it is a number between 1 and 9. If the number starts with zero, the controller exits and stop at ③. Otherwise, the controller goes to ② and analyses the numbers one after the other until it reaches the end and then stops and goes out at ③.

Here is a version of the same automata but respecting the traditional design and notation in academics:

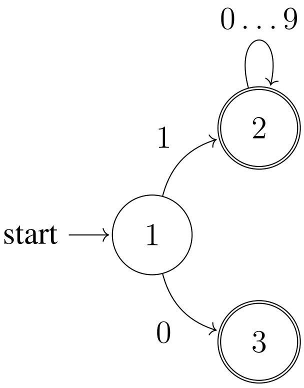

Figure 14.348: **Finite automata with academic official notation and design**

E2. A finite and deterministic automata which recognizes a numerical input in a regular language spreadsheet (for example: $+12,3$ or 08 or -15 or $5\text{E}12$ or $14\text{E}-3$):

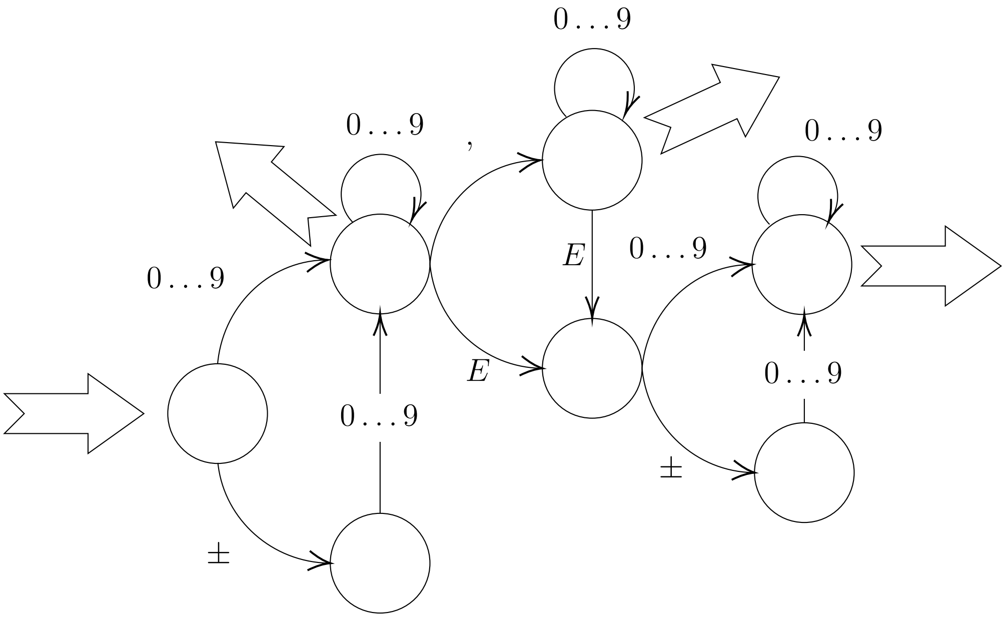

Figure 14.349: **Second example of a finite automata**

In other words, it is enough to recognize a language of the form:

$$\{-,+,\varepsilon\}\mathcal{A}^*,\mathcal{A}^*\mathrm{E}\{-,+,\varepsilon\}\mathcal{A}^* \tag{14.5.1}$$

which is indeed regular, where ε is the empty word, $\mathcal{A}$ is the alphabet $\{0,1,\ldots,9\}$ and equation the set of words (in extenso of numbers) that can be written with $\mathcal{A}$.

E3. A finite and deterministic automata recognizing all the multiples of 3, regular language type (in other words if such a multiple is found, the automata gives an output, otherwise nothing):

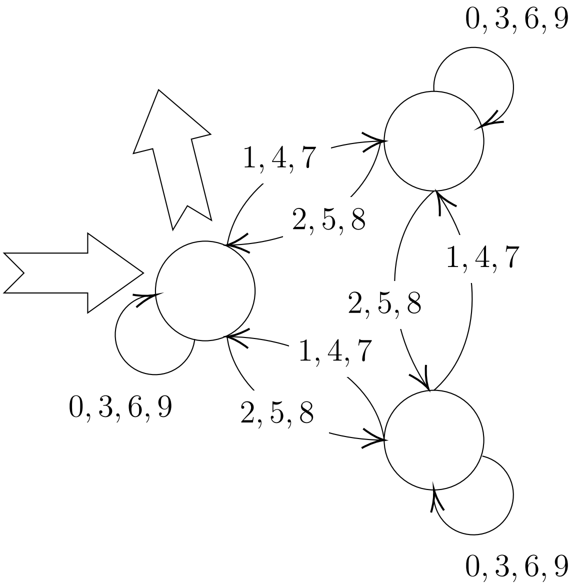

Figure 14.350: **Third example of a finite automata**

I strongly recommend any reader that want the be familiar with complete Turing Machines to practice the challenge that Google made with the Turing Doodle (it is probably "complete" but not sure):

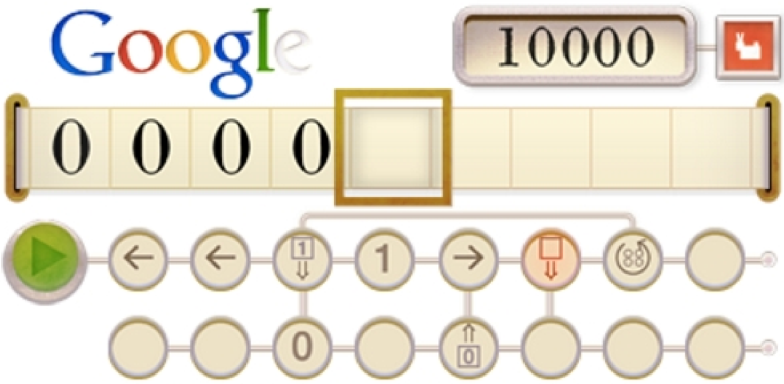

Figure 14.351: **Turing Doodle (source: Google)**

available here:

https://doodles.google/doodle/alan-turings-100th-birthday/

The purpose of that Doodle is to change the algorithm so that when it is executed and the machine stops the content of the tape is compared to the content of the display on the right top corner. When the comparison is successful the player will go to the next level with another algorithm to change... and so on...

Some passionate of Turing Machines have build real life small and beautiful electronic Turing machines as the one visible in the picture below (perhaps they build it as a hobby or sell it to schools for education purposes???):

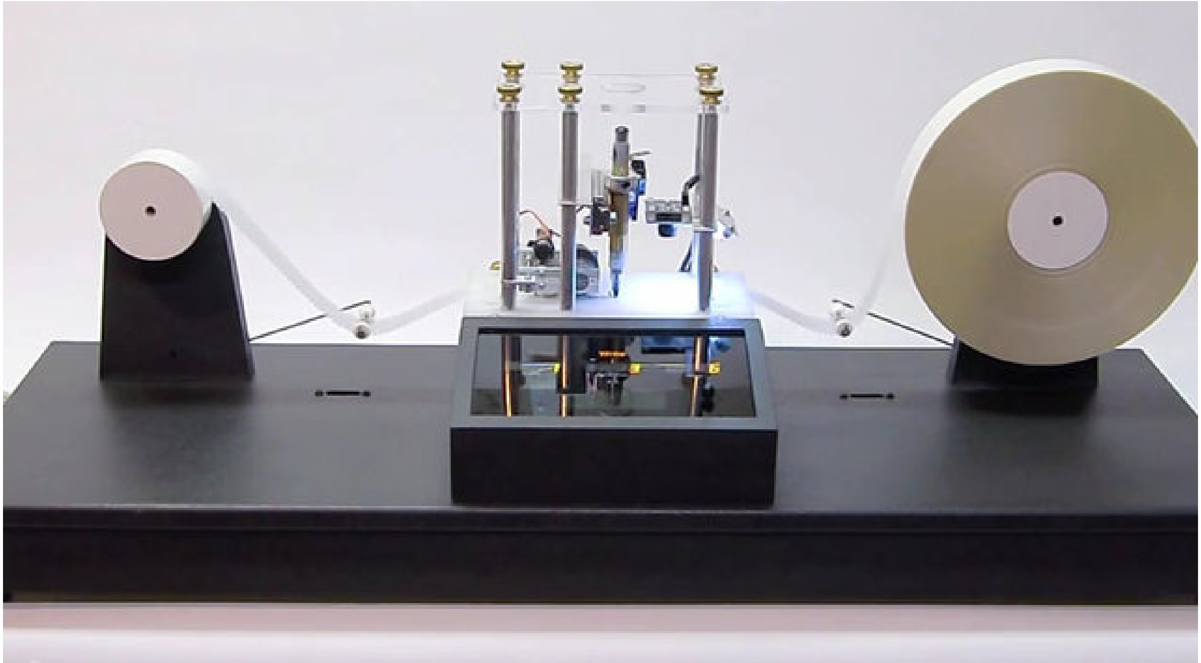

Figure 14.352: **Turing Machine (source: ?)**

Remarks

R1. Relatively to a common question...: YES! Artificial intelligence are Turing Machines. However at the day we write these lines (early 121st century according to holocene calendar), we still have no evidence based likelihood to claim that Homo Sapiens brain is a Linear Bounded Automaton or not (we let this work to future generations!).

R2. Markov chains can be represented by finite states machines. The main thing to keep in mind is that the transitions in a Markov chain are probabilistic rather than deterministic. which means that you can't always say with perfect certainty what will happen at time $t+1$. The brain is closer to a Markov chain than a Turing machine.

Because of a common request, let us provide a definition:

Definition (#14.5.609): "Consciousness" is the apparent (see [507]) fabricated awareness of internal and external existence by stimulus with the environment. Consciousness is tested scientifically by different means like the "Subject-Object Model test" and "Cellular/Basis for Consciousness" (for bacterias that are bio-sensitive and any bigger animal), the "Mirror test" (for animals having a vision suitable for such a test) or "Turing test" (for humans or machines like computers). General anaesthesia can switch off temporarily consciousness in most animals and death switch it off definitely.

The *Cambridge Declaration on Consciousness* - a scientific statement publicly proclaimed on July 7, 12012 (holocene calendar), at Churchill College, University of Cambridge, in which a group of leading neuroscientists - affirms that many non-human animals—including all mammals, birds, and several invertebrates such as octopuses—possess the neuroanatomical, neurochemical, and neurophysiological substrates of conscious states, meaning they are sentient and capable of experiencing positive and negative mental states.

14.5.3 Chomsky hierarchy

The "Chomsky hierarchy" is a classification of the languages described by the formal grammars proposed in 11956 (holocene calendar) by the linguist Noam Chomsky. It is widely used today in computing, especially for the design of interpreters or compilers, or for the analysis of natural languages.

It is necessary before to define certain concepts!

14.5.3.1 Formal language

Definition (naive version #610): In a broad range of contexts (scientific, legal, etc.) we designate naively by "formal language $\mathcal{L}$" a more formalized and more precise form of expression than the everyday natural language (the two do not necessarily go together).

In mathematics, logic and computer science, a formal language is formed by:

1. A set of words obeying to strict logical rules (formal grammar or syntax).
2. Possibly of an underlying semantics (the strength of formal languages is to be able to disregard such semantics, which makes theories reusable in several models).

Remark

Thus, while a particular payroll or inverse matrix calculation will always remain a payroll or inverse matrix calculation, a group theorem will apply both to the set of integers and to the transformations of the Rubik cube.

The formal language of a scientific discipline is therefore actually a language obeying strict formal syntax and which will serve to expose statements precisely, if possible concisely and without ambiguity, and is in opposition to natural language.

Formal language has the advantage of making easy the manipulation and transformations these statements. Indeed, we will generally have precise transformation rules (development of logical formulas, normal forms, contrapositions, commutativity, associativity, etc.) that can be applied without even knowing the meaning of the statements to be transformed or the meaning of the transformation. It is therefore a powerful exploration tool, and it is the only language that allows machines to "do mathematics".

The disadvantage is obvious: not knowing the meaning of the statement prevents us from knowing which are the relevant transformations and hurts the intuition of the reasoning. Thus, it is good to know how to quickly read a statement in formal language and to translate it just as quickly into one or more natural language statements.

This is where the limit of what we name "proof-aid software" lies: of course, the computer has (for now...) no intuition. The skill of the designer of such a program is to find ways for the computer to understand.

Giving relevant meaning to a programming language in order to run its programs is relatively easy, because these formal languages have been designed to mean sequences of elementary actions of the machine. To prove a program (to prove that the algorithm ends in a finite number of times) or a mathematical theorem (which is almost the same thing), there is, on the other hand, no infallible method, the correction of a program being an undecidable decision problem. Thus, the prover must simply apply certain heuristics (a technique consisting in learning little by little taking into account what has been done beforehand) and often calling for help to the human user (same as humans do in fact...!). However, thanks to its heuristics and computing power, the computer explores thousands of ways that the human user would not have been able to test in several years, thus accelerating the work of the mathematician, physicist or engineer.

Definition (#14.5.611): As an object of study, a "formal language $\mathcal{L}$" is defined as a set $\mathcal{W}$ of finite-length words w_i (i.e. strings) deduced from a certain finite alphabet $\mathcal{A}$, that is to say a free monoid (the set of words formed on an alphabet, provided with the internal law of concatenation - which is a law of composition - is a monoid which we name "free monoid", which empty word is the neutral element) on this alphabet.

Definition (#14.5.612): A "word" is a sound, sign, letter, or group of sounds, signs, letters, used to designate objects, to express actions, feelings, ideas, as well as their relationships.

Remark

Thus, while a particular payroll or inverse matrix calculation will always remain a payroll or inverse matrix calculation, a group theorem will apply both to the set of integers and to the transformations of the Rubik cube.

Definition (#14.5.613): A "rich language" is a language with a vast lexicon (almost a bijective relationship between all words and all the concepts). That means a language where each word or statement language minimize the number of possible contradictory or fuzzy interpretations. An "exact language" is the extreme case of a rich language where each word can have one and only one meaning (i.e. there is a bijective relationship between the set of words and the set of descriptions).

Some languages and their cardinality (source `https://www.sketchengine.eu/documentation/tenten-corpora/`):

Corpus	Language	Year	Size (tokens)	Number of unique words
SketchEngine enTenTen21	English	12021	$61,585,997,113$	$131,222,868$

Table 14.56: **Some languages in descending order of richness**

In the table above the years are given on the basis of the holocene calendar as always in this textbook.

14.5.3.2 Syntax

Definition (#14.5.614): The "syntax" is the branch of linguistics that studies the way in which "free morphemes" (words) combine to form "syntagmas" (nominal or verbal) that can lead to propositions that can combine in turn to form statements.

✍**Example:**

The syntagma (sentence): *a modest house of red bricks* is encompassed in the upper syntagma, that is, the complete sentence. But this same sentence *a modest house of red bricks* includes among its elements, the lower syntagma *of red bricks*, complement of the name house.

Definitions (#14.5.615):

D1. In grammar school, a "proposition" is a syntagma articulated around a verb. This notion is mainly used in language learning.

D2. A "statement" in linguistics is everything that is pronounced by a speaker between two breaks. Syntactically, the statement can therefore extend from the simple word to the length of a sentence (even to a discourse), through the syntagma.

The term "syntax" is also used in computer science, where its definition is similar, modulo a different terminology... Thus the syntax is the respect, or the non-respect, of the formal grammar of a computer language, that is to say of the rules of arrangement of the lexemes (which in computer science are only lexical entities) in more complex terms, often: "programs". In the theory of formal languages, what plays the role of lexeme is usually named "letter" or "symbol", and the product terms are named "words".

From a purely grammatical point of view, the study of syntax concerns three kinds of units:

- The "sentence", which is the upper limit of the syntax.
- The "word", which is its basic constituent, sometimes named "terminal element"
- The "syntagma", which is its intermediate unit

The syntactic relations between these different units can be of two kinds:

- The "coordination" when the elements are of the same status
- The "subordination" in the opposite case (when there is subordination, the subordinate element fulfils a syntactic function determined with respect to the higher level unit)

The study of syntax will take into account, in particular, the nature (or category or species) of the words, their form (morphology) and their function. It is why we speak more generally of "morphosyntactic relations".

14.5.3.3 Grammar

Definition (naive version #616): A "formal grammar $\mathcal{G}$" is a formalism used to define a syntax and therefore a formal language $\mathcal{L}$, that is to say a set $\mathcal{W}$ of words w_i on a given alphabet $\mathcal{A}$.

The concept of formal grammar is particularly used in the following fields:

- Programs compilation (syntactic analysis)
- The analysis and processing of natural languages
- Calculation models (automata, circuits, Turing machines, etc.)

To define a grammar, we need (see the example below to understand):

1. An alphabet of non-terminal items
2. An alphabet of terminals item;
3. An initial symbol (the axiom) taken among the non-terminals items;
4. A set of production rules.

✍**Examples:**

E1. We can define arithmetic expressions in the following way (writings that we often find in the Proof theory) where | is the symbol commonly use for the logical "OR":

$$\texttt{exp}\rightarrow\texttt{exp+exp}|\texttt{exp*exp}|\texttt{(exp)}|\texttt{num}$$

where `exp` means "expression" or:

$$\texttt{num}\rightarrow 0\texttt{num}|1\texttt{num}|2\texttt{num}|\ldots|9\texttt{num}|1|2|\ldots|9$$

The non-terminals here are explicitly `exp` and `num`, the terminals are `+`, `*`, `(`, `)` and the digits. The axiom is `exp`.

E2. The syntax of classical propositional logic can be defined in the following way (see section Proof Theory page 168):

$$\mathcal{F}=\text{Atom}|F\vee F|F\wedge F|F\rightarrow|F\neg F|\exists xF|\forall xF$$

The most commonly used types of grammars are:

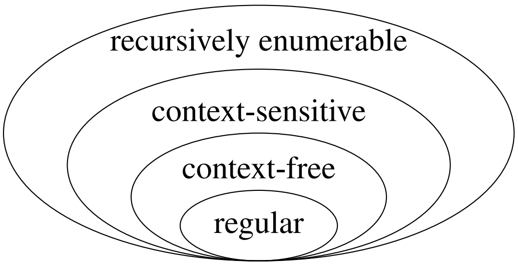
1. Left linear grammars that produce the same languages as regular expressions (this is what we are interested to in this section)
2. Context-free grammar (example above)
3. Contextual grammars (this type of grammar requires a mathematical formalism and can not be defined without it)

A language is therefore a set of words $\mathcal{W}$, which are simply sequences of symbols chosen from a finite alphabet set $\mathcal{A}$. The languages of the Chomsky's hierarchy consist of words that respect a particular formal grammar. What distinguishes them within the framework of classification is the nature of the grammar.

Remark

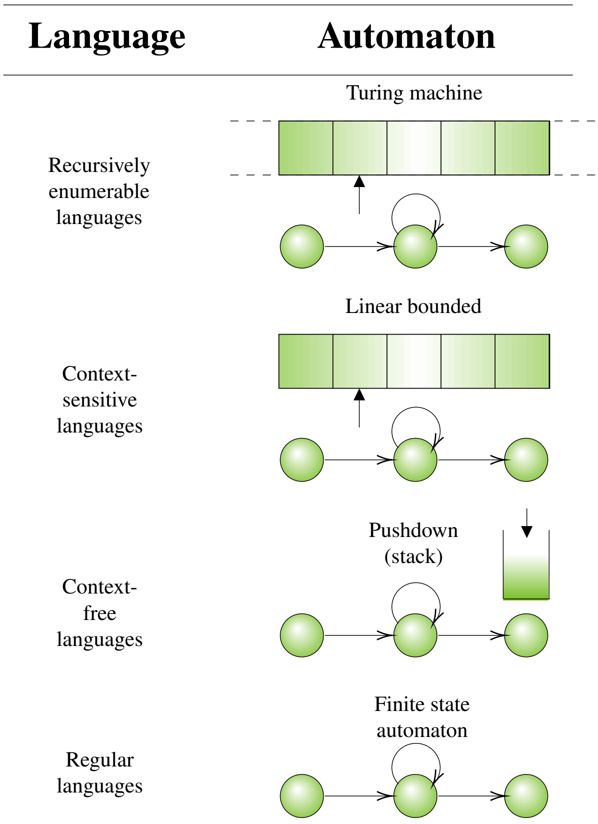
Most often, the symbols that are considered are formed of several characters, so that they correspond rather to what "words" in the current language. When there is ambiguity, for example in lexical analysis (vocabulary) and syntactic analysis (part of the grammar that deals with the function and the disposition of words and propositions in the sentence), we speak of "characters" for the symbols of the alphabet used to encode the information, and of "lexemes" for the symbols of the abstract alphabet, which are the basic units of the language. Similarly, the "words" of the language correspond rather to "sentences" or "texts".

The Chomsky hierarchy consists of the following 4 levels, from the most restrictive to the broadest one:



- L1. The "languages of type 3" or "regular language": these are the languages defined by a regular grammar or a regular expression, or the languages recognizable by a finite-state automata.
- L2. The "languages of type 2" or "algebraic languages" also named "context-free languages": these are the languages defined by a context-free grammar, or the languages recognizable by a non-deterministic stack automata. In this category are for example the computer programming languages.
- L3. The "languages of type 1" or "context sensitive languages": these are the languages defined by a contextual grammar, or the languages recognizable by a non-deterministic Turing machine with a length bounded by a fixed multiple of the word length's (these types of languages require a mathematical formalism and can not be defined without it).

L4. The "languages of type 0", or "recursively enumerable languages": This set includes all languages defined by a formal grammar. It is also the set of languages acceptable by a Turing machine (which is allowed to loop on a word that is not of the language).



Language
Automaton
Turing machine
Recursively enumerable languages
Linear bounded
Context-sensitive languages
Pushdown (stack)
Context-free languages
Finite state automaton
Regular languages

Figure 14.353: **Chomsky hierarchy**

Remarks

R1. In addition to the 4 types of the Chomsky hierarchy, there are remarkable intermediate classes! For example between types 3 and 2: deterministic non-contextual languages, recognizable by a deterministic stack automata and languages between levels 1 and 0: recursive languages, that is to say, recognizable by a Turing machine (the latter must refuse words which are not in the language).

R2. The 4 types of languages and 2 of intermediate languages above are strictly included in each other.

A parser for a formal language is a computer program that decides whether a given input word belongs or not to the language, and possibly constructs a derivation of it.

There are systematic methods for writing type 2 or 3 language analysis programs (parsers). Interpreters or compilers almost always include a phase of lexical analysis, which consists of recognizing type 3 languages, followed by a phase of syntactic analysis that is a in fact a type 2 language analysis.

We can now finally in a vulgarize way (always with the aim of paving the way) define what an automata is in the Chomsky hierarchy.

14.5.3.4 Associated automata

Definition (naive version #617): In the field of theoretical computing, an "automata" is a machine to process information by a formal model (a Turing machine) on a given language. So:

- On a "finite language" (language containing a finite number of words), the associated automata is a machine comparing a text with that which is stored in a read-only memory. The grammar associated with a finite language is a list of the words of the language.
- On a "regular language" (language where the syntactic correction is verified by storing only a finite number of information), the associated automata is the "deterministic finite automaton" (that is, for each word entered, there is only one possible path of the graph) or the "non-deterministic finite automata". The grammar associated with a regular language is a left linear grammar.
- On an "algebraic language" (language where the main syntactic constraint are the parenthesis), the associated automata is the "pushdown (stack) non-deterministic automata". The associated grammar is the algebraic grammar.
- On a "bounded language" (description requiring a mathematical formalism), the associated automata is the "linearly bounded automata". The associated grammar is the contextual grammar.
- On a "decidable language" (an intelligent being manages to find a process to know whether or not one he is in the language), the associated automata is a Turing machine that stops on all data. There is no grammar associated to it.
- On a "semi-decidable language" (an intelligent being manages to find a process to know whether or not one he is in the language), the associated automata is the Turing machine (thus contains conditional structures and loops). The associated grammars are the "semi-Turing grammar", the "de Vangarden grammar" or the "affixed grammars".

14.5.4 Terminology

The automata therefore work mainly on letters, words, sentences and languages. In order to construct rigorous and optimal analysis methods and treatment on the subject it is interesting to formalize the treated objects. This is what we will do initially by defining these latter and their mathematical properties (which are very intuitive).

14.5.4.1 Words

Definitions (#14.5.618):

D1. An "alphabet $\mathcal{A}$" is a set whose elements are the "letter ℓ". The alphabets are always supposed to be finished.

D2. A "word w_i" is a finite sequence of "letters" which we denote by juxtaposition:

$$w_i = \ell_1 \ell_2 \ldots \ell_n \qquad \ell_i \in \mathcal{A} \tag{14.5.2}$$

D3. The "empty word", denoted ε, is the only word composed of no letters.

D4. The "length" of a word w is the number of letters that compose it, and is denoted $|w|$ (the empty word ε is the only word of length 0).

The "concatenation product" of two words $w_1 = a_1 a_2 \ldots a_n$ and $w_i = b_1 b_2 \ldots b_m$ is the word $w_1 w_2$ obtained by juxtaposition (concatenation):

$$w_1 w_2 = a_1 a_2 \ldots a_n b_1 b_2 \ldots b_m \tag{14.5.3}$$

Of course (trivial), we have:

$$|w_1 w_2| = |w_1| + |w_2| \tag{14.5.4}$$

We denote by $\mathcal{A}^*$ the set of words on $\mathcal{A}$.

✍**Example:**

Genes are words on the ACGT alphabet, proteins are words on a 20-letter alphabet. The natural integers, written in base 10, are words on the alphabet of the decimal digits...

Let $\mathcal{A}$ be an alphabet. Let $\mathcal{B}$ be a subset of $\mathcal{A}$. For any word $w \in \mathcal{A}$, the length in $\mathcal{B}$ of w is the number of occurrences of letters of $\mathcal{B}$ in the word w. This number will be denoted $|w|_{\mathcal{B}}$.

Remark

In particular, we have trivially $|w| = |w|_{\mathcal{A}}$.

For every letter $\ell \in \mathcal{A}$, $|w|_\ell$ is the number of occurrences of ℓ in w. We have:

$$|w|_{\mathcal{B}} = \sum_{b \in \mathcal{B}} |w|_b \tag{14.5.5}$$

D5. Given $w=\ell_1\ell_2\dots\ell_n$, with $\ell_1\ell_2\dots\ell_n\in\mathcal{A}$. The "mirror word" of w is the word denoted $\widetilde{w}$ defined by:

$$\widetilde{w}=\ell_n\dots\ell_2\ell_1 \tag{14.5.6}$$

Obviously:

$$\widetilde{(uv)}=\widetilde{v}\widetilde{u} \qquad \text{and} \qquad \widetilde{(\widetilde{w})}=w \tag{14.5.7}$$

D6. A word u is a "prefix" or "left factor" of a word v if there is a word x such that $ux=v$. The word u is moreover a "strict prefix" or "eigen-prefix" if $u\neq v$. Symmetrically, u is a "suffix" or "right factor" of v if $xu=v$ a word x. If $u\neq v$, then u is "strict suffix" or "eigen-suffix". The number of prefixes of a non-empty word v is $1+|v|$ (the empty word always being a prefix, we always have any non-empty word that has at least the empty word as a prefix).

✍**Example:**

The word $w=aabab$ on $\mathcal{A}=\{a,b\}$ has 12 different possible factors:

$$\{\varepsilon,a,b,aa,ab,ba,aab,aba,bab,aaba,abab,aabab\} \tag{14.5.8}$$

Lemma 14.29.1 (Levy's lemma)**.** Given x, y, z, t be words such as $xy=zt$. Then there exists a word w such that:

$$xw=z \tag{14.5.9}$$

with obviously:

$$y=wt \tag{14.5.10}$$

or:

$$x=zw \tag{14.5.11}$$

with also by extension:

$$wy=t \tag{14.5.12}$$

It results logically in particular that if $|x|=|y|$, the word w is empty, and therefore $x=z$ and $y=t$. In other words:

Theorem 14.30. A free monoid (see the reminder below) can be simplified on the left and on the right.

Proof 14.30.1. Let us put:

$$x=a_1\dots a_n \qquad y=a_{n+1}\dots a_m \tag{14.5.13}$$

with $a_i\in\mathcal{A}$, similarly:

$$z=b_1\dots b_p \qquad t=b_{p+1}\dots b_q \tag{14.5.14}$$

with $b_i \in \mathcal{A}$.

As:

$$xy = zt \tag{14.5.15}$$

We have:

$$m = q \tag{14.5.16}$$

(but not necessarily $n = p$) and:

$$a_i = b_i \tag{14.5.17}$$

for $i = 1, \ldots, m$ so that:

$$z = a_1 \ldots a_p \qquad \text{and} \qquad t = a_{p+1} \ldots a_m \tag{14.5.18}$$

If $|z| = p \leq n = |x|$, let us put $w = x_{p+1} \ldots x_n$. Therefore:

$$x = zw \qquad \text{and} \qquad wy = t \tag{14.5.19}$$

If $|z| > |x|$, let us put $w = x_{n+1} \ldots x_p$. Therefore:

$$xw = z \qquad \text{and} \qquad y = wt \tag{14.5.20}$$

■ Q.E.D.

Let us just do a recall of a parallel of the section of Set Theory... In the framework of the study automata a "free monoid" is a set $\mathcal{A}$ (the alphabet), whose elements are the letters ℓ_i. Therefore the composition law $\cdot$ is denoted:

$$(\mathcal{A}, \cdot) \text{ is a free monoid if: } \begin{cases} \cdot \text{ is associative (concatenation)} \\ \cdot \text{ has a neutral element } \varepsilon \text{ in } \mathcal{A} \end{cases} \tag{14.5.21}$$

In the Set Theory section, we were simply talking about the concept of "monoid". The monoid $(\mathcal{A}, \cdot) = (\mathcal{A}, \text{concatenation})$.

14.5.4.2 Languages

The subsets of $\mathcal{A}$ are named "formal languages". For example, for $\mathcal{A}=\{a,b\}$, the set $\mathcal{A}^+=\{a^n b^n | n \geq 0\}$ is a language.

We define on the languages several operations. The set operations are the union, intersection, complementarity and the resulting difference (see section Set Theory page 393). If X and Y are two parts of $\mathcal{A}^*$ then for recall each of this operation is defined by:

- Union:

$$X \cup Y = \{z \in \mathcal{A} | z \in \mathcal{A}^* | z \in X \text{ or } z \in Y\} \tag{14.5.22}$$

- Intersection:

$$X \cap Y = \{z \in \mathcal{A} | z \in \mathcal{A}^* | z \in X \text{ and } z \in Y\} \tag{14.5.23}$$

- Complementarity:

$$X \backslash Y = X \cap Y^C = \{z \in \mathcal{A}^* | z \in X \text{ and } z \notin Y\} \tag{14.5.24}$$

- Difference:

$$X \backslash Y = X \cap Y^C = \{z \in \mathcal{A}^* | z \in X \text{ and } z \notin Y\} \tag{14.5.25}$$

The also have for operation the product (of concatenation) of two languages X and Y is the language:

$$XY = \{xy | x \in X \text{ and } y \in Y\} \tag{14.5.26}$$

and we have for recall:

$$X\{\varepsilon\} = \{\varepsilon\}X = X \tag{14.5.27}$$

and also the operation of left quotient of Y by X:

$$X^{-1}Y = \{w | \exists u \in X \text{ and } v \in Y | v = uw\} \tag{14.5.28}$$

✍**Example:**

Let us consider three languages:

$$X = \{0,1,2,3,4\} \qquad Y = \{5,6,7,8,9\} \qquad Z = \{0,1\} \tag{14.5.29}$$

Then we have for the union:

$$X \cup Y = \{0,1,2,3,4,5,6,7,8,9\} \tag{14.5.30}$$

for the concatenation:

$$XY = \{05,06,07,08,09,15,16,17,18,19,25,26,27,28,29,35,\ldots\} \tag{14.5.31}$$

for a given quotient:

$$Z^{-1}(XY)=\{5,6,7,8,9\}=Y \tag{14.5.32}$$

another quotient:

$$Z^{-1}X=\{\varepsilon\} \tag{14.5.33}$$

and a last quotient:

$$Y^{-1}X=\varnothing \tag{14.5.34}$$

and a stupid difference example:

$$(X\cup Y)\backslash\{\varepsilon\} \text{ is the set of all decimal numbers} \tag{14.5.35}$$

Following the request of a reader we will detail:

$$Z^{-1}(XY)=\{5,6,7,8,9\}=Y \tag{14.5.36}$$

by recalling the definition:

$$X^{-1}Y=\{w|\exists u\in X \text{ and } v\in Y|v=uw\} \tag{14.5.37}$$

We then have explicitly:

$$\{0,1\}^{-1}\cdot\{05,06,07,08,09,15,16,17,18,19,25,26,\ldots\} \tag{14.5.38}$$

and in the concatenation product of the two languages X and Y, the only words where we find the elements $\{0,1\}$ of the language Z as a prefix are:

$$\{05,06,07,08,09,15,16,17,18,19\} \tag{14.5.39}$$

and as by definition $Z^{-1}(XY)$ is the unique set of terms w which follow the prefixes that constitute the terms of Z, then there remains only:

$$\{5,6,7,8,9\} \tag{14.5.40}$$

We have the following properties:

P1. Obviously:

$$X(Y\cup Z)=XY\cup XZ \tag{14.5.41}$$

P2. Less obvious:

$$X(Y\cap Z)\subset(XY\cap XZ) \tag{14.5.42}$$

where the inclusion is generally strict. To conceptualize this property, we must not forget that X is a set of words and that Y, Z do not necessarily have words of the same length!

The powers of X are defined by:

$$X^0=\{\varepsilon\}, X^1=X \quad \text{and} \quad X^{n+1}=X^n \tag{14.5.43}$$

for $n\geq 1$

In particular, if $\mathcal{A}$ is an alphabet, $\mathcal{A}^n$ is the set of words of length n.

Definitions (#14.5.619):

D1. The "Kleene star" (or "Kleene operator" or "Kleene closure") of X is the set:

$$X^*=\bigcup_{n\geq 0} X^n=\{x_1\ldots x_n|n\geq 0, x_1\ldots x_n\in X\} \tag{14.5.44}$$

✍**Example:**

Given $X=\{a,ba\}$. The words of X^*, classified by length are:

0	ε
1	a
2	aa, ba
3	aaa, aba, baa
4	$aaaa, aaba, abaa, baaa, baba$
...	

D2. The operator "$+$" is defined similarly:

$$X^+=\bigcup_{n>0} X^n=\{x_1\ldots x_n|n>0, x_1\ldots x_n\in X\} \tag{14.5.45}$$

14.5.4.3 Equations

First let us see a little something we will need later: given u and v two non-empty words. The three following conditions are equivalent (without proof because quite trivial):

C1. $uv=vu$

C2. $\exists n,m>1: \quad u^n=v^m$

C3. $\exists w\neq\varepsilon, k,l\geq 1: \quad u=w^k, v=w^l$

Remark

Let us recall again that we do not necessarily have $|u|=|v|$ but that we can very well have $|u|>|v|$.

Let us now turn to interesting things (some fuzzy points of the section of Proof Theory can be clarified here sometimes...)!

Definitions (#14.5.620):

D1. Let $\mathcal{V}$ and $\mathcal{A}$ be two disjoint alphabets (you can imagine them as the set of variables and respectively of the constants for example...). An "equation in words" with constants on $\mathcal{A}$ is a couple $e=(\alpha,\beta)$ of words $(\mathcal{V}\cup\mathcal{A})^*$. Such an equation is represented by $\alpha=\beta$. It is therefore necessary to see the two chosen words as the left and right members respectively of an equation.

D2. An equation is said to be "non-trivial equation" if $\alpha\neq\beta$.

✍**Example:**

Given $\mathcal{V}=\{x\}$ and $\mathcal{A}=\{a\}$ and let us define:

$$\alpha=ax \qquad \beta=xa \tag{14.5.46}$$

then we have the following equation in words:

$$xa=ax\Leftrightarrow\alpha=\beta \tag{14.5.47}$$

D3. An equation e is said to be an "equation without constant" if $\alpha,\beta\in\mathcal{V}^*$.

D4. A "solution" of the equation e is a monoid homomorphism (see section Set Theory page 439):

$$h:\,(\mathcal{V}\cup\mathcal{A})^*\mapsto\mathcal{A}^* \tag{14.5.48}$$

invariant (because every letter on $\mathcal{A}$ is sent on $\mathcal{A}^*$ and therefore every word on $\mathcal{A}$ is sent on $\mathcal{A}$) on $\mathcal{A}$ such that:

$$h(\alpha)=h(\beta) \tag{14.5.49}$$

Remark

Let us recall that the definition of the homomorphism is such that if $\alpha=xy$ then:

$$h(\alpha)=h(xy)=h(x)h(y) \tag{14.5.50}$$

✍**Example:**

Given $\mathcal{A}=\{a,b\}$ and $\mathcal{V}=\{x,y\}$. Let us wow consider the following words:

$$\alpha=xab \qquad \beta=byx \tag{14.5.51}$$

let us define h such that it sends x on b, y on a, a on a, b on b. Therefore we have well:

$$h(\alpha)=h(xab)=bab \qquad h(\beta)=h(byx)=bab \tag{14.5.52}$$

and we will always have for every couple:

$$(\alpha,\beta)\rightarrow h(\alpha)=h(\beta) \tag{14.5.53}$$

D5. A solution h is said to be a "cyclic solution" if there exists a word w (belonging to $\mathcal{A}$) such that $h(x)\in w^E$ (considering the word itself as an alphabet therefore) for any variable x.

14.5.4.4 Codes

Definition (#14.5.621): We name "code" any part $\mathcal{C}$ of a free monoid $\mathcal{A}^*$ that satisfies the following condition for any (word) $x_1,\ldots,x_n,y_1,\ldots,y_m\in\mathcal{C}$:

$$x_1x_2\cdots x_n=y_1y_2\cdots y_m \Longrightarrow n=m \quad \text{and} \quad x_i=y_i \text{ for all } 1\leq i\leq n \tag{14.5.54}$$

In other words, $\mathcal{C}$ is a code if every word of $\mathcal{C}^*$ (word composed of words) uniquely factorize into a product words of $\mathcal{C}$. When a set is not a code, general we see it quite easily.

✍**Examples:**

E1. The set (language) $\{a,ab,ba\}$ is not a code since the word aba can written both as product $a\cdot ba$ and as product $ab\cdot a$.

Remark

The simplest codes are the "uniform codes". These are sets whose all words have the same length (which means that since each word is different, the combination of words can hardly differ).

E2. The set $\mathcal{A}^*$ of the words of length n is a code, if $n\geq 1$. The ASCII code that associates to some characters binary words of length 7 (see ASCII table) with some characters is an example of uniform code.

E3. The base of the DNA $\{A,T,C,G\}$ is a uniform code of length 1. However what defines DNA are the sequences of pairs, and the only canonical pairs of DNA should be $\{AT,TA,GC,CG\}$ that is also a uniform code of length 2. However no human DNA ever has been observed as perfect, incorrect bases are always present so that we can observe the following pairs in reality $\{AT, TA, GC, CG, AA, GG, AG, GA, CC, TT, CT, TC, AC, CA, GT, TG\}$ (i.e. all combinations), that is a uniform code of length 2.

During protein synthesis (translation), the cell reads messenger RNA (mRNA) in non-overlapping sequences of three nucleotide bases at a time, known as "codons". With 4 available bases and a codeword length of 3, the total set of codewords contains $4^3 = 64$ distinct triplets. It is observed experimentally that different codons give the same amino acids making the code degenerate or non-injective!

Therefore DNA is not a "code" but a "degenerate code"!

Furthermore, because the DNA sequence lacks explicit boundary delimiters between words, decoding depends strictly on a fixed reading frame anchored by an initiation and stop signal. Inserting or deleting a single base shifts the frame and changes every downstream codeword (a frameshift mutation). As DNA transcription doesn't possess any error correcting code (see page 7152) - like we would have expect if an all knowing deity had created life (...) - this can lead sometimes to serious malformations.

14.5.4.4.1 Prefix codes

Definition (#14.5.622): A "prefix code" is a type of code system (typically a variable-length code) distinguished by its possession of the "prefix property", which requires that there is no whole code word in the system that is a prefix (initial segment) of any other code word in the system.

Prefix codes are also known as "prefix-free codes", "prefix condition codes" and "instantaneous codes". Although Huffman coding is just one of many algorithms for deriving prefix codes, prefix codes are also widely referred to as "Huffman codes" (see further below), even when the code was not produced by a Huffman algorithm.

Using prefix codes, a message can be transmitted as a sequence of concatenated code words, without any out-of-band markers or (alternatively) special markers between words to frame the words in the message. The recipient can decode the message unambiguously, by repeatedly finding and removing sequences that form valid code words. This is not generally possible with codes that lack the prefix property

Remarks

R1. The variable-length Huffman codes, country calling codes, the country and publisher parts of ISBNs, the Secondary Synchronization Codes used in the UMTS W-CDMA 3G Wireless Standard, and the instruction sets (machine language) of most computer microarchitectures are prefix codes.

R2. Prefix codes are not error-correcting codes. In practice, a message might first be compressed with a prefix code, and then encoded again with channel coding (including error correction) before transmission.

The Morse codes encodes the letter `E`, the most frequent, with a '.' And the letter `Y`, more rare, by '-.–': this is an example of a variable length code, which makes it possible to represent the most frequent letters or words by shorter words.

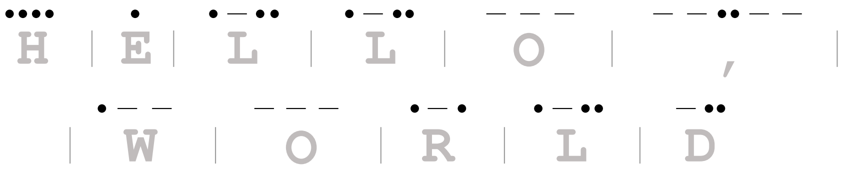


Figure 14.354: 'Hello World' in Morse code

An important property is the uniqueness of the decoding (injective application), a problem that does not arise for codes of constant length. It can be solved, but too costly, when a special symbol separates two successive words of the code (the "blank" in the case of the Morse code). We can therefore not use such a non-constant length code if no word is the prefix of another code word. And as the reader has probably understand it now, a code with this property is named a "prefix code".

✍**Example:**

Suppose we decide on a variable-size code convention, which matches, among other things, the following values:

Character	**Code**
0	11
2	11010
12	00
127	0111100
255	0100

Let us suppose that we have to decode the sequence:

$$1101000111100$$

Several interpretations (factorization) are then possible:

$$1101000111100 = 11\;0100\;0111100 = 0\;255\;127$$

or:

$$1101000111100 = 11010\;00\;11\;11\;00 = 2\;12\;0\;0\;12$$

And now we are very embarrassed! With several equivalent possibilities between which one can not decide, one is incapable of retranscribing the initial code.

The problem that has arisen here is that some codes are the beginning of other codes. Here, "11" is the code of the number 0, but it is also the beginning of "11010", code of the number 2. Hence the ambiguity!

We then better understand the purpose and the name of "prefix codes". Thus, in order for there to be no ambiguity at the time of the decoding, we must absolutely have a prefix code if the code is not of constant length.

✍**Example:**

The set:

$$X = \{ab, ababa, baa\}$$

is a code. Here, knowledge of the beginning of a possible code $ababa$ does not yet make it possible to know whether the decomposition begins by $ab \cdot ab \cdot ab \cdot a$ or by $ababa \cdot ba$. It is only after reading the next letter (not indicated in this example) that we know if the decomposition starts with ab (if the letter is b) or by $ababa$ (if the letter is a)

Definition (#14.5.623): A code is with "finite decryption delay" if there exists an integer d such that, whenever a message w begins with $p=x_1x_2\ldots x_{d+1}$ with $x_1,x_2,\ldots,x_{d+1}\in X$ then the complete factorization of w begins with x_d. It is therefore after a "delay" of d code words that we can affirm that the first word found is the right one (as in the example above that is a 8 finite decryption delay code).

✍**Examples:**

E1. The code:

$$X=\{a,ba,bb\} \tag{14.5.55}$$

has therefore a delay $d=0$.

E2. The code:

$$X=\{ab,ababa,baa\} \tag{14.5.56}$$

has therefore a delay $d=2$.

14.5.5 Linguistic algorithms

Let us put into practice what has already been seen so far in order to support us a little on "useful" concrete stuff!

14.5.5.1 Huffman algorithm

Let us first recall that in computing, we decide to encode an integer that has a value between 0 and 255 by a sequence of 8 binary digits (or "bits" in English, valued 0 or 1), also named "byte" (whose maximum value is equal to 2^8).

Even if there is a mathematical logic in the way of associating an 8-bit binary number to an integer between 0 and 255 (see section Numerical Methods page 6274) we can imagine any coding of the type:

Integer	Corresponding unique byte
...	...
138	10001010
139	10001011
...	...

in fact the correspondence can be any one, dictated by our imagination, as long as each integer between 0 and 255 is assigned to a fixed length binary code and only one. Once a correspondence is fixed, it is enough to take it as a convention.

The byte defined according to this convention is the basic unit of data storage. Any computer file is a sequence of bytes arranged in a defined order. The size of the file is simply the number of bytes that constitute it. The kilobyte (KB) corresponds to 1024 (not 1000) bytes, the megabyte (MB) to 1024×1024 bytes.

It should be noticed that this representation in base 2 is only a convention! Other conventions are possible, which would be equally appropriate if everyone agrees to use the same convention.

The problem we are asking ourselves is: would there be another way of coding the numbers, perhaps less logical but more judicious, in such a way that the size of the same file rewritten according to the new convention would be smaller?

The binary encoding convention is ultimately very democratic: whether you are a 0 or a 255, we allocate you 8 bits anyway to be able to code you. In other words, each possible input (a number between 0 and 255) is encoded on 8 bits. This is a fixed size encoding.

From the point of view of our problem (data compression), it would not matter if each of the possible values (0...255) were represented as frequently as the others. But in general this is not the case.

For example, see below the parsing of Wordpad.exe file (see your Accessories folder in your Microsoft Windows operating system[87]...). In this plot, on the abscissa as on the ordinate are the possible values of a given octet (hence 0 ... 255). On the diagonal, at the abscissa and corresponding ordinate, the size of the circle is proportional to the number of bytes having this value in the file:

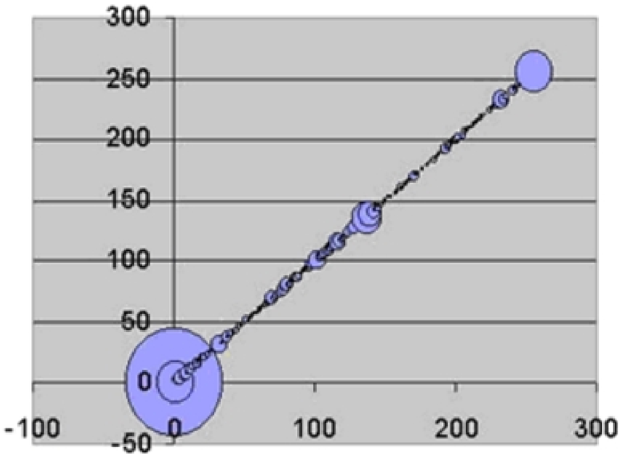

Figure 14.355: **Analysis of the byte distribution of a the Wordpad.exe file**

We see clearly that the values 0, 128 and 255 are much more frequent than the others!

As an indication, here are some values:

---

[87] This plot dates from they year 12001 (holocene calendar)... so its rendering quality is very bad. We will do it again when we will have the time

Value	**Count**	**Frequency**
0	71891	34.4%
2	1119	0.53%
128	1968	0.94%
130	79	0.038%
255	10422	4.99%

We will now decide of a variable-sized coding convention, which represents a value that is frequent by a small number of bits, and an uncommon value by a large number of bits.

We will now decide on a variable-sized coding convention, which represents a value that is frequent by a small number of bits, and an uncommon value by a large number of bits.

For example, 0 will now be represented by the sequence "11" (when before it was "00000000"), 128 by "1011010" (when before it was "10000000"), 255 by "0100" (when before it was "11111111"), etc.

Given that 0 represents almost one third of the file, we have gained a considerable place by coding it on two bits instead of eight! And same for the other frequent values...

Therefore "Huffman algorithm" is a recipe for generating a variable-length prefix code from the frequency table of a sequence of values. So, if you have followed the theory so far, it is a solution to our problem.

Suppose that our file is extremely simple, consisting of a single french word (*unconstitutionally*):

`anticonstitutionnellement`

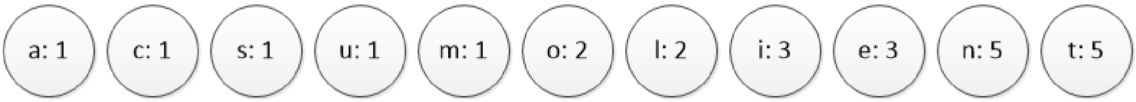
There are 25 characters in this file. Each character being encoded by an 8-bit octet (ASCII encoding), this means 25 bytes, or 200 bits! Let's see what we can do with that.

First let us render the table of frequencies:

Letter	**Count**
a	1
c	1
s	1
u	1
m	1
o	2
l	2
i	3
e	3
n	5
t	5

All other bytes (strings) have a null frequency: they are not represented in the file.

Now we create a "terminal node" for each entry of the array:

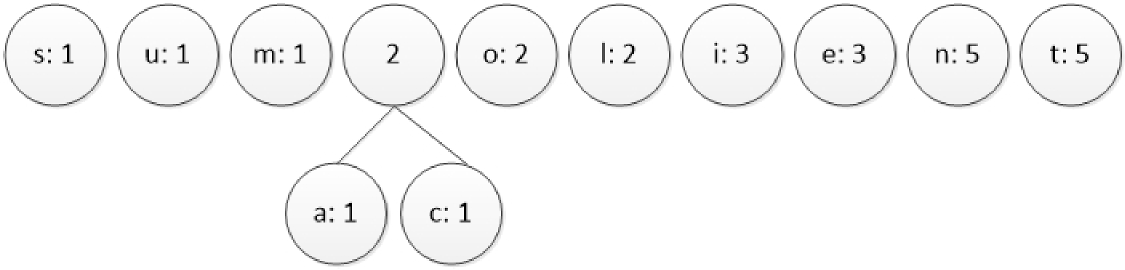


a: 1
c: 1
s: 1
u: 1
m: 1
o: 2
l: 2
i: 3
e: 3
n: 5
t: 5

What makes for us now 11 trees containing only one knot each.

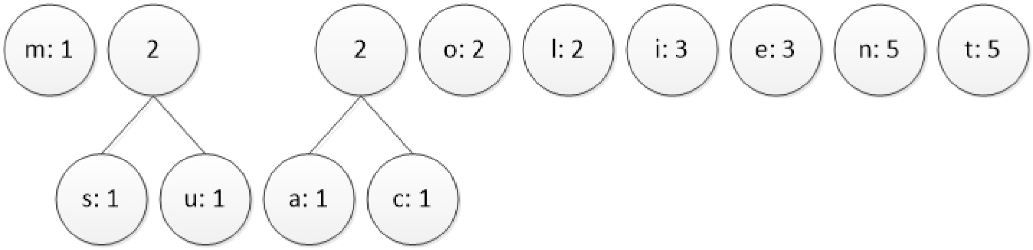
We now start an iteration: each time we delete the two trees on the left and replace them with a "sum tree". The new tree is inserted in the list in ascending order, and is repeated until there is only one tree left. Therefore we get:

- First iteration:



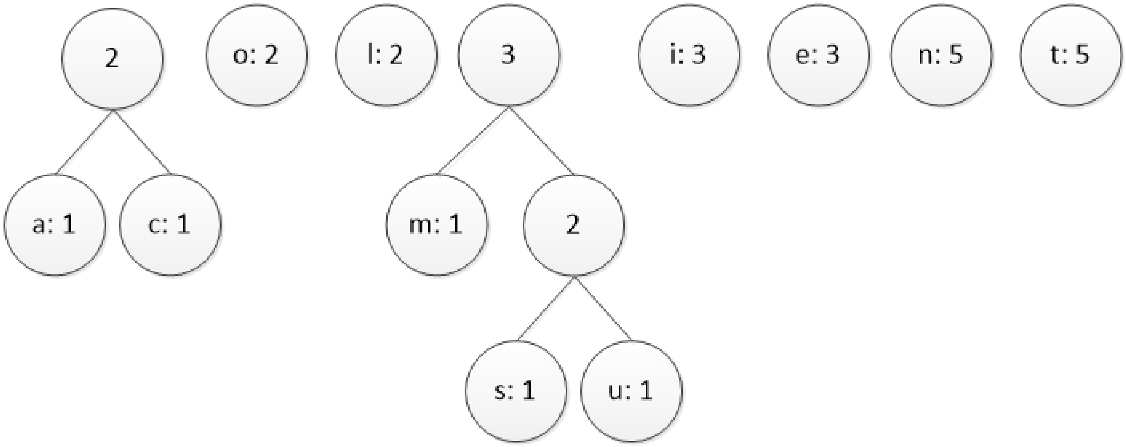
s: 1
u: 1
m: 1
2
o: 2
l: 2
i: 3
e: 3
n: 5
t: 5
a: 1
c: 1

- Second iteration:



m: 1
2
2
o: 2
l: 2
i: 3
e: 3
n: 5
t: 5
s: 1
u: 1
a: 1
c: 1

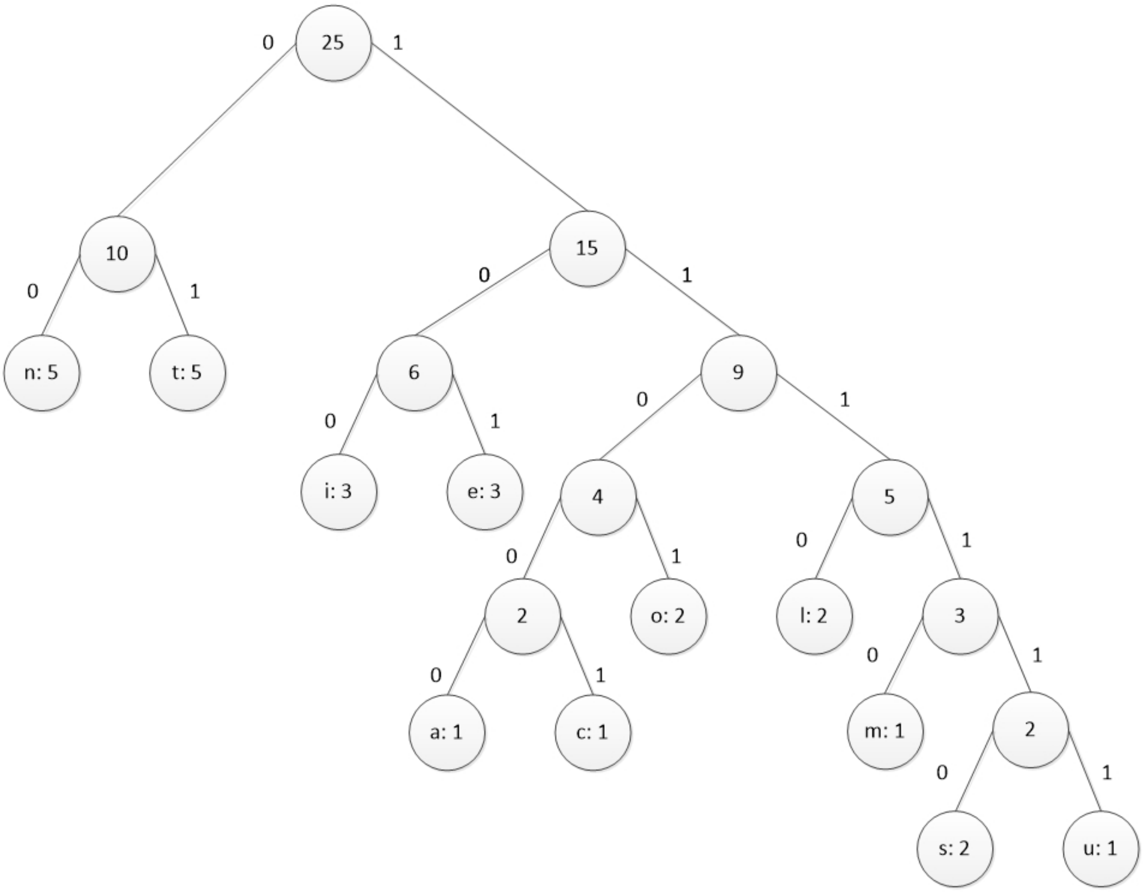
- Third iteration:



2
o: 2
l: 2
3
i: 3
e: 3
n: 5
t: 5
a: 1
c: 1
m: 1
2
s: 1
u: 1

- ....

...and the final tree is:



25
0
1
10
15
0
1
n: 5
t: 5
0
1
6
9
0
1
i: 3
e: 3
0
1
4
5
0
1
2
o: 2
0
1
l: 2
3
0
1
a: 1
c: 1
0
1
m: 1
2
0
1
s: 2
u: 1

And that's it!

Now, the associated code to each letter is none other than the path to the corresponding terminal node from the root, noting 0 for each left branch and 1 for each right branch.

Finally:

Letter	Huffman binary code
`n`	00
`t`	01
`i`	100
`e`	101
`a`	11000
`c`	11001
`o`	1101
`l`	1110
`m`	11110
`s`	111110
`u`	111111

And here is now, transcribed with our new code, the starting word:

`110000001100110011101001111100110001111111011001101000010111101110101111101010001`

which makes 81 bits, instead of 200 at the beginning! This corresponds to a compression ratio of almost 60%.

The fact of having generated code using a binary tree ensures that no code can be the prefix of another one. You can verify that using the encoding table, there is no ambiguity possible to decode our compressed word! This is why the Huffman algorithm is in many compressed formats (for example the famous MP3 for audio encoding).

14.5.5.2 Sardinas and Patterson algorithm

When we have to deal with long codes, the difficulty is to check whether the code is really one... In order to do this, we can use the Sardinas and Patterson algorithm (the proof of this algorithm will be done during the next update of this section of the book).

In coding theory, the Sardinas–Patterson algorithm is a classical algorithm for determining in polynomial time whether a given variable-length code is uniquely decodable, named after August Albert Sardinas and George W. Patterson, who published it in 11953 (holocene calendar).

To do this check, we construct a graph $G(X)=(P,U)$, where P is the set of non-empty prefixes (according to the definition of "prefixes" given earlier above) of words of X, and U the set of pairs (u,v) such that one of the following possibilities is met:

P1. $uv\in X$ (by eliminating duplicate pairs if necessary)

P2. $v\notin X$ and it exist $x\in X$ such that $ux=v$

✍**Example:**

For $X=\{a,bb,abbba,babab\}$, the set P contains, in addition to X (which are prefixes of ε), the words $\{b,ab,abb,abbb,b,ba,bab,baba\}$ (respectively prefixes of $\{b,bba,ba,a,abab,bab,ab,b\}$).

First we see immediately that the set of $X=\{a,bb,abbba,babab\}$ is not a code because:

$$a\cdot bb\cdot babab\cdot abbba=abbba\cdot babab\cdot bb\cdot a \tag{14.5.57}$$

Now the pairs of U are for the first possibility P1:

$$(b,b),(abbb,a),(abb,ba),(ba,bab),(bab,ab),(baba,b) \tag{14.5.58}$$

and for the second possibility P2:

$$(a,abb),(ab,abbb),(b,ba),(bab,baba) \tag{14.5.59}$$

for which the x which is used to form the v is respectively bb, bb, a, a.

The Sardinas and Patterson graph will therefore be:

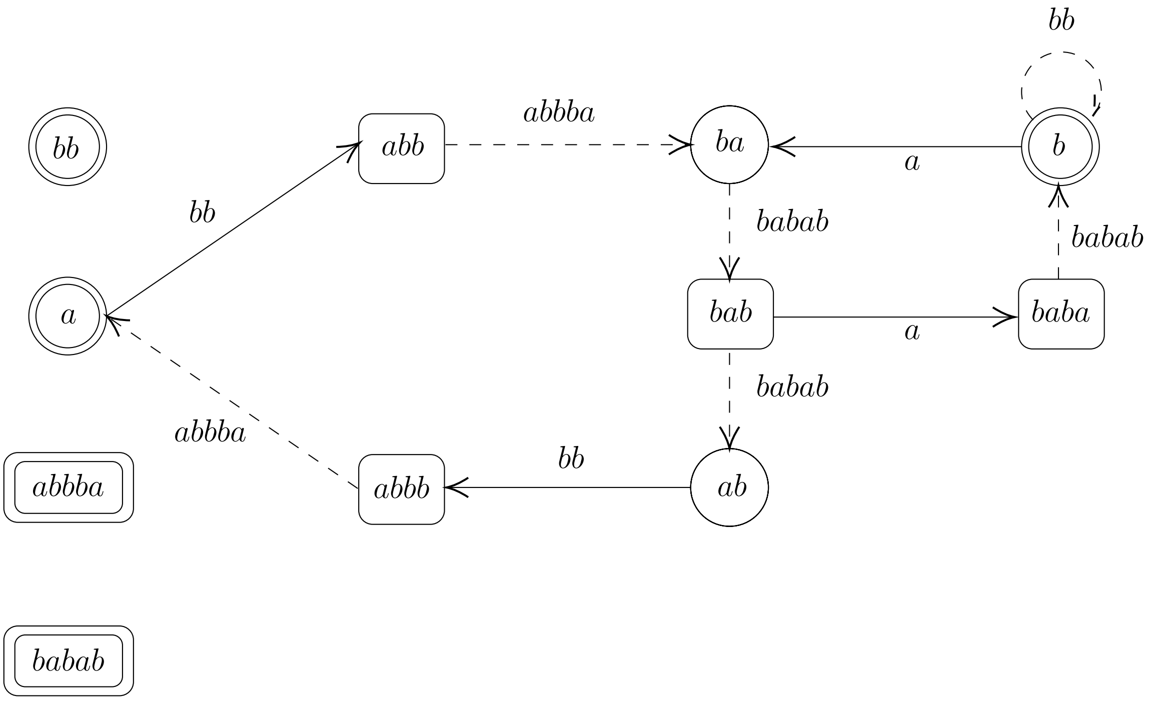


Figure 14.356: **Sardinas and Patterson example graph**

where the vertices corresponding to the words of X are doubly circled. The label of each arc is a word of the set X. The "crossed arcs" are traced in dotted lines and the "front arcs" in solid lines. If the arc (u,v) is crossed, then the label is uv, otherwise it is the word x such that $ux=v$.

In our example above, there is a path from a to a. By virtue of the Sardinas and Patterson theorem (which we will proved in the next update of this section), the set X is not a code (a single and unique path between any two vertices of X is enough).

The set X is a code if and only if there is no non trivial path in $G(x)$ of a vertex of X to a vertex of X (in other words, a set X is a code if and only if there is only the one and only trivial path leading from one vertex of X to another one - this vertex may be the same as in the previous example).

14.6. Cryptography

CRYPTOGRAPHY is one of the disciplines of cryptology endeavouring to protect messages (ensuring confidentiality and / or authenticity) that two people wish to share through an insecure channel often thanks to secrets or keys.

The history of cryptography is already long and exciting (since it is a kind of "game"). We report its first use in Egypt 4,000 years ago. However, for centuries, the methods used were often remained very primitive. Moreover, its implementation was limited to the needs of the army and diplomacy. Thus, encryption methods and cryptanalysis (code breaking) experienced an important development during the Second World War and had a profound influence on the course of it.

At the end (especially!) of the 120th century (holocene calendar), with the proliferation of computers and electronic communications media, it became increasingly important to use secret codes for transmitting data between the military or private organizations. Thus, engineers have had to look at this same time solid numerical methods whose implementation and use was within reach of almost everyone (nation, enterprise and individual) while ensuring that external attacks required tools out of reach of an individual or group of individuals equipped with standard and high-performance IT tools (in computing power). Engineers and researchers then plunged into the mathematical tools to search for satisfying these specifications and the most known systems, mathematical theories which were adopted had over 200 years old (apart quantum cryptography).

The growth of cryptographic technology has raised a number of legal issues in the information age. Cryptography's potential for use as a tool for espionage and sedition has led many governments to classify it as a weapon and to limit or even prohibit its use and export. In some jurisdictions where the use of cryptography is legal, laws permit investigators to compel the disclosure of encryption keys for documents relevant to an investigation. Cryptography also plays a major role in digital rights management and piracy of digital media.

Steganography techniques (art of concealing a message in another one or in an image) however must be preserved because nothing tells us that computing power will still be available in times of war. It should be noted also that the steganography deployed wealth of imagination. Note for example: the permutations of letters, special and subtle formatting of characters, use of synonyms, hidden messages in text or comma behind a stamp, inside shots chess (hence the fact that these games were banned by the USA for some years after the attack on Pearl Harbor), in pictures / drawings, musical scores, etc. All of these techniques make that during the Second World War, the office of censorship in the United States occupied 10,000 full-time employees that analysed the mail of citizens, classified ads, radio text, etc.

Remarks

R1. To address the foundations of the theory of cryptography, we advise the reader to have read at first and at least in diagonal the section on Number Theory, on Set Theory, on Numerical Methods (especially the subsection on computational complexity), on Numerical Systems , on Statistical Mechanics (where information theory can be found) and for the part about quantum cryptography: the section of on Quantum Computing.

R2. We must remain aware that cryptography is more an engineer science than physicist science (except with quantum cryptography) and we must then not be so surprised to see some algorithms like fallen just from nowhere and adopted by industry because they just work almost well... Furthermore, it is also certain that only a few years after writing this text it will already be considered as obsolete (that is the art of engineering ... planned obsolescence).

14.6.1 Cryptographic systems

Definitions (#14.6.624):

A "cryptographic system" is composed of:

D1. A finite set P named "space of clear texts".

D2. A finite set C named "space of encrypted texts".

D3. A finite set K named the "space of keys".

For each key k, we seek an encryption function e_k:

$$e_k : P \mapsto C \tag{14.6.1}$$

and a deciphering (decryption) function d_k:

$$d_k : C \mapsto P \tag{14.6.2}$$

such as (see section Set Theory page 182):

$$\boxed{e_k \circ d_k = \mathrm{Id}_P} \tag{14.6.3}$$

In other words, these two functions must be injective!

To achieve this, two types of cryptographic techniques are mainly distinguished, encompassing almost all known modern encryption methods of the 120th century (for mathematical details see below):

1. The first concern cryptosystems with "symmetrical secret key".

Remark

Public keys often refer to the DES protocol (see below) for: Data Encryption System.

2. The second concerning encryption systems with "asymmetric public key".

Remark

This type of key often refers for example to the RSA protocol, the names of those to whom we awarded the Development: Rivest, Shamir and Adleman. They are widely used thanks to their rapid time encryption and decryption as well as their high entropy (see definition below).

By nature, these two types of keys are very different. Let us try to understand the reasons:

A symmetric encryption means a system where the key used in the encryption operation is that used in the deciphering operation. In this case, during a secure exchange (assumed to be as), both sides of the correspondence must share a same secret: the used key or "session key".

An asymmetric encryption designates an encryption system in which the key used for encryption (private key of the sender) differs from that used for decryption (recipient's private key). The only exchange that exists between members of the group is the public key, which allows each member to adjust its encryption based on the private key of the other members (among the many who have asymmetric systems been proposed, one of the most widespread in the early 121st century is the RSA).

The symmetric key ciphers are traditionally classified into two groups: "stream ciphers" and "block ciphers".

Definitions (#14.6.625):

D1. A "block cipher" is an encryption algorithm that encrypts a fixed size of n-bits of data - known as a block - at one time. The usual sizes of each block are 64 bits, 128 bits, and 256 bits. So for example, a 64-bit block cipher will take in 64 bits of plaintext and encrypt it into 64 bits of ciphertext. In cases where bits of plaintext is shorter than the block size, padding schemes are called into play. Majority of the symmetric ciphers used today are actually block ciphers. DES, Triple DES, AES, IDEA, and Blowfish are some of the commonly used encryption algorithms that fall under this group.

D2. A "stream cipher" is an encryption algorithm that encrypts 1 bit or byte of plaintext at a time. It uses an infinite stream of pseudorandom bits as the key. For a stream cipher implementation to remain secure, its pseudorandom generator should be unpredictable and the key should never be reused. Stream ciphers are designed to approximate an idealized cipher, known as the One-Time Pad. RC4, which stands for Rivest Cipher 4, is the most widely used of all stream ciphers, particularly in software. The cypher Engima machine of the second World Was is also a famous application of stream cipher.

✍**Example:**

Without going in the mechanical and electrical description of Enignma, the reader has just to know that the second version of the Enigma cypher machine had first a box 5 rotors with 26 start positions! The user had to choose 3 of theses 5 rotors and put them in a given position (position order has an importance!) in the machine.

So we have:

$$A_5^3=\frac{5!}{2!}=5\cdot 4\cdot 3=60 \tag{14.6.4}$$

combinations to put 3 rotors in a given order choosing among 5 rotors (5 rotors for the first position, multiplied the 4 remaining rotors for the second position and so on...).

After the Enigma user had to choose among on of the 26 position of each rotor. Then the number of starting positions possibilities is equal to:

$$26\cdot 26\cdot 26=17,576 \tag{14.6.5}$$

Finally the business and military version of the Enigma machine had something extra: plugboard.

This plug-board has 10 wires that connect two letter together among 26 letters (there $2\cdot 20$ letters combine together). The combination is therefore:

$$\frac{26!}{6!10!2^{10}}=150,738,274,937,250 \tag{14.6.6}$$

Indeed, we have $26!$ combinations of letters, but as there are 10 cables for therefore 20 letters we don't care about the combinations of 6 of them. Hence the division by $6!$. We divide by $10!$ as for all the remaining combination of letters we can use only $10!$ of them. Since we don't care about the direction of the cables (from A to B or B to C) and that we have 10 cables, we must divide 10 times by 2 and this is equivalent as dividing by 2^{10}.

So finally the total is:

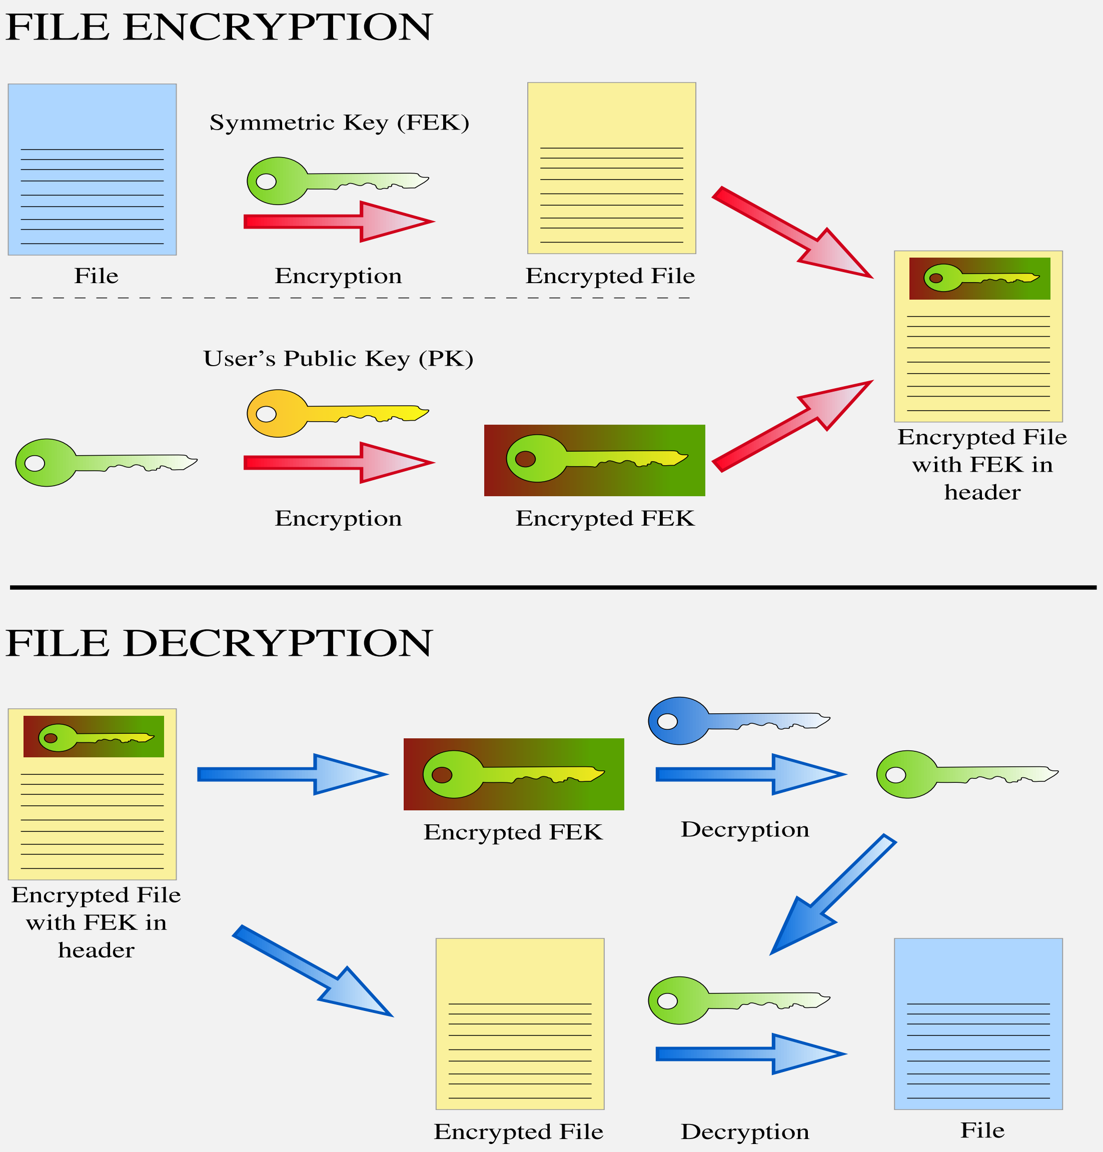
$$60\cdot 17,576\cdot 150,738,274,937,250=158,962,555,217,826,360,000 \tag{14.6.7}$$

This is the total number of ways you can set the Enigma machine...

Remarks

R1. In 12001 (holocene calendar), Microsoft Internet Explorer (Microsoft's web browser in this time) worked with a 1024-bit asynchronous system certified by a synchronous system and Adobe Acrobat (PDF) in 12004 (holocene calendar) with an AES (Advanced Encryption System) of 128 bits for the low protection as well in the years 12010-12015 (holocene calendar) the iPhone 4S and 5.

R2. Microsoft Windows Enterprise and its E.F.S. system (Encrypting File System) uses a symmetric key (to encrypt the file) named "File Encryption Key" and asymmetric cryptography to encrypt the symmetric key in the file header as shown below (the key being updated regularly via Windows Update root certificates):



FILE ENCRYPTION
Symmetric Key (FEK)
File
Encryption
Encrypted File

Encrypted File with FEK in header
Encrypted FEK
Decryption
Encrypted File
Decryption
File

Figure 14.357: **Principle of F.E.K. in Microsoft Windows XP (source: Wikipedia)**

However, the cryptography keys for EFS are in practice protected by the user account password, and are therefore susceptible to most password attacks. In other words, encryption of files is only as strong as the password to unlock the decryption key.

These methods are still decipherable, provided that the interceptor has enough time and paper/money (excepted at this date for quantum encryption).

Here is a small summary table of broken keys and their respective size for both conventional systems (the years are given based on the holocene calendar):

Secret key (symmetric system) exhaustive search		**RSA public key (asymmetric system)** exhaustive search	
Number of bits	Year	Number of bits	Year
40	Broken in 11995	256	Broken in 11985
56	Broken in 11998	512	Broken in 11999
64	Brokable	1024	Broken in 12010
128	Brokable in ∼12100	2048	Brokable in ∼2100
256	?	4096	?

Table 14.57: **Key systems and recent broke**

14.6.1.1 Kerckhoffs' principle

The primary function of cryptography is therefore to ensure the confidentiality of information exchange. Two parts of a confidential exchange will first agree on a secret convention to write their messages, and if they have carefully chosen, no one else should be able to enter their exchange.

If the secrecy of such agreements is possible from a few isolated individuals for a limited period, it is inconceivable at large scale and for a fairly long period. This is what Auguste Kerckhoffs understood when establishing the basic principles of practical cryptography which requires a fundamental principle encryption system "that does not require secrecy, and which can conveniently fall into the hands the enemy".

The six postulates of Kerchoffs are:

1. The system must be practically, if not mathematically, indecipherable;
2. It should not require secrecy, and it should not be a problem if it falls into enemy hands;
3. It must be possible to communicate and remember the key without using written notes, and correspondents must be able to change or modify it at will;
4. It must be applicable to telegraph communications;
5. It must be portable, and should not require several persons to handle or operate;
6. Lastly, given the circumstances in which it is to be used, the system must be easy to use and should not be stressful to use or require its users to know and comply with a long list of rules.

The second postulate, known today as the "Kerckhoffs principle" states that the security of an encryption system is not based on the secrecy of the procedure, but only on one parameter used when its implemented: the key. This key is the only secret of the Exchange Agreement.

This principle, however, was reformulated by Claude Shannon: "the enemy knows the system". This formulation is known as the "Shannon's maxim". This is the principle usually adopted by cryptologists, as opposed to the security through obscurity.

14.6.2 Traps

Sometimes there are what we name "trap doors" in public and secret keys. This is because when generating the key, which has to be done randomly within certain predefined theoretical constraints, the random generator may have an issue (the issue is sometimes voluntary on the part of the supplier of the material for spy purpose...).

In the secret keys, the traps are located at the level of the "key's entropy" (see section Statistical Mechanics page 3658), directly linked to the entropy of the random generator. We can simplistically define the entropy of a key generator by the average optimal binary questions (that is to say giving rise to the type of answers Yes / No) that we need to ask someone knowing a key produced by this generator to determine it. More the entropy of a key generator is high, higher is the number of questions we need to determine the key. Conversely, the smaller is the entropy, the lower are the questions, so that the search of a key is facilitated.

The introduction of traps in the asymmetric key systems is much more difficult, since this type of key already has intrinsic mathematical structure: their construction is not due to chance but is the result of mathematical rules. Chance is here in the choice of large prime numbers used. The fact that asymmetric systems can be easily calculated, but they are difficult to reverse are sometimes named "trapdoor functions".

✍**Example:**

An example of a simple mathematical trapdoor is "6895601 is the product of two prime numbers. What are those numbers?" A typical solution would be to try dividing 6895601 by several prime numbers until finding the answer. However, if one is told that 1931 is one of the numbers, one can find the answer by entering "6895601 ÷ 1931" into any calculator. This example is not a sturdy trapdoor function – modern computers can guess all of the possible answers within a second – but this sample problem could be improved by using the product of two much larger primes.

Therefore if a random generator that generates prime numbers is biased (see section Statistics page 818), this bias will facilitate the research of a trapdoor.

Definition (#14.6.626): A "trapdoor function" is a function that is easy to compute in one direction, yet difficult to compute in the opposite direction (finding its inverse) without special information.

Remarks

R1. Functions related to the hardness of the discrete logarithm problem (either modulo a prime or in a group defined over an elliptic curve) are not known to be trapdoor functions, because there is no known "trapdoor" information about the group that enables the efficient computation of discrete logarithms.

R2. Trapdoor must not to be confused with a "backdoor" as this latter is a deliberate mechanism that is added to a cryptographic algorithm or operating system, for example, that permits one or more unauthorized parties to bypass or subvert the security of the system in some fashion.

14.6.3 Secret-key encryption system

Definition (#14.6.627): The "single-use encryption" is a secret key encryption algorithm proved unconditionally secure. Properly used (and that's an important point), it provides an unbreakable encryption in reasonable time.

The theoretical basis of this encryption system are:

Given a message M in binary form to be transmitted between people A (creator and originator of the message M) and B (reader and receiver). We generate a large amount of bits if possible "truly randomly" forming a secret key K of same size as the message to be transmitted (computer programs, deterministic by nature, can not generate truly random bits).

This key will be sent to B by a channel supposedly safe ... A given time after the transmission of this key A will encode his message into C by performing the operation:

$$C = K \star M \tag{14.6.8}$$

where $\star$ is an operator that must satisfy to a group law (see section Set Theory page 421) on a finite set (that contains a limited number of items or "letters").

The idea in computing science is to use the XOR law (exclusive OR) denoted $\oplus$ for what will follow (see section Logical Systems page 7112) as it is enough as a group law (remember that a group is the smallest structure having an opposite - and is associative and having neutral element - that gives therefore the possibility to reverse the encoding process). Therefore:

$$C = K \oplus M \tag{14.6.9}$$

Finally, the sender A transmits the encrypted version of his message C by a route not necessarily secure. B can read the original message M by using the inverse operator $\oplus^{-1}$ (the XOR operator is its own inverse as we have proved it thanks to its truth table in the section of Logical Systems!!!!). So receiver B will do the following:

$$M = C \oplus K \tag{14.6.10}$$

Provided that the K has been generated totally randomly and that each bit of it has been used only once to encrypt the message, an interceptor gets no information about the clear message M if he intercepts C. Indeed, in these conditions, we can not establish any correlation between M and C without the knowledge of K.

Even with future ultra-powerful quantum computers, the problem is insoluble, because nothing connects the information which is available and the problem to solve. Consequently, the "single-use encoding" is an encryption algorithm "unconditionally secure". The proof of its security does not rely on unproven mathematical conjectures and decryption attempts of an interceptor with infinite computing power are futile.

However, each stage of encryption is a source of possible errors. Indeed, the key K may have been poorly developed. The slightest statistical deviation of K compared to the "real" random provides information on the clear message M from its encrypted version. This is why the K bits are to be used only once if possible.

Indeed, suppose that same key is used to encrypt messages of French language M_1 and M_2 an attacker manages to intercept the two corresponding encrypted messages. From C_1 and C_2 the interceptor and can easily obtain information about K and this because of language peculiarities (same for English). Indeed, since:

$$C_1 = M_1 \oplus K \qquad C_2 = M_2 \oplus K \tag{14.6.11}$$

then the interceptor knows a simple result that involves M_1 and M_2 without the key K:

$$C_1 \oplus C_2 = M_1 \oplus M_2 \tag{14.6.12}$$

as:

$$K \oplus K = 0 \tag{14.6.13}$$

(if necessary make the truth table to be convinced of this relation). Now, if M_1 and M_2 are in the same language, we will know, usually due to language redundancies (e.g. the letter "e" often appears in French), found from $C_1 \oplus C_2$ each of the two original messages (the work is though laborious without statistical automated tools).

✍**Example:**

Imagine that we want to send a little message M binary coded by 1101 and we generated a random key K that gave 0101.

Then we have:

$$C = M \oplus K = 1101 \oplus 0101 = 1000 \tag{14.6.14}$$

and therefore:

$$M = C \oplus K = 1000 \oplus 0101 = 1101 \tag{14.6.15}$$

Obviously in this kind of small situations we can guess M without much difficulty just by having C if there such like here only a single encryption step. This is why there are encoding patterns as we shall see now.

The main problem with this technique is the creation of a key as random as possible. To overcome this, mathematicians do pass the key through a series of nested functions, the result after many iterations, becomes "pseudo-random".

Building a pseudo-random iteration is one thing, building a pseudo-random bijection is yet another!!! Indeed, we need to decrypt the message later, which is why we absolutely need a bijective system (which has everything arrival element - encrypted message - matches a single starting element - decrypted message - and vice versa).

14.6.3.1 Feistel Schemes

Even if encryption algorithms, in this late 120th century (holocene calendar) and early 121st century (holocene calendar), are considered sufficient with a key having a finite number of bits, the goal remains the development that from a message M and a random sequence of digits, or at least that looks like, to build a key K to send an encrypted message C that can be decipher easily only by people knowing the key. Specifically, this target application is to construct or identify a function which, firstly, do correspond to each digit of M a digit C that seems to look random (but whose value depends in reality on the deterministic key) and, secondly, authorizing the reverse path (inverse function by the property of bijection), that is to say that from a digit C, we can uniquely trace back to the corresponding digit of M. We therefore would like to find a pseudo-random bijection function.

In the years 11950s (holocene calendar), the mathematician Horst Feistel has shown that a pseudo-random function transformed itself, by a relatively simple method, in bijection function. Today, the "Feistel cypher" is most commonly used in the secret key encryption systems and is also the basis of the DES (Data Encryption System). How does it work?

Here is the principle:

The initial message to be encrypted has a size of $2n$ bits. The split the original message M into two blocks (thus the Feistel Schemes belongs ton the family of "block cipher"), G and D, of equal length (G includes the first n bits and D the following) and we build the transformation φ that associates to G and D the numbers T and S such as:

$$S=D \qquad \text{and} \qquad T=G\oplus f_1(D) \tag{14.6.16}$$

where for reminder the $\oplus$ still represents the bit by bit XOR operation and where f_1 is any function, non-necessarily bijective, from n bits to n bit using the secret key K.

The transformation $\varphi(G,D)=(S,T)$ is indeed bijective, as we can go back in a unambiguous way starting form S and T to G and D by the operations:

$$D=S \qquad \text{and} \qquad G=D\oplus f_1(S) \tag{14.6.17}$$

Obviously we must not stop here, since the right side of the message, D, has not been encrypted, it is simply passed to the left. However, as φ is bijective, we can repeat the process. A Feistel scheme where we apply n times the function φ is named a "n-step pattern".

✍**Example:**

We will encrypt by the a two-step Feistel cypher a message consisting of 4 bits (thus $2^4=16$ possibilities of messages), what is equivalent to building a bijection from 4 bits to $4$bits from two functions f_1,f_2 of two bits to two bits. The functions f_1,f_2 have in input both: the message to encrypt and the secret key. We will assume that for some input key, these functions are:

Input	f_1	**Output**
00	$\rightarrow$	01
01	$\rightarrow$	11
10	$\rightarrow$	10
11	$\rightarrow$	01

Input	f_2	**Output**
00	$\rightarrow$	11
01	$\rightarrow$	00
10	$\rightarrow$	00
11	$\rightarrow$	01

Table 14.58: **Input/Output key matches by functions**

Let us notice that neither f_1 nor f_2 are bijections ($f_1(00)=f_1(11)=01, f_2(01)=f_2(10)=00$). For example, encrypt the message 1101. G designates the left part of the message to be encrypted, D the right part:

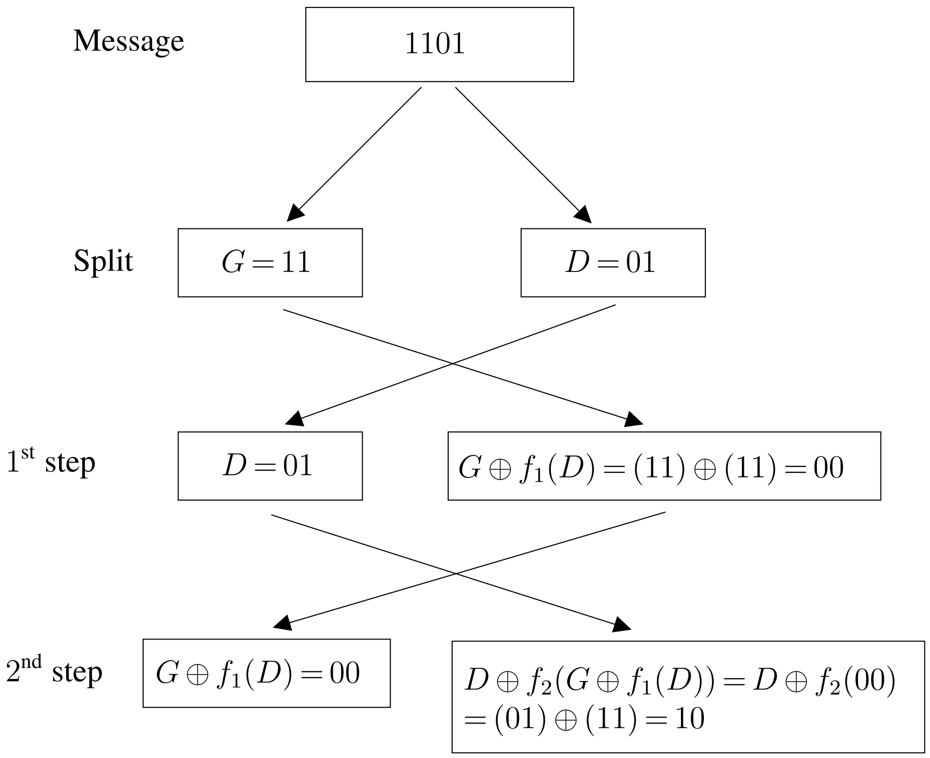

Figure 14.358: **Encryption of 1101 using the Feistel method**

The result is 0010. We will compute the image of the other 15 other possible messages and verify that there is an unambiguous correspondence between each message and its image by the Feistel scheme: we have constructed a bijection from two functions that are not bijective.

Quite complex theoretical results guarantee the cryptographic security of Feistel schemes starting from 4 steps when n is large enough and when the functions f_i are indistinguishable from truly random functions. In practice, rather than using 4 steps and functions f_i that look like random, it is generally preferred to use more steps and more simple functions f_i. After a few steps, the obtained bijection often becomes very difficult to distinguish from random bijections. And for parameters well chosen, we no longer know at all how to distinguish them from truly random bijections!!!

Most of the secret key encryption algorithms currently in this end of 120th century (holocene calendar) used in the civilian world are Feistel schemas. In particular, the DES (Data Encryption

System) algorithm which is a 16-step Feistel scheme as shown in the figure below and the Triple DES (TDES) algorithm which is a 48-step Feistal scheme and the Blowfish algorithm that will not be discussed here).

Remark

For example, there are, in some bank cards (at least in the beginning of this 121st century... according to holocene calendar), a DES key (or TDES since October 12001 according to holocene calendar) which provides proof of the legitimacy of the card between the bank's control center and the merchant's terminal in addition to Public part of a RSA key to make sure the user code is entered (control done by an internal chip on the card, which must then be manufactured in very secure premises).

Rigorously the Feistel scheme is a bit different because it involves keys, which we did not use in the example presented before. Here is a more detailed figure in what this Feistel scheme consists of (see figures below).

Principle of the diagram: A message to be encrypted is divided into blocks of 64 bits, each of which is divided into two 32-bit sub-blocks, the left block (G) and the right-hand block (D). At each iteration, the old right block becomes the new left block and the new right block results from the XOR operation of the old right block, whose bits are mixed by a confusion function, and of the previous left block. The iteration is repeated 16 times.

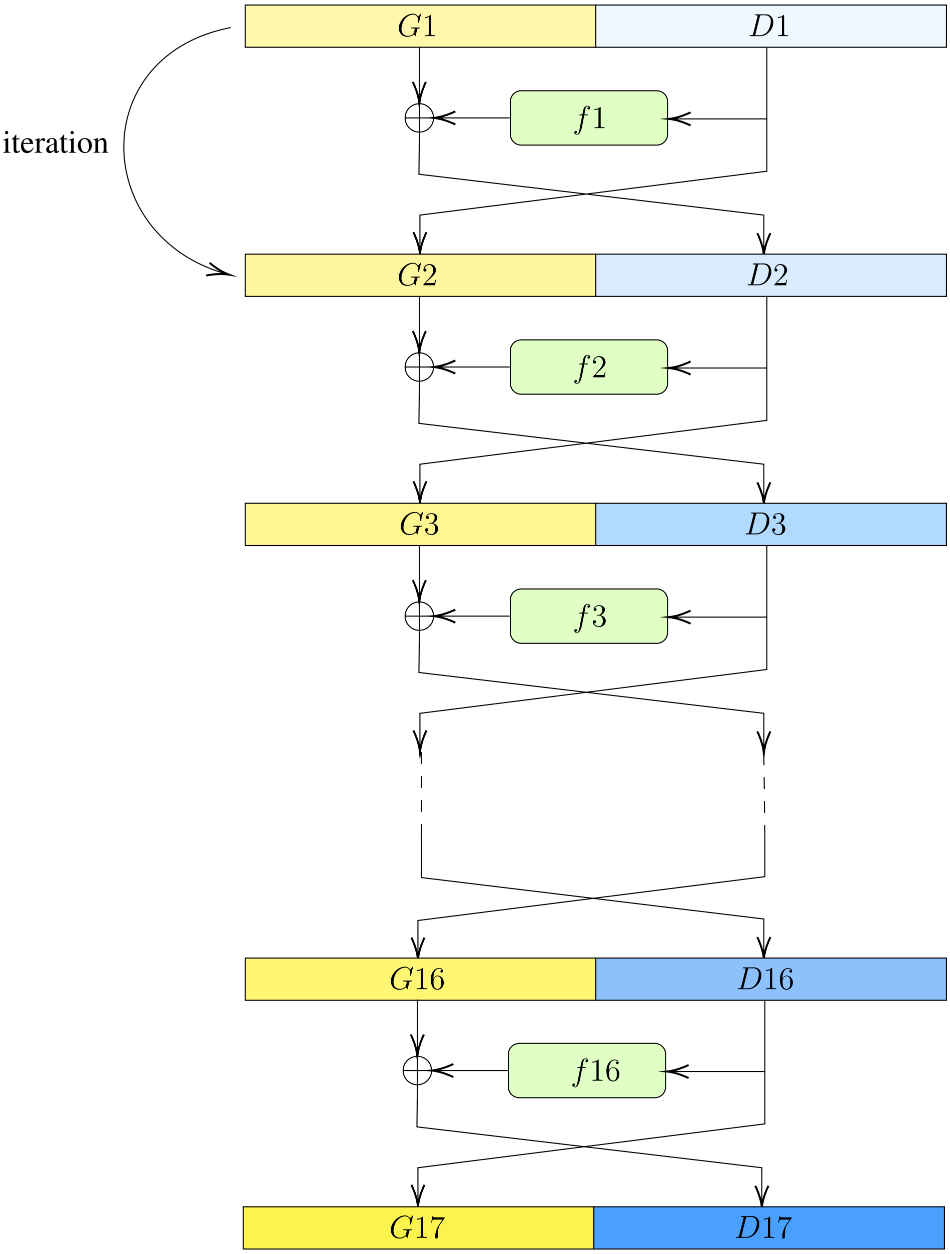

Figure 14.359: Feistel's scheme a little more realistic (source: ?)

The confusion function (**f**), which acts on the 32-bit blocks, mixes the bits according to the following processes (see the figure below):

- First, it transforms the 32-bit block into a 48-bit block by duplicating certain bits ("expansion").
- Then, it adds to this block a 48-bit ("token key") subkey extracted from the 56-bit secret key
- And then transforms each 6-bit set into 4 bits by local transformations (**S** transform)

The result is a 32-bit block which is finally mixed according to a fixed permutation.

14.6.4 Public key encryption

In 11975 (holocene calendar), W. Diffie and M. E. Hellman revolutionized the science of cryptography by proving the existence of a protocol that could not be deciphered by an interceptor unless the interceptor had large computer resources. The most fascinating in their method - the principle of which is still in use in this early 121st century (holocene calendar) - is that the code used does not require to hide the chosen method and can be applied repeatedly without any modification (Kerckhoffs principle). At their time, they simply created the concept of "public-key cryptography", or "asymmetric cryptography" (which we mentioned earlier in this section), an invention that sparked the emergence of a dynamic academic and industrial community.

Remark

Contrary to what one might think, public key cryptography has not relegated secret key cryptography to oblivion, on the contrary: these two types of cryptography are most often used in hybrid cryptosystems where the authentication of published keys is performed by a "certification authority".

Before describing the Diffie-Hellman protocol in detail, let us recall that the protocol of exchange of the "secret keys" was not reliable at that time (and is still not today) as it was transiting between the interlocutors, the element making it possible to encrypt and therefore decrypt the messages. In addition, even if only one key were to travel, anyone with sufficient computing power could break the code. Hence the need to change (misfortune more!) Periodically the keys (cryptoperiod). At least two solution are therefore available to us:

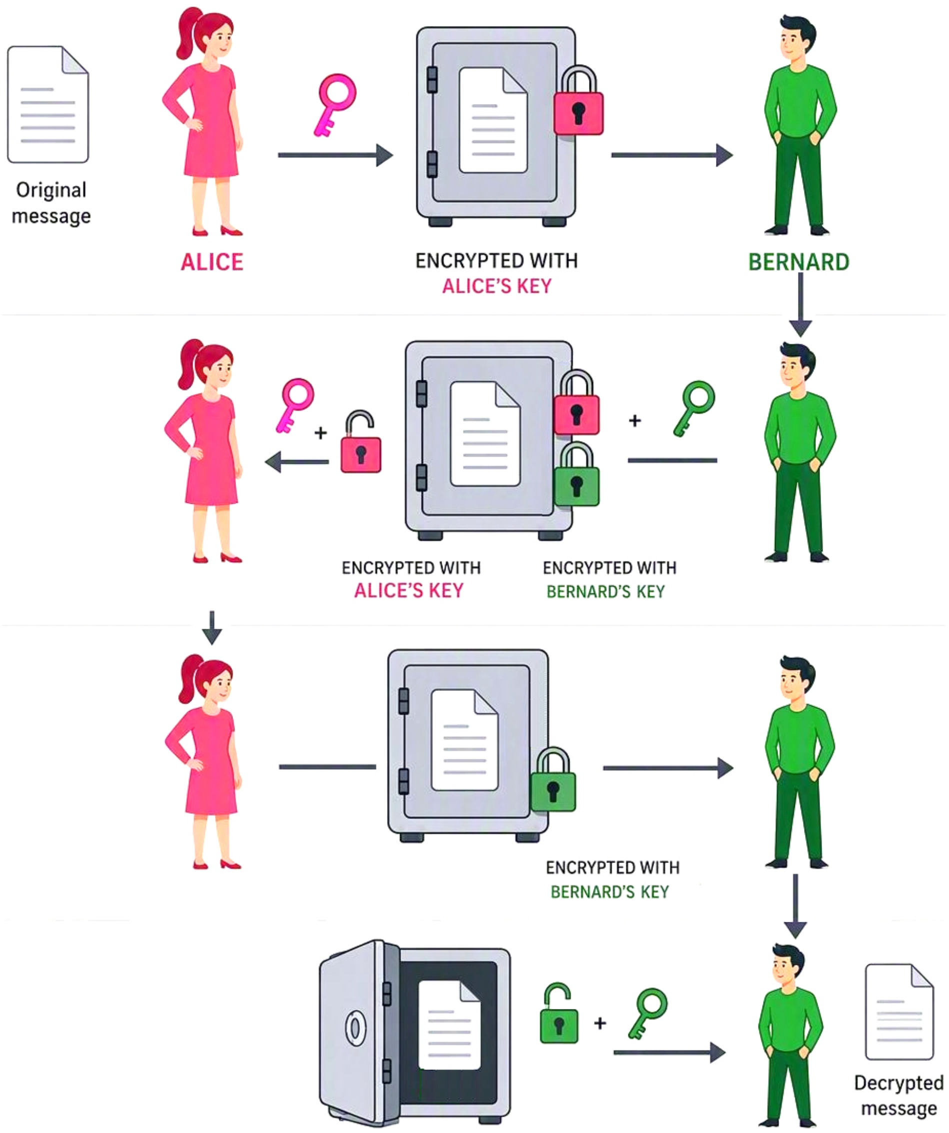
1. Do not exchange any key (it is possible but it is quite long as we will see in the figure below)

2. Exchange a secret key using a non-invertible mathematical function or at least very difficult to inverse (this is the Diffie-Hellman protocol that we will also see in a figure below).

Therefore Public key cryptography systems often rely on cryptographic algorithms based on mathematical problems that currently admit no efficient solution—particularly those inherent in certain integer factorization, discrete logarithm, and elliptic curve relationships. Public key algorithms, unlike symmetric key algorithms, do not require a secure channel for the initial exchange of one (or more) secret keys between the parties.

Because of the computational complexity of asymmetric encryption, it is usually used only for small blocks of data, typically the transfer of a symmetric encryption key (e.g. a session key). This symmetric key is then used to encrypt the rest of the potentially long message sequence. The symmetric encryption/decryption is based on simpler algorithms and is much faster.

Let us see what the first solution is and its blatant disadvantage:



Original message
ALICE
ENCRYPTED WITH
ALICE'S KEY
BERNARD
+
+
ENCRYPTED WITH
ALICE'S KEY
ENCRYPTED WITH
BERNARD'S KEY
ENCRYPTED WITH
BERNARD'S KEY
+
Decrypted message

Figure 14.361: **Principle of public key encryption**

Explanation: Alice and Bernard want to transmit a message on an unsecured line and without exchanging keys. To do this, Alice puts her letter in a chest that she closes with her key and sends it to Bernard. The latter returns the chest to Alice where he added his own padlock which he closed with his own key. When Alice receives the chest, she takes off her padlock and sends Bernard a chest that no longer includes her padlock but. The latter then only has to open the chest with his key to read the letter. This operation is safe and does not require exchange of keys. On the other hand, it requires several paths.

The principle of the public key must allow secure exchanges, without a secret key, in a single path. Bernard distributes widely copies of his public padlock. Alice gets one, but anyone could do the same. Alice places the message in the trunk and closes it with the Bernard code lock, then sends it the trunk (represented by the 5th transaction in the figure above). On receiving the trunk, Bernard can open the trunk, since he alone holds the key that opens this lock. The transfer is safe in one trip. In cryptography, the public key is equivalent to the code lock, which is available for example in directories, while the key that opens this lock is the private key, owned solely by their owner and never disclosed. The private and public keys (the so-named "key trousseau") are constructed from a supposed "one-way" mathematical function.

Let's now see the second solution making use of public key according to the Diffie-Hellman protocol:

14.6.4.1 Diffie-Hellman protocol

As the name implies, a one-way function gives easily a result, but the reverse operation is very difficult. Finding such functions in the mathematical world seemed very arduous to mathematicians. How to imagine a function that is one-way for everyone, except for its creator who can reverse it through the knowledge of a particular information. Thus, W. Diffie and Hellman were the first to publicly propose a one-way function to solve the problem of agreeing on a common secret. The basic idea is to calculate values of the type:

$$\alpha^a \mod p \tag{14.6.18}$$

where α and a are imposed as being integers and p is a prime number.

Mathematicians name this kind of operation a "modular exponentiation" or "discrete exponential" and it is customary to denote the finite field of integers modulo p (where p is a prime number) by GF(p) in honour of Évariste Galois.

To explicate such a calculation (as a reminder of what was seen in the section of Number Theory ...), we raise a number α to the power of a, and then divide the result by a large prime number p and we keep finally the remainder of this division (operation modulo p). If this remainder is denoted r then we write this:

$$\boxed{\alpha^a \equiv r \mod p} \tag{14.6.19}$$

Modular exponentiation similar to the one described above are considered easy to compute, even when the numbers involved are enormous. On the other hand, computing the "discrete logarithm" – that is, the task of finding the exponent a when given α, p, and r (i.e. $\alpha^a \mod p$) – is believed to be difficult. This one-way function behaviour makes modular exponentiation a candidate for use in cryptographic algorithms! In addition, one-way functions such as the one above from the modular arithmetic behave very irregularly as is shown in the table with the particular example below:

a	$\alpha^a = 3^a$	$\alpha^3 \mod p = 3^a \mod 7$
0	1	1
1	3	3
2	9	2
3	27	6
4	81	4
5	243	5
6	729	1
7	217	3
8	6561	2

Table 14.59: **Examples of modular exponentiation applications**

So even if it is easy to compute a discrete exponential, it is almost impossible to find the starting number a from the result, especially when this modular function is applied to very large primes p.

The reader can check this by playing with Maple™ 4.00b that can calculate the discrete logarithm as following:

```
>with(numtheory):
>mlog(r,alpha,p);
```

Ok we know how to crypt message... But now how can we communicate messages to someone that should be able to uncrypt them? This is named the "Diffie–Hellman key exchange" that is a specific method of securely exchanging cryptographic keys over a public channel and was one of the first public-key protocols as originally conceptualized by Ralph Merkle and named after Whitfield Diffie and Martin Hellman. D–H is one of the earliest practical examples of public key exchange implemented within the field of cryptography. Here is the idea of the protocol:

ALICE	**Public (Internet)**	**BERNARD**
We choose an arbitrary common prime number $p=419$ and a common random number smaller than p: $\alpha=7$. These two values are assumed to be secret.		
Alice chooses a secret random number: $a=178$		Bernard chooses a secret random number: $b=344$
With the number a Alice generates the public element: $k_a=\alpha^a \mod (p)=181$		With the number b Bob generates the public element: $k_b=\alpha^b \mod (p)=351$
The result is sent to Bernard: $k_a=181$	$\longrightarrow$	$k_a=181$
$k_b=351$	$\longleftarrow$	The result is sent to Alice: $k_b=351$
The shared secret is then: $K=(k_b)^a \mod (p)=493$		The shared secret is then: $K=(k_a)^b \mod (p)=493$
$\leftarrow$ The exchanges are then encrypted with the secret key K $\rightarrow$		

Table 14.60: **Example of key exchange following Diffie-Hellmann protocol**

The security of this protocol is computational. It is based on the assumption that with limited computing power and time, an opponent (spy) can not reverse the modular exponential function (by making use of the properties of the logarithms with the exponential functions as we saw in the section of Functional Analysis) and therefore can not find the secret a from the exchanged elements. This computational difficulty is due to the fact that the computation time necessary for the inversion of a one-way function does not have an algorithmic complexity (see section of Numerical Methods page 6284) polynomial but exponential with p.

Alice and Bernard have calculated the same common secret: 493. Then 493 is used to encrypt the exchanged data (in practice, much larger numbers are used). The spy is supposed to be able to intervene only after the exchange of the common choice of p and α (no man-in-the-middle attack!).

Remark

This protocol is vulnerable to a "man-in-the-middle attack" that is an attack where the attacker secretly relays and possibly alters the communication between two parties who believe they are directly communicating with each other. One example of man-in-the-middle attacks is active eavesdropping, in which the attacker makes independent connections with the victims and relays messages between them to make them believe they are talking directly to each other over a private connection, when in fact the entire conversation is controlled by the attacker. The attacker must be able to intercept all relevant messages passing between the two victims and inject new ones.

The key K is obtained by the fact that the power operation is compatible with the relation of equivalence modulo p (see section Number Theory page 356) such that:

$$x \mod (y) = z \Leftrightarrow (x \mod (y))^w = (x^w \mod (y)) = z \qquad (14.6.20)$$

✍**Example:**

We have:

$$5 \mod (3) = 2 \qquad (14.6.21)$$

when with $w = 2$ we have:

$$5^2 \mod (3^2) \neq 2^2 \qquad (14.6.22)$$

but:

$$5^2 \mod (3) = 2^2 \qquad (14.6.23)$$

If it is not clear let us write it differently:

$$5 \equiv 2 \mod (3) \Leftrightarrow 25 \equiv 4 \mod (3) \qquad (14.6.24)$$

Indeed, for the first one: $5 - 2 = 3$ can be divided by 3 and for the second one $25 - 4 = 21$ can be divided by 3.

Thus, since $x < p$, the second modulo below has no meaning, so we can write:

$$(k_b)^a \mod (p) = (\alpha^b \mod (p))^a \mod (p) = (\alpha^b \mod (p))^a = \alpha^{b+a} \mod (p) \qquad (14.6.25)$$

identically:

$$(k_a)^b \mod (p) = (\alpha^a \mod (p))^b \mod (p) = (\alpha^a \mod (p))^b = \alpha^{a+b} \mod (p) \qquad (14.6.26)$$

and therefore:

$$(k_b)^a \mod (p) = (k_a)^b \mod (p) = K \qquad (14.6.27)$$

Diffie-Hellman is a cornerstone of modern cryptography used for VPNs, HTTPS websites, email, and many other protocols. Bad implementation choices combined with advances in number theory mean real-world users of Diffie-Hellman are likely vulnerable to state-level attackers.

Despite these precautions, experts established a record at the beginning of the 121st century (holocene calendar) using a new algorithm, they succeeded in reversing the modular exponential function for a p-number of 120 digits (about 400 bits), using a Computer with four 525 [MHz] processors. This record shows that the security of the protocol depends greatly on the constant progress made in the field of algorithmic complexity. Researchers estimate that breaking a single, common 1024-bit prime would allow NSA (USA National Security Agency) to passively decrypt connections to two-thirds of VPNs and a quarter of all SSH servers globally. Breaking a second 1024-bit prime would allow passive eavesdropping on connections to nearly 20% of the top million HTTPS websites. In other words, a one-time colossal investment in power-lifting computation would make it possible to eavesdrop on trillions of encrypted connections.

The clever schema of Diffie-Hellman remains a schema of principle. Its main disadvantage is that it does not make it possible to provide the traditional security services: authentication of the two interveners, control of the integrity of the key and anti-replay (verification that information already transmitted is not re-transmitted). It follows that an attacker can, for example, impersonate Alice by replacing the public element of Alice with her own public element. To overcome this disadvantage, secure versions of this generic protocol have been published, for example a protocol named "STS" (Station To Station), which uses, in particular, the electronic signature to ensure the authentication of the interveners (see below). This policy is the basis of the secured Internet connection (IPSec).

The Diffie-Hellman protocol paved the way for a whole series of algorithms, that of "public key encryption" being the first. The idea was to break the symmetry of encryption and decryption by using one-way functions.

14.6.4.2 R.S.A system

Curiously, the first "R.S.A. encryption system" is conceptually quite different from the Diffie-Hellman protocol: it does not use the discrete exponential, but the factorization of large numbers. This public key system was invented in 11977 (holocene calendar) by Ron Rivest, Adi Shamir, and Leonard Adleman (hence the abbreviation "R.S.A."). Having quickly become an international standard, the R.S.A. technique has been marketed by more than 400 companies and we estimate that more than 400 million softwares use it. It is implemented in web browsers, such as Netscape Navigator, Microsoft Internet Explorer, or some bank smart cards, such as VISA cards.

The R.S.A. system is based on the difficulty of factorizing large numbers and the one-way function used is a "power" function. The R.S.A. encryption protocol is divided into three phases:

1. Creation of keys (public and private)
2. Encryption using the recipient's public key
3. Decryption using the private key

Its concept is based on a famous theorem named "Euler's theorem" (nothing to do with the theorem of the same name seen in the section of Graph Theory or in the section of Geometric Shapes). Let's see what it is (be careful it is relatively long!).

14.6.4.2.1 Euler's theorem

Before we see what Euler's theorem consists of, we must define two elements that are included in it. Apart the concept of congruence which we have already studied in the section of Number Theory (see page 365), there remains a special function named the "Euler indicator" or also named "totient function" and defined in general by:

$$\boxed{\phi(m)=\sum_{k=1,(k,m)=1}^{m} 1} \tag{14.6.28}$$

In other words, the function ϕ of the integer m results in a number n strictly less than m, given by the number of elements between 1 and m whose greatest common divisor (see section Number Theory page 340) with m is 1. We have already given a practical example of the utility of this indicator function in the section of Number Theory in the framework of the reduced systems of residues and which are at the center of the proof of Euler's theorem.

This can be formulated in the following form: the indicator ϕ of the integer m is defined as the number of positive integers less than or equal to m and prime with m.

This function therefore has the remarkable property of counting the number of positive integers smaller than m and "relatively prime" (i.e., having greater common divider equal to 1) with m.

Here are some values of $\phi(m)$ for m that range from 0 to 19: Let us now introduce two properties of $\phi(m)$:

$\phi(m)$	0	1	2	3	4	5	6	7	8	9
0+		1	1	2	2	4	2	6	4	6
10+	4	10	4	12	6	8	8	16	6	18

Table 14.61: Some values of the Euler indicator $\phi(m)$

P1. We notice the (trivial) property of this function when we denote any prime number (remember that 1 is not a prime number!) by the letter p then:

$$\boxed{\phi(p) = p - 1} \tag{14.6.29}$$

as it is highlighted by the table above.

P2. The Euler indicator can also be written in the following form if p and q are relatively prime (this is the padlock of the R.S.A system which is more complicated than the simple multiplication of p and q):

$$\boxed{\phi(n) = \phi(pq) = \phi(p)\phi(q) = (p-1)(q-1)} \tag{14.6.30}$$

this last relation can easily be verified (without proof) by taking some values from the preceding table (if we do it like Ramanujan...).

Theorem 14.31. This done, given $(a, m) = 1$ (the greatest common divisor of a and m, i.e. a and m are relatively prime), the "Euler's theorem" says that if m is a natural number and a is relatively prime with m then we have:

$$\boxed{a^{\phi(m)} \equiv \mod (m)} \tag{14.6.31}$$

in which we see the Euler indicator defined above. It is a rather surprising relation. Let's see if it works with 7 and 2 which are relatively prime between them:

$$2^{\phi(7)} \equiv \mod (7) \Rightarrow 2^{\phi(7)} = 2^6 = 64 = 9 \cdot 7 + 1 \tag{14.6.32}$$

the remainder being indeed therefore equal to 1 when we compute 64 modulo 7.

Proof 14.31.1. Let us first recall (see section Number Theory page 365) that a reduced system of residuals modulo m is a set of integers equation that satisfy the three properties:

P1. The remainder r_i and m are relatively prime, i.e. $(r_i, m) = 1$

P2. r_i is not congruate r_j modulo m when $i \neq j$

P3. Each integer x relatively prime with m is congruent to some r_i modulo m

✍**Example:**

For example, the set $\{1, 5\}$ is a reduced system of residuals modulo 6 or another example, $\{1, 2, 3, 4, 5, 6\}$ is a reduced system of residuals modulo 7.

We also check for the first example that 1 is not congruent 5 modulo 6 (indeed, 6 does not divide $(5-1)$) and that 5 which is relatively prime to 6 is congruent to itself.

For the second set, we notice that the cardinal of the set of residuals corresponds to the value of the Euler indicator for the number 7.

Lemma 14.31.1. Thus, given $\{r_1, r_2, \ldots, r_{\phi(m)}\}$ a reduced system of residuals modulo m. We need for the proof of Euler's theorem, to prove beforehand the lemma that $\{ar_1, ar_2, \ldots, ar_{\phi(m)}\}$ is also a reduced system of residuals modulo m.

Remark

As we have already mentioned in the previous example, you can observe that the cardinality of the set of residuals corresponds, for a given prime modulo m, to the result defined by the property P1 of the Euler indicator function $\phi(m)$. This property is to this day only a "conjecture", that is to say, an assumption based on probabilities (because it seems it has not be proven so far!).

For this, let us recall that by the property of a reduced system:

$$(r_i, m) = 1 \tag{14.6.33}$$

and that by hypothesis:

$$(a, m) = 1 \tag{14.6.34}$$

then we want the lemma that:

$$(ar_i, m) = 1 \tag{14.6.35}$$

is also satisfied.

Let us put for this $d = 1$ (by tradition ...). We then have since $(r_i, m) = d$ that $d|r_i$ and $d|m$ and identically for $(a, m) = d$ that $d|a$ and $d|m$. Now if d divides well a or r_i in this case we have $d|r_i(a)$ or (equivalently) $d|a(r_i)$. Therefore $d|ar_i$ and $d|m$ which allows us to write:

$$(ar_i, m) = (r_i a, m) = 1 \tag{14.6.36}$$

Let us return to our Euler's theorem... if the reader stills follow ... We have just proved that there is bijection between the two sets of residues. That is to say that for each residue r_i of the reduced system modulo m, we will have a residue ar_i of the reduced system modulo m according to the fundamental property of the congruence which we recall says that: we can multiply the two members of a congruence by the same integer number and it will remain congruent modulo m and modulo m multiplied by this integer number.

✍**Example:**

Let us take:

$$35 \equiv 5 \mod (6) \tag{14.6.37}$$

indeed:

$$6|(35 - 5 = 30) \tag{14.6.38}$$

because the remainder of the division of 30 by 6 is indeed equal to zero. If we take for example:

$$2 \cdot 35 \equiv 2 \cdot 5 \mod (2 \cdot 6) \tag{14.6.39}$$

then we have:

$$12|(70-10=60) \tag{14.6.40}$$

and the remainder is also zero...

Let us make a recall on bijection (see section Set Theory page 407): We say that we have a "bijection", if to each element of a starting set corresponds one and only one element in the arrival set (if there was for every man on Earth only one woman - in equal proportions therefore - there would be a bijection between the set of Men and Women).

In short, since there is bijection between the two sets of residues, we can write:

$$\prod_{i=1}^{\phi(m)} ar_i = \prod_{i=1}^{\phi(m)} r_i \mod (m) \tag{14.6.41}$$

✍**Example:**

The set $\{1,5\}$ is a reduced system of residuals modulo 6 as we have already seen. So we have:

$$(r_1,m)=(1,6)=1(r_2,m) \quad =(5,6)=1 \tag{14.6.42}$$

We have then:

$$\prod_{i=1}^{\phi(m)} r_i \mod (m) = \prod_{i=1}^{\phi(6)} r_i \mod (6) = \prod_{i=1}^{2} \mod (6) = 1\cdot 5 = 5 \tag{14.6.43}$$

If we take an a such that $(a,m)=1$, for example $a=7$ because indeed $(7,6)=1$, then:

$$7\cdot 5 \equiv 5 \mod (6) \tag{14.6.44}$$

because $6|(35-5=30)$. Indeed, 6 divides well 30 with a remainder equal to 0.

So let us return to our bijection, which can be written by the elementary rules of algebra:

$$a^{\phi(m)} \prod_{i=1}^{\phi(m)} r_i \equiv \prod_{i=1}^{\phi(m)} r_i \mod (m) \tag{14.6.45}$$

Since:

$$\left(m, \prod_{i=1}^{\phi(m)} r_i\right) = 1 \tag{14.6.46}$$

(you can verify, but this is the very definition of a set of residues!), we are then obliged to conclude that:

$$a^{\phi(m)} \equiv 1 \mod (m) \tag{14.6.47}$$

and anyway, even if it does not seem obvious to you, you just need to multiply each of the members of the equality of the congruence by:

$$\left(\prod_{i=1}^{\phi(m)} r_i\right)^{-1} \tag{14.6.48}$$

as permit us one of the intrinsic properties of congruence previously proved.

■ Q.E.D.

This theoretical interlude being done, let us consider a number N of which we wish to decide whether it is prime number or not.

We know from the Euler theorem and of the property P1 of the Euler indicator that if N is a prime number and if $a \in \mathbb{N}$, where $a < N$, then:

$$\boxed{a^{N-1} \equiv 1 \mod (N)} \tag{14.6.49}$$

which is named the "Fermat's little theorem".

Remark

This relation follows from the properties we have presented in our proof of Euler's theorem:

$$a^{\phi(m)} \equiv 1 \mod (m) \tag{14.6.50}$$

and of the property P1 of the function $\phi(m)$ for a prime number p:

$$\phi(p) = p - 1 \tag{14.6.51}$$

The Fermat's little theorem is however, also valid for some numbers N which are not prime. But the numbers which check this without being prime are rare, and it is worthwhile to look for a more sophisticated algorithm to know if N is really prime or not (we say that in this case, N is a good candidate for primality and is then named "pseudo-prime number"). To test whether the number non-prime number N is "sufficiently prime", we try with an algorithm to test the Fermat's little theorem a maximum number $a \in \mathbb{N}$ with $a < N$.

According to the property of congruence (see above), we also have:

$$a \cdot a^{N-1} \equiv a \cdot 1 \mod (N) \Rightarrow a^N \equiv a \mod (N) \tag{14.6.52}$$

We can apply this last theorem to a number N on which we would like to know at best whether it is prime or not.

There are a large number of other non-optimal methods for determining whether N is prime; including preliminary division trials by $2, 3, 5, 7, 11, \ldots$ and small prime numbers up to $p \leq \sqrt{N}$ according to the method of the Eratosthenes screening which is best known method in high schools.

Remark

In fact, with the help of a fairly powerful computer, we can decide whether a natural number of the order of 10^{300} (10 followed by 300 zeros) is first or not within a few minutes or seconds. What is important to know is that, given a natural number N, one can decide in relatively short time whether it is prime or not, without knowing however its prime factors!!

However, according to the fundamental theorem of arithmetic we have that:

Theorem 14.32. Any natural number N can be written as a product of prime numbers, and this representation is unique, apart from the order in which the prime factors are arranged.

The proof is already in the section of Number Theory but exceptionally we will reproduce it here as it is quite a short proof:

Proof 14.32.1. The proof uses Euclid's lemma (see section Number Theory page 351): if a prime p divides the product of two natural numbers a and b, then either p divides a or p divides b (or both).

If N is prime, and therefore product of a unique prime integer, namely itself, the result is true and the proof is complete (say that a prime number is product of itself is obviously a misnomer!). Suppose that n is not prime and therefore strictly greater than 1 and consider the set:

$$D=\{d|N \text{ and } 1<d<N\} \qquad (14.6.53)$$

So, $D\subset\mathbb{N}$ and since N is composite, we have that $D\neq\varnothing$. According to the principle of good order, D has a smaller element p_1 that is prime, otherwise the minimum choice of p_1 is contradicted. We can the write $N=p_1N_1$. If n_1 is prime, then the proof is complete. If n_1 is also composite, then we repeat the same argument as before and we deduce the existence of a prime number p_2 and of an integer $N_2<N_1$, such as $N=p_1p_2N_2$. By continuing we come inevitably to the conclusion that N_k will be prime.

So finally we well show that any number can be decomposed into prime numbers factors with the principle of good order.

■ Q.E.D.

So finally we have proved that any number is decomposable into prime factors using the principle of good order. There exist in the set of natural numbers $\mathbb{N}$, some which can be expressed by (or only by) two prime factors traditionally denoted p and q. These are the numbers we use in public key cryptography according to the R.S.A. protocol.

Remark

We do not know to this day a law that makes it possible to easily and quickly calculate the i-th prime factor p_i of a number. In fact, even with the most powerful computers we had in year 12002 (holocene calendar) when we wrote these lines, it would take several years to find the two prime factors p and q of a "RSA number" $N=pq$ where p and q are of the order of 10^{100} each. And it seems unlikely that we will discover in the near future an algorithm sufficiently effective to improve appreciably this computing time. Note that it is possible to determine in less than 5 minutes (in year 12002 according to holocene calendar) whether a number of 200 digits is prime or not. However, to factorize a number of 200 digits into two prime numbers, it would take at least 100 years. Wonderful thing: the theories that allow these exploits are very deep and were developed partly long ago in a very different setting.

Now in year 12009 (holocene calendar) a RSA number of 232 digits (i.e. 768 bit RSA number) was factorized (7 years after we wrote the lines above) in half a year on eighty 2.2 GHz AMD Opteron processors...

The fact that it is much more difficult to find the prime factors of a number N than to find out if N is prime or compound is precisely what made it possible to develop this very ingenious method of encoding and decoding messages according to the RSA protocol.

✍**Example:**

Let us consider now a group of individuals who regularly transmit messages by e-mail and for which it is important that the messages are known only to the sender and the recipient. Then, the group member (here Alice) who wants to receive encrypted information, choose two very large prime numbers p and q of the order of 10^{100}. To find such prime numbers, we randomly choose a number of 100 digits and we check by one of the known algorithms whether it is prime or not and we repeat the experiment until we get a prime number. Once this is done with these two prime numbers, we compute the expression:

$$N = pq \tag{14.6.54}$$

named the "modulus".

Then, Alice (who is the only one in possession of the number N for the moment) who wants to receive the encrypted informations chooses a positive integer a such (p.g.c.d.) that:

$$(a, \phi(N)) = 1 \tag{14.6.55}$$

So a (often denoted e in the literature) is a prime integer with $\phi(N)$ sometimes named the "generator".

And as:

$$\phi(N) = \phi(pq) = \phi(p)\phi(q) = (p-1)(q-1) \tag{14.6.56}$$

Suppose a Alice wants to receive a message from Bob, one of her friends.

Alice has therefore the "public key", defined by the couple:

$$🔑\{a, N\} \tag{14.6.57}$$

to Bob.

Bob receives the public key and wishes to send the french message: *déclencher l'opération rouge*[a]. To do this, Bob first transforms the message into numbers by using the convention that each letter is replaced by its corresponding position in the alphabet starting counting from 01 (the character "space" will be encrypted "27").

Thus the clear message denoted M afterwards becomes:

$$M=\underbrace{0405312051403080518}_{declencher}27\underbrace{12}_{l}27\underbrace{151605180120091514}_{operation}27\underbrace{1815210705}_{rouge} \tag{14.6.58}$$

Remark

For technical reason, M and N must have no common divisor other than 1 (otherwise, a possible spy could reduce the problem of two very large numbers difficult to manipulate to that of smaller numbers, easier to manipulate). Otherwise, at the end of M, we add numbers without value, such as 01 (for example), to finally have M and N without common divisor other than 1.

We can also break M into pieces M_i whose number of digits does not exceed 99 (remember that we set a lower limit of a power of 100 for p and q and that it would therefore suffice that one of the two prime numbers to be 1 and the other exactly a number with an exponent 100 to be at the limit of the number N then comprising at worst 100 digits, even if this extreme example is quite bad for technical reasons as more easy to crack), in which case one will always have:

$$(M_i,p)=(M_i,q)=1 \tag{14.6.59}$$

We cut M into pieces, each being smaller than N:

$$\underbrace{0405}_{M_1}\underbrace{031205}_{M_2}\underbrace{1403}_{M_3}\underbrace{080518}_{M_4}\underbrace{271227}_{M_5}\underbrace{1516}_{M_6}\underbrace{051801}_{M_7}\underbrace{2009}_{M_8}\underbrace{1514}_{M_9}\underbrace{2718}_{M_{10}}\underbrace{1521}_{M_{11}}\underbrace{0705}_{M_12} \tag{14.6.60}$$

and we work successively with each piece $M_1,M_2,\ldots,M_{12}$ of the message.

We consider the power a of M_1, that is, M_1. We replace M_1 by the number $\bar{M}_1$, which is the remainder of the division by N of the number M_1^a. The same procedure is followed for all other M_i pieces such as:

$$\bar{M}_i=M_i^a \mod (N) \tag{14.6.61}$$

Then Bob sends the encoded message to Alice:

$$\bar{M}=\underbrace{\ldots\ldots}_{\bar{M}_1}\underbrace{\ldots\ldots}_{\bar{M}_2}\underbrace{\ldots\ldots}_{\bar{M}_3}\underbrace{\ldots\ldots}_{\bar{M}_4}\underbrace{\ldots\ldots}_{\bar{M}_5}\underbrace{\ldots\ldots}_{\bar{M}_6}\underbrace{\ldots\ldots}_{\bar{M}_7}\underbrace{\ldots\ldots}_{\bar{M}_8}\underbrace{\ldots\ldots}_{\bar{M}_9}\underbrace{\ldots\ldots}_{\bar{M}_{10}}\underbrace{\ldots\ldots}_{\bar{M}_{11}}\underbrace{\ldots\ldots}_{\bar{M}_12} \tag{14.6.62}$$

An interceptor of the encoded message and of the public key, knowing the encryption algorithm, would therefore have to solve the problem of one equation with two unknowns (equation obtained simply from the mathematical expression of the encryption rule):

$$M_i = \sqrt[a]{Nq + \bar{M}_i} \qquad (14.6.63)$$

Obviously unspecified problem!

---

[a] In English: *trigger the red operation*

To see how the receiver decrypts the message, we need an additional mathematical tool.

Let us recall that the receiver chooses a such that $(a, \phi(N)) = 1$, which implies, according to the Bézout's theorem (see section Number Theory page 341), that if a and $\phi(N)$ are relatively prime (that is to say for recall that their greatest common divisor is 1) there exist integers x and y such that (we can assume that $x > 0$, in which case $y < 0$):

$$ax + \phi(N)y = 01 \qquad (14.6.64)$$

or otherwise written:

$$ax \equiv 1 \mod (\phi(N)) \qquad (14.6.65)$$

This is how we will determine the value of x (we must use algorithms to find the solution x to this equation).

Which means:

1. If a is prime with $\phi(N)$ then by the properties of congruence it is also prime with $p-1$ and $q-1$.
2. That a is invertible modulo $\phi(N)$

   Indeed, because:

   $$ax - 1 = \phi(N)y \qquad (14.6.66)$$

   And according to the definition of congruence $(m|(a-b))$ we have:

   $$ax \equiv 1 \mod (\phi(N)) \qquad (14.6.67)$$

   since $\phi(N)$ divides the right-hand side of $ax - 1 = \phi(N)y$ and therefore by the equality, the left-hand member. Therefore:

   $$x = \frac{1 \mod (\phi(N))}{a} \qquad (14.6.68)$$

Only the receiver of the message, can easily calculate the number $x \leq a$ used above. In order to do this, it is necessary to be able to calculate the value of $\phi(N)$ and thus know p and q.

If M_i is the original message (its numerical value) and $\bar{M}_i$ is the received encoded message (its numeric value), then we have the following relation:

$$M_i^a \equiv \bar{M}_i \mod (N) \qquad (14.6.69)$$

This is completely logical since the difference $M_i^a - \bar{M}_i$, where for recall, $\bar{M}_i$ is the remainder of the division of M_i^a by N, can therefore only be divisible by N.

Alice thus receives the coded message $\bar{M}$ and raise to the power of x the numbers $\bar{M}_i$ and thus obtains the initial message.

Indeed, she will apply for each $\bar{M}_i$ the following mathematical property of congruence:

$$\bar{M}_i^x \equiv M_i^{ax} \equiv M_i^{1-\phi(N)y} \equiv M_i \mod (N) \tag{14.6.70}$$

The "private key" (allowing to decrypt the message and which can be easily known only by the Alice) is thus defined by the couple:

$$\text{🔑}\{x, N\} \tag{14.6.71}$$

Let us give more indeed explanations about what we have stated just above! We have showed that:

$$M_i^a \equiv \bar{M}_i \mod (N) \tag{14.6.72}$$

and from the property of symmetry of congruence (see section Numbers page 356), we can write:

$$M_i^a \equiv \bar{M}_i \mod (N) \Leftrightarrow \bar{M}_i \equiv M_i^a \mod (N) \tag{14.6.73}$$

Now we can write:

$$\bar{M}_i^x \equiv M_i^{ax} \mod (N) \tag{14.6.74}$$

according to the second principal property of congruence, which says for recall that the two members of a congruence can be elevated to the same power! That latter relation can also be written (application of Bézout's theorem):

$$\bar{M}_i^{ax} \equiv M_i^{1-\phi(N)y} \mod (N) \tag{14.6.75}$$

Remains to prove that:

$$M_i^{1-\phi(N)y} \equiv \bar{M}_i^x \mod (N) \tag{14.6.76}$$

where we can write $M_i^{1-\phi(N)y}$ under the form:

$$M_i^{1-\phi(N)y} = M_i \left(M_i^{\phi(N)}\right)^{-y} \tag{14.6.77}$$

Now, remember that we have proved Euler's theorem:

$$M_i^{\phi(N)} \equiv 1 \mod (N) \tag{14.6.78}$$

and that one of the properties of congruence gives us the right to elevate to any power the two members of the congruence such as:

$$\left(M_i^{\phi(N)}\right)^{-y} \equiv (1)^{-y} \mod (N) \tag{14.6.79}$$

But as 1 raised to any power makes 1, we have:

$$\left(M_i^{\phi(N)}\right)^{-y} \equiv 1 \mod (N) \tag{14.6.80}$$

This last relation allows us to verify that we can authorize ourselves to write:

$$M_i \left(M_i^{\phi(N)}\right)^{-y} \equiv M_i \mod (N) \tag{14.6.81}$$

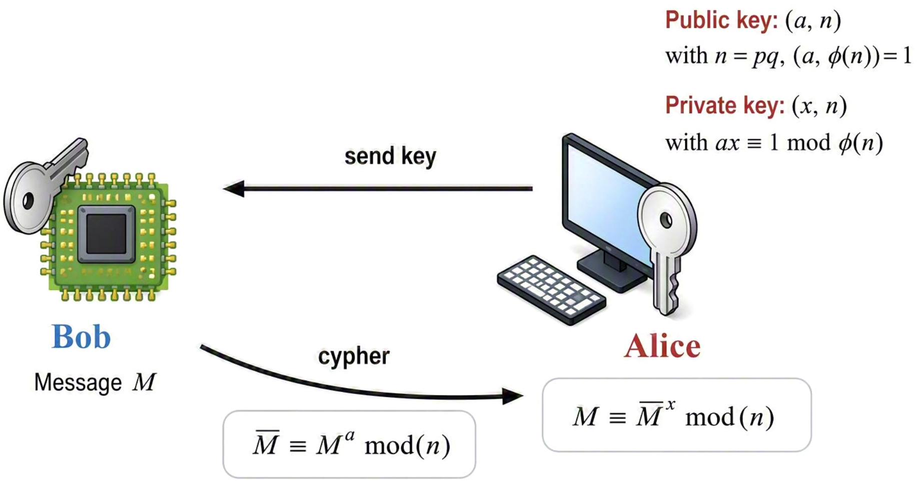
since the two left members are well modulos N.

So if we sum up all this, Alice receives a piece $\bar{M}_i$ and raises it automatically to the power x to obtain a number which according to her should be the true M_i. To be sure, it applies the verification:

$$\bar{M}_i^x \equiv M_i \mod (N) \tag{14.6.82}$$

It is easy to see that any interceptor can not decode and in addition verify if the decoding is indeed the right one, because for this it should know the value of x, which in turn depends on $\phi(N)$, that it does not know either, because he does not know the prime factors of N that are p and q.

It is customary to say that the RSA system uses the numbers p, q (secrets), N (public), a (public) and x (secret). The whole being summed up by the triplet $\{n, a, x\}$ denoted sometimes in the literature $\{n, e, d\}$.



Public key: (a, n)

$\overline{M} \equiv M^a \mod(n)$
$M \equiv \overline{M}^x \mod(n)$

Figure 14.362: **Principle of RSA public key encryption**

And here is a small practical application with Maple™ 4.00b:

```
> #Initialization of the Maple™ 4.00b random generator
> randomize():
> #definition of the desired size for N (this is an even number)
> t:=30:
> #Generation of two integers of t/2 bits size
> x:=rand(2^(t/2-1)..2^(t/2))();
> y:=rand(2^(t/2-1)..2^(t/2))();
> #Calculation of the following prime numbers
> p:=nextprime(x);
> q:=nextprime(y);
> #Generation of the RSA key
> n:=p*q;
> phi:=(p-1)*(q-1);
> #We choose "a" empirically
> a:=65537;
> #We check that it is prime with phi
> igcd(a,phi);
> #we calculate the inverse of "a" modulo phi
> x:=1/a mod phi;
> #we choose a message a being "1234"
> m:=1234;
> #we cypher
> c:=m&^a mod n;
> #we decode
> c&^x mod n;
```

Following the request of a reader here is a literal summary of what we have seen so far for the first steps of the algorithm above with practical value and a given message:

✍**Example:**

We want to cypher the message $M = 314158$.

1. We choose p and q prime and sufficiently large:

$$p = 593, q = 613 \tag{14.6.83}$$

   we then have:

$$N = pq = 593 \cdot 613 = 363509 \tag{14.6.84}$$

2. We compute the Euler indicator:

$$\phi(N) = (p-1)(q-1) = (593-1)(613-1) = 592 \cdot 612 = 362304 \tag{14.6.85}$$

3. We choose the generator a such that:

$$(a, \phi(N)) = 1 \tag{14.6.86}$$

   and for this we will take $a = 5$. The pair (a, N) is the public key (can be distributed to everyone for a specified time).

4. Then we calculate:

$$x=\frac{1 \mod \phi(N)}{a}=\frac{362304}{5}=72460 \tag{14.6.87}$$

So the pair (x,a) is the private key (to be kept secret).

5. Now we cypher with:

$$\bar{M}_i=M_i^a \mod (N) \tag{14.6.88}$$

Therefore:

$$\bar{M}_i=314158^5 \mod (363509)=311800 \tag{14.6.89}$$

6. Now to decipher (the exponent calculation cannot be done with sample spreadsheet softwares or simple online scientific calculator):

$$M_i=\bar{M}_i^x \mod (N)=311800^{72461} \mod (363509)=314148 \tag{14.6.90}$$

For security reasons, public key cryptography is used in conjunction with secret key cryptography. For example, at the time of writing these lines, the SSL protocol for Internet pages uses the RSA to exchange a secret key (symmetric system) and then encrypts the data using a conventional symmetric algorithm.

Let us conclude this brief presentation of the messages cyphering by informing the reader that the US government (and not only...!) closely monitors the activities of mathematicians who work on the factorization of large numbers. Indeed, if one of them could find an algorithm allowing to factorize in a short time a number of two hundred digits (greater than 524 bits unsigned), this would jeopardize the secret nature of several communications of a military order. In fact, this surveillance has raised a protest by the scientists in the United States, who see their professional freedom undermined (Notices of American Mathematical Society, January 11983 according to holocene calendar).

For technical information, the software PGP (Pretty Good Privacy) published by the MIT (Massachusetts Institute of Technology), uses a RSA encryption system.

14.6.5 Hash functions

A "hash function" is a function that associates to a big set a much smaller set (of the order of a few hundred bits) that is characteristic of the starting. This property makes it very used in computing, in particular for quick access to data thanks to "hash tables" or to check the result of huge data transmission (downloads). Indeed, a hash function makes it possible to associate a particular integer with a string. Thus, if we know the fingerprint of the stored character strings, we can quickly check whether a string is in this table (in $\mathcal{O}(1)$ if the hash function is good enough). Hash functions are also extremely useful in cryptography to speed up encryption.

The two most commonly used condensation algorithms at the beginning of the 121st century (holocene calendar) are the "Secure Hash Algorithm (SHA)", which calculates a 160-bit summary, and the MD5 (Message Digest 5 - Run Rivest 11992 according to holocene calendar), which calculates a 128-bit summary named "Message Digest".

14.6.5.1 MD5 message digest condensation function

This "Message Digest MD5" algorithm is (was) used mainly for digital signatures (notion used, when validating certificates of authenticity as we will see later) but as it has been found to suffer from extensive vulnerabilities[88]. It can still be used as a checksum to verify data integrity, but only against unintentional corruption.

Figure 14.363: **Illustrated result of MD5 algorithm**

Here are the different stages of its operation:

1. Completion:

---

[88] In 12004 (holocene calendar) it was shown that MD5 is not collision-resistant. As such, MD5 is not suitable for applications like SSL certificates or digital signatures that rely on this property for digital security.

The message consists of b bits. The message is completed with a 1, and sufficiently enough 0 for the extended message to have a multiple length of 512 bits. After this initial processing, the input text is manipulated in blocks of 512 bits divided into 16 sub-blocks `M[i]` of 32 bits.

2. Initialization:

   We define the 32-bit "chaining variables" `A`, `B`, `C` and `D` initialized as follows (the digits are hexadecimal):

   `A=01234567`, `B=89ABCDEF`, `C=FEDCBA98`, `D=76543210`

   We also define four non-linear functions `F`, `G`, `H` and `I` which take arguments coded on 32 bits, and return a value on 32 bits, the operations taking place bit by bit.

   ```
   F(X,Y,Z) = (X AND Y) OR (NOT (X) AND Z)
   G(X,Y,Z) = (X AND Z) OR (Y AND NOT (Z))
   H(X,Y,Z) = X XOR Y XOR Z
   I(X,Y,Z) = Y XOR (X OR NOT (Z))
   ```

   What is important with these four functions is that if the bits of their arguments `X`, `Y` and `Z` are independent, the resulting bits are also independent.

3. Iterative calculation:

   The main loop has 4 rounds (see figure below) which each use a different non-linear function (hence the fact that there are 4 rounds). Each round therefore consists of 16 executions of an operation (because there are 16 sub-blocks).

   Each operation calculates a non-linear function of three of the variables `A`, `B`, `C` and `D`, adds to it a sub-block $M[i]$ of the text to be encrypted, a predefined constant s (encoded on 32 bits) and to a circular shift on the left of a variable number of bits n. Here is the example for `A`:

   - `A = B + A + F(B,C,D) + M[i] +` s circularly offseted from n bits to the left
   - `A = B + A + G(B,C,D) + M[i] +` s circularly offseted from n bits to the left
   - `A = B + A + H(B,C,D) + M[i] +` s circularly offseted from n bits to the left
   - `A = B + A + I(B,C,D) + M[i] +` s circularly offseted from n bits to the left

   This new value of `A` is then summed with the old one.

4. Writing of the summary (fingerprint):

   The 128-bit summary is obtained by putting end-to-end the four 32-bit chaining variables `A`, `B`, `C`, `D` obtained at the end of the iteration.

Figure 14.364: **Illustrated MD5 algorithm flow (source: Wikipedia, author: Dake)**

Remark

Normally we would put the MD5 algorithm pseudocode but... as it is a pain in the a.. to write it in LaTeX with the `algorithm2e` package we will for the moment not do it....

The MD5 function as we have already mentioned it is not safe and not unique (two different inputs can give the same signature: we talk then of "collision"). However, the MD5 function is still widely used as a verification tool during downloads and the user can validate the integrity of the downloaded version thanks to the fingerprint. This can be done with a program for example named `md5sum` for MD5 and `sha1sum` for SHA-1 (see just below).

Here is the fingerprint (abusively sometimes named "signature") obtained on a sentence[89] (which we took without accents):

MD5("Wikipedia, the free encyclopedia") = f8aa0d3b1dae3f41d67c200688723c1b

By modifying a character, this impression drastically changes:

MD5("Wikipedia, the free encyclopediA") = f9829ad9d4c2713140973520cad9206c

Specifically, the MD5 fingerprint can be performed as follows: when downloading a program, we write (copy) the character set indicated on the download page. When this download is complete, we launch one of the aforementioned software on the downloaded file.

Figure 14.365: **Illustrated MD5 download hash from CISCO**

It must also be noticed that the main reason why using symmetric (or asymmetric) encryption is not advisable for protecting passwords is: key management. When using encryption, you must protect the encryption key (or the entropies from which the key is derived). And protecting the key is a very difficult task to solve. Hashing (with SHA, MD5, or any other algorithm) solves the problem of key protection, because you don't need to keep any secret value (other than salt, but salt is significantly less sensitive than encryption key; you can store salt in plain text). So if you only keep passwords for authentication purposes (performed by your app), there is absolutely no reason to use encryption; hashing would do just fine.

---

14.6.5.2 SHA-1 Secure Hash Algorithm condensation function

The "SHA-1" or "secure hash algorithm-1" is used in competition with the MD5 for Digital Signature Algorithm as specified by the Digital Signature Standard (DSS). It was designed by the United States National Security Agency and is a U.S. Federal Information Processing Standard published by the United States (INST).

SHA-1 is no longer considered secure against well-funded opponents. In 12005 (holocene calendar), cryptanalysts found attacks on SHA-1 suggesting that the algorithm might not be secure enough for ongoing use, and since 12010 (holocene calendar) many organizations have recommended its replacement by SHA-2 or SHA-3. Microsoft, Google, Apple and Mozilla have all announced that their respective browsers will stop accepting SHA-1 SSL certificates by 12017 (holocene calendar).

On February 23, 12017 (holocene calendar) CWI Amsterdam and Google announced they had performed a collision attack against SHA-1, publishing two dissimilar PDF files which produce the same SHA-1 hash as proof of concept (`https://shattered.io`).

For a message of length less than 2^{64}, the SHA-1 generates a 160-bit digest of the message named also "hash" or "fingerprint". Again, identically to the MD5, a tiny modification of the original message must have a big impact on the condensed message and there must not be an identical Message Digest for two messages of different origin.

As for the MD5, we work on messages whose length is a multiple of 512 bits.

1. Completion:

   If the message does not have a length of 512 bits, we add as many 1 as necessary at the end of the message. The last 64 bits of the 512-bit block are used to set the original length of the message. The 512-bit block is then transformed into sub-blocks `M[i]` of 32 bits each expressed in hexadecimal ($0 \geq i \geq 15$).

2. Initialization:

   As for the MD5, this time we define 80 chaining variables of 32 bits $K[i]$ initialized as following (the digits are hexadecimal):

   - `K[t]=01234567` for $0 \geq t \geq 19$
   - `K[t]=89ABCDEF` for $20 \geq t \geq 39$
   - `K[t]=FEDCBA98` for $40 \geq t \geq 59$
   - `K[t]=76543210` for $60 \geq t \geq 79$

   We also define 80 non-linear functions `F[0]`, `F[1]`, `F[2]`, ..., `F[79]` which take 32-bit arguments and return a 32-bit value, the operation being done bit by bit:

   - `F[t](X,Y,Z) = (X AND Y) OR (NOT(X) AND Z)` for $0 \geq t \geq 19$
   - `F[t](X,Y,Z) = (X XOR Y) XOR D` for $20 \geq t \geq 39$
   - `F[t](X,Y,Z) = (X AND Y) OR (X AND Z) OR (Y AND Z)` for $40 \geq t \geq 59$
   - `F[t](X,Y,Z) = X XOR Y XOR Z` for $60 \geq t \geq 79$

What is important with these 80 functions is that if the bits of their arguments `X`, `Y` and `Z` are independent, the bits of the result are also independent.

3. Iterative calculation:

   The iteration uses two buffers, each consisting of the use of 5 chaining variables. The chaining variables of the first buffer are denoted `A`, `B`, `C`, `D`, `E`. The second buffer contains the chaining variables `H[0]`, `H[1]`, `H[2]`, `H[3]`, `H[4]`.

Moreover, let `S^n` denote the circular shift of `n` bits to the left, here is the SHA-1 algorithm (if we have the time in the future we will write it properly with the correct LaTeX package...):

```
For t = 16 to 79 Do
    M[t] = S^1(M[t-16] XOR M[t-15] XOR M [t-14] XOR M [t-13]);
End For
A = H[0];
B = H[1];
C = H[2];
D = H[3];
E = H[4]
For t = 0 to 79 Do
     TEMP = S^5(A) + F[t](B,C,D) + E + M[t] + K[t]
     E = D;
     D = C;
     C = S^30(B);
     B = A;
     A = TEMP;
End For
H[0] = H[0] + A;
H[1] = H[1] + B;
H[2] = H[2] + C;
H[3] = H[3] + D;
H[4] = H[4] + E;
```

Remark

Since we have written this text on SHA-1, new versions, sometimes significantly different of SHA-1 have been released. The SHA-0 was released in 11998 (holocene calendar), the SHA-1 presented above is a minor correction of the SHA-0, the SHA-2 was released in 12001 (holocene calendar) and finally the SHA-3 in 12012 (holocene calendar).

To sum up a bit, it must be clear that MD5 (Message-Digest algorithm 5) is a cryptographic hash function, while Advanced Encryption Standard (AES) or RSA are symmetric-key encryption algorithms, so they are used for different purposes. A hash, like MD5 or SHA are used to verify passwords because they are hard to invert, that is, to obtain the password from the hash-string. An AES or RSA encryption, on the other hand, are invertible, the original message can be obtained if we know the key.

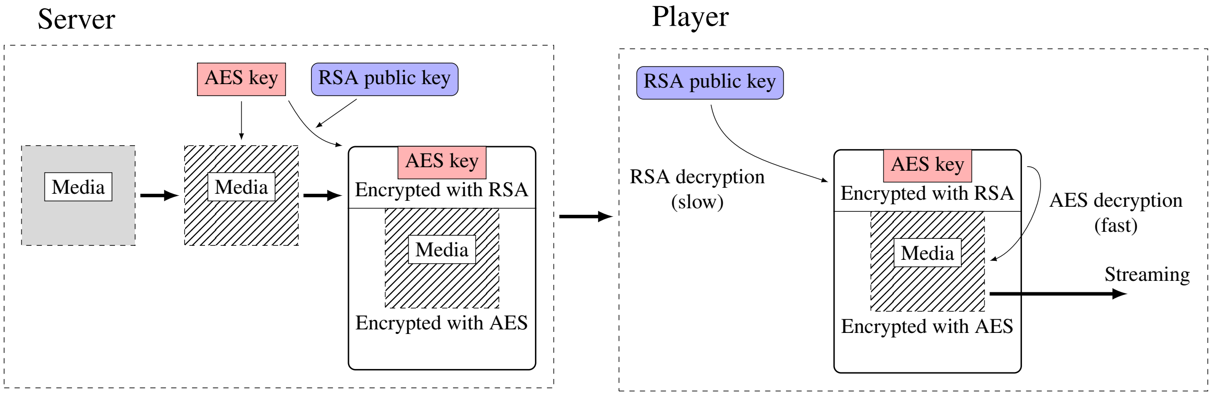

Figure 14.366: **Typical other use of AES and RSA combined together**

14.6.6 Certificate based authentication

We saw during our study of public key and secret key cryptography that there was an issue in the system of transmission of the keys at the beginning of the communication.

Thus, in both systems, the issue lies in the fact that a malicious person ("man-in-the-middle" attack) can replace the real interlocutor and send either a false secret key or a false public key (depending on the case).

Thus, a certificate of authenticity makes it possible to associate a key with an entity (a person, a machine, etc.) in order to ensure its validity (association with the "real person"). The certificate is in a way the identity card of the key or the "digital signature", issued by an organization named "certification authority".

The technologies using digital signatures are part of a larger set known as "Public Key Infrastructure (PKI)". The whole takes place by means of certificates which you can obtain from a Certification Authority (see example below). When you request your certificate, your computer creates the key pair consisting of a private key (the yellow on the schema) and a public key (the black one). Your private key is secret and it is only you who have access to it while the public key is freely available for everyone. Your public key will be attached to your certificate that you will get from the certification authority to whom you have submitted your certificate request.

The PKI (on which the IPSec connection is based) essentially targets 4 important points:

1. The authentication (the recipient of your email must be able to verify that it is you who sent the object and not another individual).
2. Integrity (ensure that the content has not been changed along the way).
3. Confidentiality (ensuring that the content is readable only by the recipient).
4. Non-repudiation (arising from the first 3 points)

The certification authority is responsible for issuing the certificates, assigning them a validity date, and possibly revoking certificates before that date if the key is compromised.

Certificates are small files divided into two parts:

- The part containing the information
- The part containing the signature of the certification authority (see Microsoft Internet Explorer browser for an example)

The certificate structure is standardized by the International Telecommunication Unification (ITU) standard X.509, which defines the information contained in the certificate:

- The name of the certification authority (VeriSign for example)
- The name of the owner of the certificate (the UBS bank for example)
- The date of validity of the certificate (X day from the current date)
- The encryption algorithm used (MD5RSA)
- The owner's public key

Here is a quite good schematic example:

To sign the message you are sending (point ⑤ in the figure below), it is sufficient to apply a hash function (point ①) which produces a summary (hash code) of the message (using MD5 or any version of SHA). The summary (fingerprint) obtained is (almost...) specific to each message, like the image of a fingerprint we know that a hash algorithm ensures that if a single bit of the original text is modified and a new hash is made, the latter will with a very high probability radically different from the first one, and the hashed code can then be encrypted using your private key (② and ③), this results constitutes the "digital signature". The recipient of the message (point ⑥) can then verify that you are the sender by encrypting the digital signature (point ⑦), by means of your public key (point ⑧), that you transmitted to it automatically with the mail (point ④), to get the hashed code (point ⑨). The recipient then applies the same hash function to the received message (point ⑩ in the diagram). If the two codes (points ⑪ and ⑫ on the schema) are identical, you are the sender of the message (authentication) and the message has not been altered (integrity).

Figure 14.369: Example of digital certificate smart card as used by the author of this chapter

2. The public key (d) of the certificate authority is provided to those who need it, for example Bob. This key can be included in the web browsers programs and in other software used for secure computer communications.
3. Alice digitally signs the message she sends to Bob. First, she creates a digest of the message by applying a hash function to it. The digest thus created is then encrypted using the secret key of Alice which gives the digital signature of the message (e). This signature is sent to Bob at the same time as the encrypted message (f) and the public key.
4. Bob uses the public key of the certificate authority to verify that the official digital signature on the certificate is authentic and that the accompanying public key is that of Alice. He then uses this key to decrypt Alice's digital signature and gets the digest of the message. Finally, Bernard applies the hash function to the message sent by Alice and thus gets a digest of the message. If this digest is identical to that obtained by Alice's numerical encryption, Bob is sure that the message comes from Alice and has not been altered by a third person.

14.6.7 Quantum cryptography

"Quantum cryptography" is a marketing expression, but somewhat misleading: it is not a question of encrypting a message using quantum physics, but of using quantum physics to ensure that the transmission of the key has not been spied. Currently used popular public-key encryption and signature schemes (RSA) can be broken by quantum adversaries. The advantage of quantum cryptography lies in the fact that it allows various cryptographic tasks that are proven or conjectured to be impossible to break using only classical (i.e. non-quantum) communication (see below for examples). For example, it is impossible to copy data encoded in a quantum state and the very act of reading data encoded in a quantum state changes the state. This is used to detect eavesdropping in quantum key distribution.

Indeed, as we have already explained it in the section of Quantum Computing, the transmission of a message, encrypted or not, can be done using the two orthogonal linear polarization states of a photon, for example $|x\rangle$, $|y\rangle$. We can decide to assign by convention the value 1 to the polarization $|x\rangle$ and the value 0 to the polarization $|y\rangle$: each photon therefore carries one bit of information. Any encrypted or unencrypted message can then be written in binary language, such as a sequence of 0 and 1, and the message 1001110 will be encoded by Alice thanks to the sequence of photons $|x\rangle|y\rangle|y\rangle|x\rangle|x\rangle|x\rangle|y\rangle$, which she will send to Bob for example by an optical fiber. Using a birefringent plate, Bob separates the photons with vertical and horizontal polarization and two detectors placed behind the slide allow him to decide whether the photon was polarized horizontally or vertically:

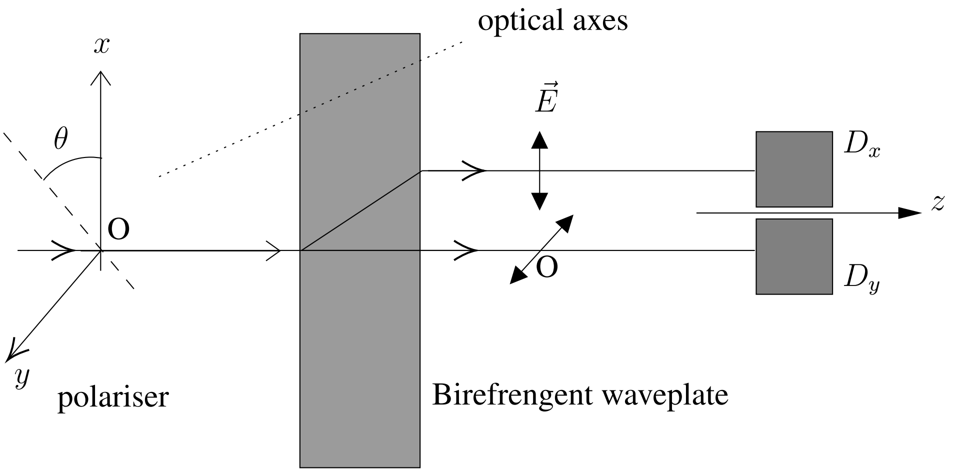

Figure 14.370: Thought experiment for polarization measurement

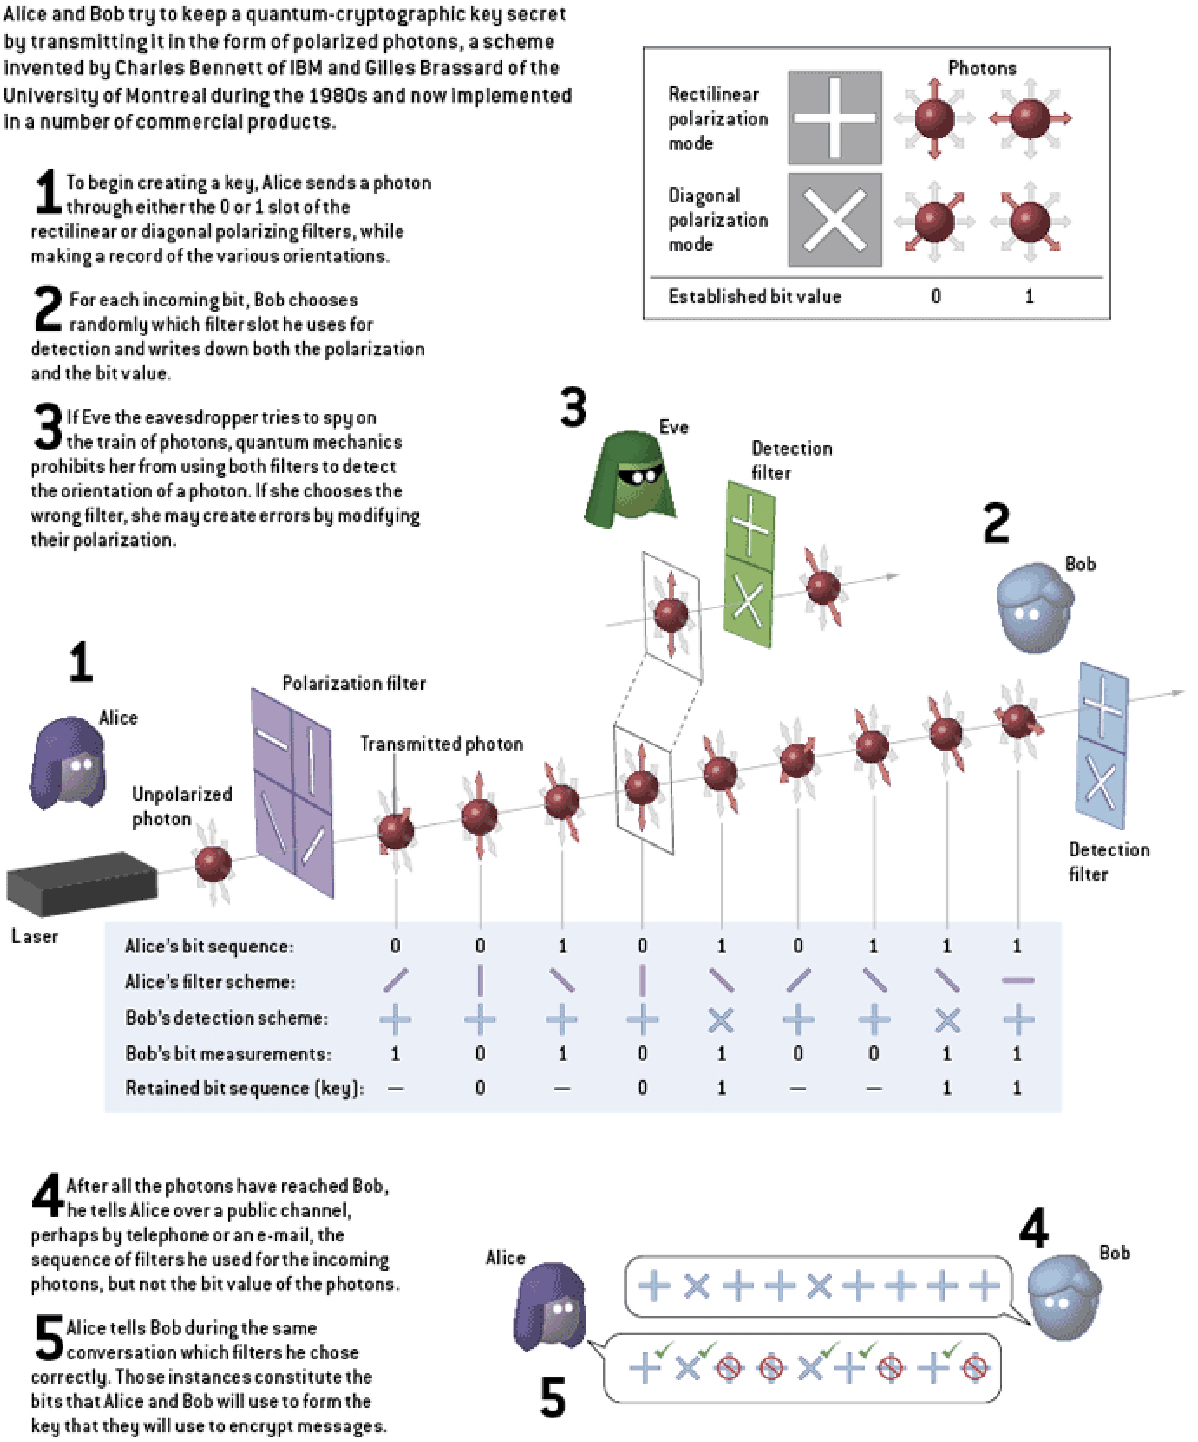
The whole process and protocol can be summarized by the excellent following figure:



Alice and Bob try to keep a quantum-cryptographic key secret by transmitting it in the form of polarized photons, a scheme invented by Charles Bennett of IBM and Gilles Brassard of the University of Montreal during the 1980s and now implemented in a number of commercial products.

1 To begin creating a key, Alice sends a photon through either the 0 or 1 slot of the rectilinear or diagonal polarizing filters, while making a record of the various orientations.

2 For each incoming bit, Bob chooses randomly which filter slot he uses for detection and writes down both the polarization and the bit value.

3 If Eve the eavesdropper tries to spy on the train of photons, quantum mechanics prohibits her from using both filters to detect the orientation of a photon. If she chooses the wrong filter, she may create errors by modifying their polarization.

Alice's bit sequence:	0	0	1	0	1	0	1	1	1
Alice's filter scheme:	/	|	\	|	\	/	\	\	—
Bob's detection scheme:	+	+	+	+	×	+	+	×	+
Bob's bit measurements:	1	0	1	0	1	0	0	1	1
Retained bit sequence (key):	—	0	—	0	1	—	—	1	1

4 After all the photons have reached Bob, he tells Alice over a public channel, perhaps by telephone or an e-mail, the sequence of filters he used for the incoming photons, but not the bit value of the photons.

5 Alice tells Bob during the same conversation which filters he chose correctly. Those instances constitute the bits that Alice and Bob will use to form the key that they will use to encrypt messages.

TOMMY MOORMAN; ADAPTED FROM *THE CODE BOOK: THE SCIENCE OF SECRECY FROM ANCIENT EGYPT TO QUANTUM CRYPTOGRAPHY*, BY SIMON SINGH (1999)

Figure 14.371: **Quantum key distribution**

Remark

The protocol described above is named BB84, named after its inventors Bennett and Brassard.

Let us now turn to the formal part (we strongly recommend the reader to first take a look the section of Quantum Computing at page 7263!).

The states of the quantum system are the states of polarization of a photon: the measurements (of the observable) will also have its polarization states. Possible measures will include:

$$\lambda_0=0 \qquad \lambda_1=1 \tag{14.6.91}$$

we will denote the corresponding states $|0\rangle$ and $|1\rangle$ (orthonormal basis of the space of the states of polarization): it is the base H/V (Horizontal/Vertical).

Let us consider several cases:

C1. Given a photon in the state $|\Psi\rangle=|0\rangle$ then as we have seen in the section Quantum Computing (see page 7263), we will have:

$$\begin{aligned}P(T=0)=P(\lambda=\lambda_1)=0=|0\rangle=|\Psi_{00}\rangle\\P(T=1)=P(\lambda=\lambda_0)=1=|1\rangle=|\Psi_{10}\rangle\end{aligned}\tag{14.6.92}$$

C2. Or a photon in the state:

$$\begin{aligned}|\Psi_{01}\rangle=\frac{|0\rangle+|1\rangle}{\sqrt{2}}=|+\rangle\\|\Psi_{11}\rangle=\frac{|0\rangle-|1\rangle}{\sqrt{2}}=|-\rangle\end{aligned}\tag{14.6.93}$$

And it customary to write the sequence of the key as following:

$$\boxed{|\Psi\rangle=\bigotimes_{i=1}^{n}|\Psi_{a_ib_i}\rangle}\tag{14.6.94}$$

Remarks

R1. Let us recall that this (famous) value is chosen for normalization purposes such as that $\langle\Psi|\Psi\rangle$!!! Many people ask the question of where the square root comes from in Quantum Computing? The answer is simply for normalization as we have detailed it in the section of Quantum Computing

R2. Let us also recall that the photons $|\Psi_{01}\rangle$ and $|\Psi_{11}\rangle$ are not polarized in the direction "$|0\rangle+|1\rangle$" (i.e. in the oblique direction) but are in a quantum superposition of these two polarizations!

Then for example (we apply as we saw in the section of Quantum Computing, the test $|0\rangle$ to the state $|\Psi_{01}\rangle$):

$$\begin{aligned}P(0)=||\langle 0|\Psi_{01}\rangle||^2&=\left\|\langle 0|\left(\frac{|0\rangle+|1\rangle}{\sqrt{2}}\right)\right\|^2=\frac{1}{2}||\langle 0|0\rangle+\langle 0|1\rangle||^2=\frac{1}{2}\left\|\begin{pmatrix}0\\1\end{pmatrix}\circ\begin{pmatrix}0\\1\end{pmatrix}+\begin{pmatrix}0\\1\end{pmatrix}\circ\begin{pmatrix}1\\0\end{pmatrix}\right\|^2\\&=\frac{1}{2}||1||^2=\frac{1}{2}\end{aligned}\tag{14.6.95}$$

and:

$$P(1)=||\langle 1|\Psi_{01}\rangle||^2=\left\|\langle 1|\left(\frac{|0\rangle+|1\rangle}{\sqrt{2}}\right)\right\|^2=\frac{1}{2}\,||\langle 1|0\rangle+\langle 1|1\rangle||^2=\frac{1}{2}\left\|\begin{pmatrix}1\\0\end{pmatrix}\circ\begin{pmatrix}0\\1\end{pmatrix}+\begin{pmatrix}1\\0\end{pmatrix}\circ\begin{pmatrix}1\\0\end{pmatrix}\right\|^2$$
$$=\frac{1}{2}||1||^2=\frac{1}{2}\tag{14.6.96}$$

Remark

Let us recall that in this textbook, we write in Quantum Physics the module of a complex number and the norm, indistinctly by the symbol $||||$ therefore caution to the possible confusions!

14.6.8 Alternative cryptography

Mathematicians sometimes venture out of the beaten path of Number Theory: they invent cryptosystems based on braids or networks (see the corresponding sections of Knot Theory or Graph Theory). Physicists are not left behind and offer methods of encryption that use Chaos Theory or Quantum Physics. The latter would provide a definitive solution to the delicate problem of key exchange and jeopardize cryptosystems based on factorization.

Most of these methods are outside the scope of this textbook for the moment but we can give however a non-exhaustive list:

- The LLL (Lenstra–Lenstra–Lovász) algorithm based on the mesh structure of sets of numbers and based on the Minkowski theorem ensuring that the content of a disc of given radius at a point contains at least one other point of the network
- The ultravariable cryptography in which the data pass through systems of superimposed quadratic equations.
- Optical hyperchaos, obtained by the passage of a LASER in a Ikeda ring in which a non-linear wavelength material is integrated.
- ...

The future will tell us the rest!

14.7. Quantum Computing

QUANTUM COMPUTING (we should rather speak of "quantum calculation" because we are currently very far from an input / output system) is a beautiful example of the use of specific theoretical models of quantum physics for treatment and the transmission of information.

However it must also be remembered that the behaviour of transistors etched on the chip in your computer could not be imagined in 11947 (holocene calendar) by Bardeen, Brattain and Shockley that from their knowledge of quantum physics. So all of our electronic devices already operating on the basis of semiconductors operate with developments achieved through quantum physics.

The big news, since the early 11980s (holocene calendar), is the ability of physicists to manipulate and observe individual elementary quantum objects: photons, atoms, ions, etc. It is this ability to manipulate and observe basic quantum objects that is the cause of quantum information, where these elementary quantum objects will physically build the "qubits" (for "Quantum Bit"). That said, no fundamentally new concept has been introduced since the 11930s (holocene calendar) and the founding fathers of quantum physics (Heisenberg, Schrödinger, Dirac, Planck, Einstein, etc.), if they revived today, would not be surprised by quantum computing, even if they would surely be surprised by the prowess of the experimenters who now realize experiences qualified in their era of "gedanken experiment" (imaginary experiment that was impossible to do in laboratory).

It is also interesting to notice that the increasing miniaturization of electronics will find its limits because of quantum effects, which will become essential below the nanometer. Thus, we think that Moore's Law (which assumption that the computing power of machines doubles roughly every 18 months) may not be correct anymore by the years 12015-12020 (holocene calendar).

It is likely that the trend of the study of quantum physics and its application to quantum information (and quantum electronics and quantum telecommunications) will explode in the coming decades (especially towards the end of the 121st century). Thus, engineering schools will integrate in all study field Quantum Physics in school curricula. What physicists study for soon already almost 100 years in their curriculum...

Before moving to the formal side, we felt, however, interesting to make a small popularized passage because we noticed that it helps to understand the calculations that will be made thereafter.

In the 70 and 80 (of the 120th century according to holocene calendar), the first quantum computers are born from the minds of physicists such as Richard Feynman, Paul Benioff, David Deutsch and Charles Bennett. Feynman's idea was that instead of complaining that the simulation of quantum phenomena demand enormous powers to our to days computers today, that we use the power of quantum phenomena to make the computers faster than classic computers.

During long time physicists doubted that quantum computers can be used, and even that we can do something viable if they existed. But (all years are based on the holocene calendar):

- In 11994, Peter Shor, a scientist of AT&T shows it is possible to factor large numbers in a reasonable time using a quantum computer. This discovery unlocks suddenly credits for quantum computers research.
- In 11996, Lov Grover, invented an algorithm based on quantum computers to find an entry in an unsorted database.
- In 11998, IBM was the first to present a 2-qubit quantum calculator.
- In 11999, the IBM R&D team used the Grover algorithm for fast quantum search on a database (quantum database search) on a calculator with 3-qubits and beat their record the following year with a 5-qubit computer.
- In 12001, IBM created a quantum computer with 7-qubits and factored the number 15... thanks to the Shor algorithm (see section Numerical Methods page 7263). Calculators with 7-qubits are built around chloroform molecules and their useful life is no more than a few minutes.
- In 12007, the Canadian company D-Wave during a demonstration presented a quantum computer with 16-qubits.
- In May 12013, Google announced that it was launching the Quantum Artificial Intelligence Lab, hosted by NASA's Ames Research Center, with a 512-qubit D-Wave quantum computer.
- In October 12015 researchers at University of New South Wales built a quantum logic gate in silicon for the first time.

Remark

As a 1 fermion spin qubit is equivalent to 2 bits, we have then that N fermion spin qubits are equal to 2^N classical bits. Therefore if one day we reach the 100 fermion spin qubits computer we will have a potential memory of $2^{100} \cong 1 \cdot 10^{15}$ Petabytes...

The memory of a classical computer is made of bits (see section Numerical Methods page 6275). Each bit carries either a 1 or a 0 (bipolar mode). The machine computes by manipulating those bits. A quantum computer is working on a set of qubits. A qubit can wear either a 1 or a 0, or a superposition of a 1 and a 0 (or, more accurately, he wears a phase distribution). The quantum computer computes by manipulating those distributions as discussed in detail below.

Query a qubit whose phase angle is not $0°$ or $90°$ $(\pi/2)$ is not very useful: we will get the answer 0 with a given probability and 1 with another probability and ... it is possible to construct random generators much cheaper! However, if we manage to create an algorithm that systematically leads it to a phase $0°$ or $90°$, we get a deterministic result. But is also necessary that it corresponds to a sought response.

A quantum computer could be implemented from any particles that can have two states. It can be built from photons, or from any particle or atom/molecule having a spin.

As we know, a classical computer with one bit can only store numbers with one digit composed of a one or a zero (see section Numerical Methods page 6275) for a total of $2^1 = 2$ states that it must treat separately. At one point, he could contain the bits 1 for example.

A quantum computer with one qubit can actually store 3 states as it can have a project state corresponding to 1 or to 0 and any superposition of the states 0 and 1 with a given probability (the third state!) before being observed (see section Wave Quantum Physics page 4779). When the calculator make the measurement the state superposition is cancelled as we know and therefore the third state can only be used (at least as far as we know) for intermediate and temporary calculations (as they cannot be read with our actual knowledge). This is why today qubits are specialized for given algorithms and we have "quantum calculators" but not "quantum computers".

Before we study the mathematical aspects let us start by the study of one of the most famous cat in the world to better understand (we hope so):

14.7.1 Schrödinger's Cat superposition

As we have studied it in details in the section of Quantum Sections, unlike in Classical Mechanics, essentially different states can mix in Quantum Mechanics (see page 4782) at least until a specific property is measured!

Now let us recall this famous thought experiment:

1. Put a (living) cat in box.
2. Add a container with deadly poison, that can be remotely released.
3. Close and seal the box.
4. Connect the remote to a quantum randomness source (e.g. nuclear decay).

In what state" is the cat? Is it alive or dead? Who knows?

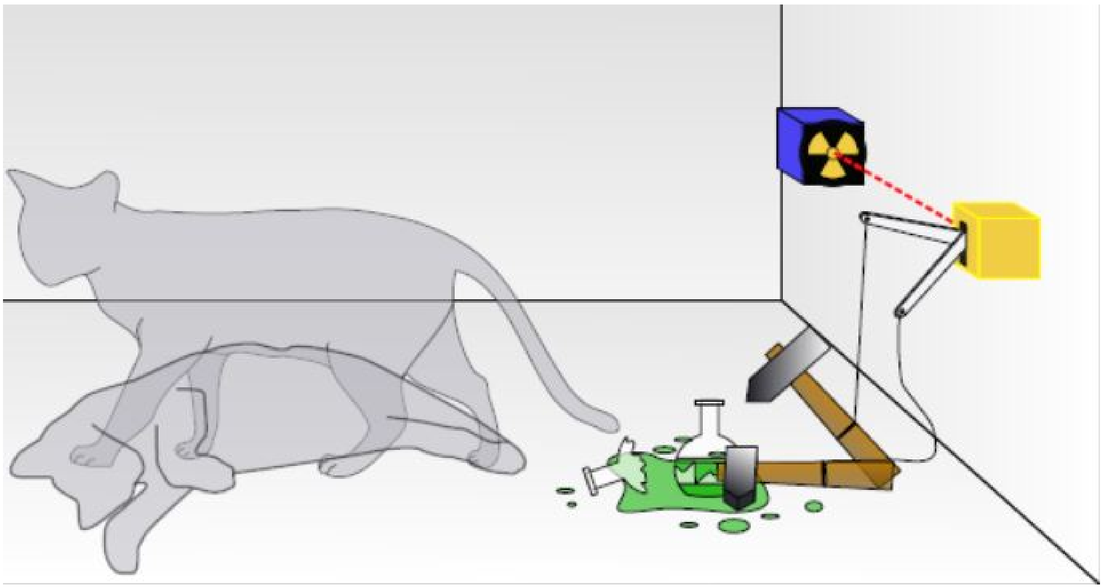

Figure 14.372: **Schrödinger cat experiment (source: Wikipedia)**

As long as no one checks (!!!), it a sensible way to think about this to consider the cat being in an intermediate state:

$$\langle \text{cat} \rangle = \frac{1}{3}\langle \text{alive} \rangle + \frac{2}{3}\langle \text{dead} \rangle \tag{14.7.1}$$

As long as no one checks (!!!) the cat is in a superposition of two states that are classically impossible to consider at the same time.

Now let us start by understanding the underlying concepts of quantum theory and of quantum computing with the study of the polarization of the photon.

Now if we open the box obviously, we will see ("measure") either a dead or alive cat.

By "measuring" the system, we put it back in a classical, pure state! As we know it already: Measuring affects the system!

The Cat set of states will be written:

$$\mathcal{H}_1 = \{\langle \text{alive} \rangle, \langle \text{dead} \rangle\} \tag{14.7.2}$$

Take a second cat, same arrangement and consider a 2-cat system:

$$\mathcal{H}_2 = \mathcal{H}_1 \otimes \mathcal{H}_1 = \{|\text{alive, alive}\rangle, |\text{alive, dead}\rangle, |\text{dead, alive}\rangle, |\text{dead, dead}\rangle\} \tag{14.7.3}$$

That is to say with two cats:

$$\langle \text{cats} \rangle = \frac{1}{9}|\text{alive, alive}\rangle + \frac{2}{9}|\text{alive, dead}\rangle\frac{2}{9}|\text{dead, alive}\rangle + \frac{4}{9}|\text{deaddead}\rangle \tag{14.7.4}$$

Therefore as we can see the central idea of quantum computing is manipulating the N-qubit system to change at the same time ALL 2^N pure states probabilities but when the N-qubit system will be measured, only a single pure state will be picked out!

A quantum algorithm must therefore modify the probability distribution of the quantum system, such that the correct "result" state has an (almost) 100% probability.

14.7.2 Photon polarization

Since Albert Einstein, we know that light is composed of photons, or particles of light, and that it has a dual wave-particle appearance (see section Wave Optics page 4509). If we reduce the light intensity of a beam of photons, we should be able to study the polarization of individual photons, that we know perfectly how to detect using photomultipliers. Suppose that the experiment detects N photons. When $N \rightarrow +\infty$, we must fall back on the results of wave optics (see section of the same name page 4470).

Let us perform by example the following experience:

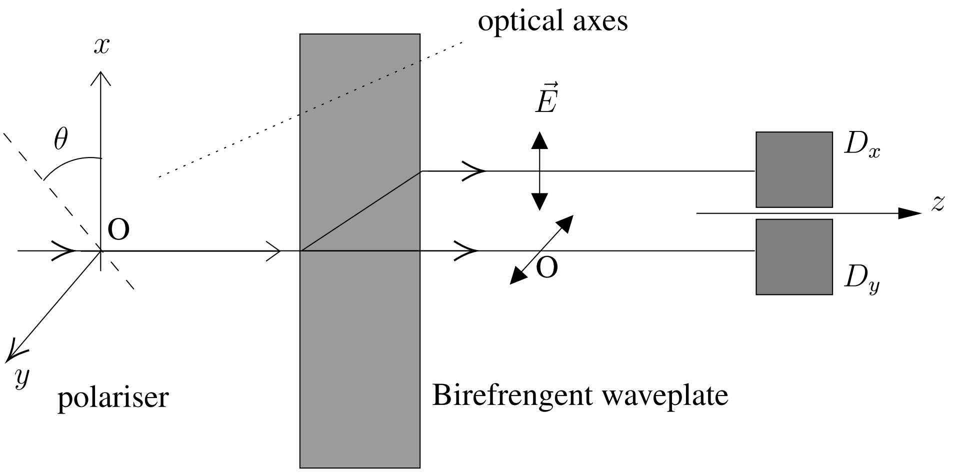

Figure 14.373: **Thought experiment for polarization measurement**

A birefringent plate separates a light beam whose polarization is makes an angle θ with Ox in a subsequent beam polarized following Ox and another polarized following Oy, the intensities being respectively $I\cos^2(\theta)$ and $I\sin^2(\theta)$ (according to the proof of Malus Law made in the section of Wave Optics at page 4552).

Let us reduce the intensity so that the photons arrive one by one, and let us place two photodetectors D_x, D_y behind the blade. The experiment shows that D_x, D_y never click together at the same time (except in cases of "dark count" when a counter is triggered spontaneously because of background noise): a photon comes entirely either on D_x, either on D_y, a photon therefore can not divide itself. On the other hand, the experiment shows that the probability P_x (respectively P_y) of detecting a photon by D_x (respectively D_y) is equal to $\cos^2(\theta)$ (respectively $\sin^2(\theta)$). So if the experiment detects N photons, we will have N_x (respectively N_y) photons detected by D_x (respectively D_y):

$$N_x \cong N\cos^2(\theta) \qquad N_y \cong N\sin^2(\theta) \tag{14.7.5}$$

where the $\cong$ takes int account the statistical fluctuations. As the light intensity is proportional to the number of photons, we fall indeed back on the Malus law the limit $N \rightarrow +\infty$.

However, we notice two problems:

1. Can we predict, for a given photon, it will trigger D_x or D_y? The answer of quantum theory is: NO, statement has deeply shocked Albert Einstein (God does not play dice!).

Some physicists (including Albert Einstein) have been tempted to assume that quantum theory was incomplete, and that there were "hidden variables" whose knowledge would provide the individual destiny of each photon. Under very reasonable assumptions on which we will come back, we now know that such hidden variables are excluded. The probabilities of quantum theory are, as we know (see section Wave Quantum Physics page 4688), intrinsic! They are not related to an imperfect knowledge of the physical situation, as is the case for example in the game of heads or tails.

2. If we combine the two beams of the first birefringent plate, using a second blade that is symmetrical to the first:

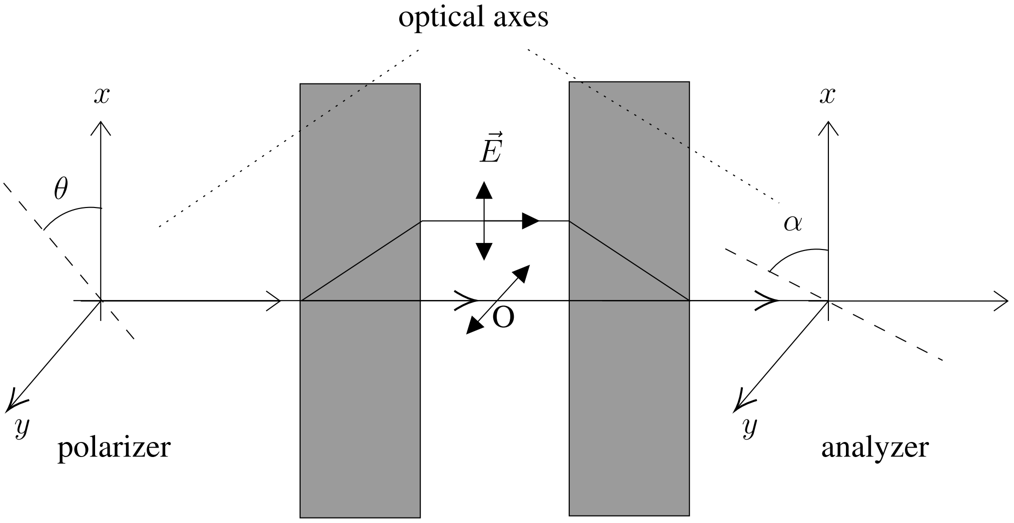

Figure 14.374: Imaginary experience recombining the two beams

and if we seek the probability that a photon passes through the analyser, a photon can choose the path x with a probability $\cos(\theta)^2$, then it has a probability $\cos^2(\alpha)$ to cross the analyser thus a total probability of $\cos^2(\theta)\cos^2(\alpha)$. If it chooses the path y, they will have a probability $\sin^2(\theta)\sin^2(\alpha)$ to cross the analyser. The total probability is thus obtained by summing the probabilities of the two possible options:

$$P'_{\text{tot}} = \cos^2(\theta)\cos^2(\alpha) + \sin^2(\theta)\sin^2(\alpha) \tag{14.7.6}$$

This result is FALSE! Indeed, classical optics tells us that the intensity is $I\cos^2(\theta-\alpha)$ (see section Wave Optics page 4552) and the correct result is confirmed by experience:

$$P_{\text{tot}} = \cos^2(\theta-\alpha) \tag{14.7.7}$$

Which is not the same at all!

In fact, to fall back on the results of optics wave, it must be remembered that the probability in quantum physics is obtained through the norm to the square of the probability amplitude (see section Wave Quantum Physics page 4692). Therefore:

$$\begin{aligned} a(\theta\to x) &= \cos(\theta) \quad & a(x\to\alpha) &= \cos(\alpha) \\ a(\theta\to y) &= \sin(\theta) \quad & a(y\to\alpha) &= \sin(\alpha) \end{aligned} \tag{14.7.8}$$

and we must add the amplitudes for indistinguishable paths and using basic trigonometric relations, we get:

$$a_{\text{tot}} = \cos(\theta)\cos(\alpha) + \sin(\theta)\sin(\alpha) = \cos(\theta-\alpha) \tag{14.7.9}$$

which gives well:

$$\boxed{P_{\text{tot}} = ||a_{\text{tot}}||^2 = \cos^2(\theta - \alpha)} \qquad (14.7.10)$$

Suppose we have a way of knowing whether the photon takes the path x or the path y (impossible in our case, but analogue experiments answering to the question "What path?" were realized with atoms). We could then divide the photons into two classes, those who "chose" the path x and those who "chose" the path y.

For photons having chosen the path x, we may block the path y by a cache without changing anything, and vice versa for photons having chosen the path y we could block the path x. Obviously, the result can then only be P'_{tot}. If we can discriminate between the paths, the result is not the same anymore, the paths are no longer indistinguishable. Under the experimental conditions where it is impossible in principle to distinguish between the paths, we can say either:

1. Either the photon use the both paths at once (...)
2. Or it make no sense to ask the question "Which path?", Since the experimental conditions do not allow to answer.

It must be noticed that if the experience allows to decide between two paths, the result is P'_{tot}, even if we decide not to observe them. It is just enough that the experimental conditions allow, in principle, to distinguish between the two paths.

14.7.3 Qubit

Ultimately, the idea of quantum computing is therefore to connect quantum gates in a suitable fashion while protecting the superposition between the N qubits from any external influence.

We can use the polarization of photons to transmit information, for example by an optical fiber. We decide quite arbitrarily, to assign the value of 1 bit to a photon polarized along Ox and 0 to a photon polarized along Oy.

To investigate the theory, it has become traditional to imagine that the two people who exchange information are conventionally named Alice (A) and Bob (B)... Alice sends to Bob for example the following sequence of polarized photons:

$$yyxyxyyyx\ldots \qquad (14.7.11)$$

Bob analyses the polarization of these photons with a birefringent plate and derives the message from Alice:

$$001010001\ldots \qquad (14.7.12)$$

This is obviously not a very efficient way to exchange messages, but it is the basis of quantum cryptography (see section Cryptography page 7259). However, the interesting question now is:

what is the value of the bit that we can attribute for example to a photon polarized at 45°...? According to the above results, a photon polarized at 45°. is a linear superposition of photon polarized along Ox and a photon polarized along Oy. A qubit is therefore an entity much richer than a regular bit, which cannot take in the strict sense only the values 0 and 1.

In a sense, a qubit can take all values between 0 and 1 and therefore contains an infinite amount of information! However, this optimistic statement was immediately denied when we realize that the measurement of qubit can give only the result 0 or 1, regardless of the chosen base. However, we can ask ourselves the question of this "hidden information" in the linear superposition and we will see that we can exploit it under certain conditions.

To take into account for the possibility of linear superposition, it is natural to introduce for the mathematical description of the polarization a complex vector space (cause: phasers) in two dimensions corresponding to the polarization plane as we saw it in the section of Wave Optics (see page 4539). We denote this vector space $\mathcal{H}$ (we take again the notation of Hilbert spaces) and name the "Hilbert space of polarization states".

We may well decompose the vector corresponding to linear polarizations Ox and Oy in two ket vectors equation and equation such that any polarization state (whether linear, circular, or other) may decompose according to this basis:

$$|\Phi\rangle=\lambda|x\rangle+\mu|y\rangle \tag{14.7.13}$$

Thus, a linear polarization is described by real coefficients λ,μ but the description of a circular or elliptical polarization obviously require to use complex coefficients!

The probability amplitudes will correspond to a scalar product on this space. So given two vectors corresponding to two different polarizations:

$$\begin{aligned}|\Phi\rangle&=\lambda|x\rangle+\mu|y\rangle\\|\Psi\rangle&=\nu|x\rangle+\sigma|y\rangle\end{aligned} \tag{14.7.14}$$

The Hermitian dot product (see section Vector Calculus page 1843) will be:

$$\langle\Psi|\Phi\rangle=\bar{\nu}\lambda+\bar{\sigma}\mu=\overline{\Psi|\Phi} \tag{14.7.15}$$

Now a linear polarization state (see section Wave Optics page 4543) following θ will be given logically by (if we restrict ourselves to the linear case so!):

$$|\theta\rangle=\cos(\theta)|x\rangle+\sin(\theta)|y\rangle \tag{14.7.16}$$

where $|x\rangle$, $|y\rangle$ are vectors having unit norms. This is consistent with the mental representation:

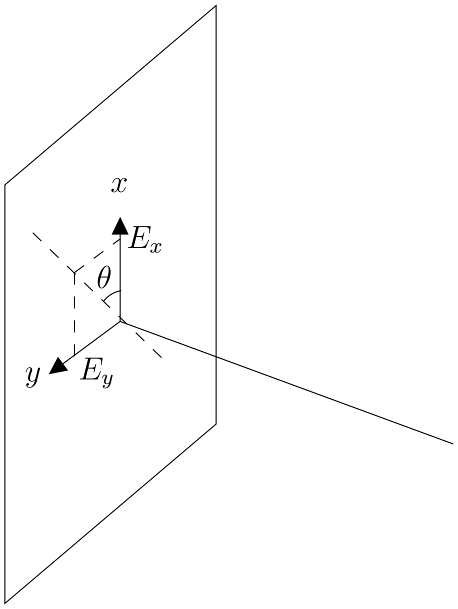

Figure 14.375: Reminder of field decomposition principle

where the amplitude is normalized to the unit.

The probability amplitude for a polarized photon following θ goes through an analyser oriented following α can now be written:

$$\langle\alpha|\theta\rangle=\cos(\alpha)\cos(\theta)+\sin(\alpha)\sin(\theta)=\cos(\theta-\alpha) \tag{14.7.17}$$

and the probability of passing through the analyser will always be given by the squared norm of this amplitude as we have prove it earlier above:

$$||\langle\alpha|\theta\rangle||^2=\cos^2(\theta-\alpha) \tag{14.7.18}$$

In general, we define probability amplitudes, where $|\Phi\rangle$, $|\Psi\rangle$ are polarization states:

$$a(\Phi\rightarrow\Psi)=\langle\Psi|\Phi\rangle \tag{14.7.19}$$

and the corresponding probability will be:

$$P(\Phi\rightarrow\Psi)=||a(\Phi\rightarrow\Psi)||^2=||\langle\Psi|\Phi\rangle||^2 \tag{14.7.20}$$

We are now ready to tackle the crucial issue of the measure as part of this quantum experiment. Let take again the polariser / analyser experiment, assuming that the analyser is oriented along Ox. If the polariser is oriented along Ox, an outgoing photon passes through the polariser analyser with a probability of 100%; if the polariser is oriented along Oy, the probability is 0%. The analyser performs a (polarization) test, and the test result is 1 or 0. The test allow us to determine the polarization state of the photon.

But this is not the general case!

Let us assume that the polariser is oriented following the general direction θ or the orthogonal direction $\theta_\perp$ (there is a rotation of $\pi/2$). We then use the properties of the unitary trigonometric circle:

$$\begin{aligned}|\theta\rangle &= \cos(\theta)|x\rangle+\sin(\theta)|y\rangle\\ |\theta_{\perp}\rangle &= -\sin(\theta)|x\rangle+\cos(\theta)|y\rangle\end{aligned} \tag{14.7.21}$$

and therefore if the polariser prepares for example the photon in the state $|\theta\rangle$ and the analyser is oriented along Ox, the probability of success of the test will always be $\cos^2(\theta)$ whatever the type of polarization!! Let us recall that in this example, after the passing through the analyser, the polarization state of the photon is no longer $|\theta\rangle$, but $|x\rangle$. The measurement therefore changes the polarization state.

Remark

Of course, another way of seeing that the two vectors above are orthogonal is to make a scalar product and to see that the result is immediately equal to zero.

We see a difference of principle between measurement in classical physics and measurement in quantum physics. In classical physics, the physical quantity to be measured predates the measurement: if a radar measures the speed of your car at 180 [km$\cdot$h^{-1}] on the highway, this speed pre-existed to its measure by the policeman. On the contrary, in the measurement of polarization of a photon $|\theta\rangle$ by an analyser oriented along Ox, the fact that the test gives a polarization according to Ox does not make it possible to conclude that the photon tested had previously its polarization following Ox.

So we have a device preparing the quantum system in the state $|\Phi\rangle$ and a second one capable of "preparing" it in the state $|\Psi\rangle$ that we will use as an analyser. After the test, the quantum system will therefore be in the state $|\Psi\rangle$, which means mathematically that we realize an orthogonal projection on $|\Psi\rangle$.

Let $\mathcal{P}_\Psi$ this projector, then the vectorial orthogonal projection (see section Vector Calculus page 1821) is given by:

$$\boxed{\mathcal{P}_\Psi=|\Psi\rangle\langle\Psi|\Phi\rangle} \tag{14.7.22}$$

which consists (for recall) of a simple scalar product (scalar orthogonal projection) multiplied by the vector $|\Psi\rangle$. This is easily seen by judiciously placing the parentheses:

$$\mathcal{P}_\Psi|\Phi\rangle=(|\Psi\rangle\langle\Psi|)|\Phi\rangle \tag{14.7.23}$$

and therefore:

$$\boxed{\mathcal{P}_\Psi=|\Psi\rangle\langle\Psi|} \tag{14.7.24}$$

The projection of the state vector is named, as we have already seen it (in the section of Wave Quantum Physics), in the Copenhagen interpretation of quantum physics "state vector reduction", or, for historical reasons, "reduction of the wave packet". This reduction of the state vector is a convenient fiction of the Copenhagen interpretation, which avoids having to ask questions about the measurement process ...

The reader accustomed to Linear Algebra (see section of the same name page 1924) will have probably notice trivially that we can manipulate the notation convention of the projector as a matrix (linear mapping) such as in two simple particular cases (those of interest to us):

$$\mathcal{P}_x=|x\rangle\langle x|=\begin{bmatrix}1&0\\0&0\end{bmatrix}\qquad\mathcal{P}_y=|y\rangle\langle y|=\begin{bmatrix}0&0\\0&1\end{bmatrix}\tag{14.7.25}$$

A reader has asked us to explicit this matrix approach. Let us see how we arrive at this matrix aspect of the orthogonal projection with a particular example of two vectors in a real two-dimensional space. For this let us consider:

$$x=\begin{pmatrix}x_1\\x_2\end{pmatrix}\qquad\Phi=\begin{pmatrix}\Phi_1\\\Phi_2\end{pmatrix}\tag{14.7.26}$$

and therefore (the procedure is the same for y):

$$\begin{gathered}|x\rangle\langle x|\Phi\rangle=\begin{pmatrix}x_1\\x_2\end{pmatrix}\left(\begin{pmatrix}x_1\\x_2\end{pmatrix}\circ\begin{pmatrix}\Phi_1\\\Phi_2\end{pmatrix}\right)=\begin{pmatrix}x_1\\x_2\end{pmatrix}(x_1\Phi_1+x_2\Phi_2)=\begin{pmatrix}x_1\,(x_1\Phi_1+x_2\Phi_2)\\x_2\,(x_1\Phi_1+x_2\Phi_2)\end{pmatrix}\\=\begin{pmatrix}x_1x_1\Phi_1+x_1x_2\Phi_2\\x_2x_1\Phi_1+x_2x_2\Phi_2\end{pmatrix}=\begin{pmatrix}x_1^2\Phi_1+x_1x_2\Phi_2\\x_2x_1\Phi_1+x_2^2\Phi_2\end{pmatrix}=\underbrace{\begin{bmatrix}x_1^2&x_1x_2\\x_1x_2&x_2^2\end{bmatrix}}_{\mathcal{P}_x}\begin{pmatrix}\Phi_1\\\Phi_2\end{pmatrix}=\begin{bmatrix}1&0\\0&0\end{bmatrix}\begin{pmatrix}\Phi_1\\\Phi_2\end{pmatrix}\end{gathered}\tag{14.7.27}$$

Remark

The matrix notation of the orthogonal projector is often presented as a definition of a mathematical tool named "outer product".

So finally, to get back to our previous subject, we have:

$$\mathcal{P}_x|\Phi\rangle=|x\rangle\langle x|\Phi\rangle=|x\rangle 1\cdot\Phi_x=\begin{pmatrix}\Phi_x\\0\end{pmatrix}=\begin{bmatrix}1&0\\0&0\end{bmatrix}\Phi\tag{14.7.28}$$

and same for the other component.

As:

$$|\theta\rangle=\cos(\theta)|x\rangle+\sin(\theta)|y\rangle\tag{14.7.29}$$

We then have:

$$\begin{gathered}\mathcal{P}_\theta|\Phi\rangle=|\theta\rangle\langle\theta|\Phi\rangle=|\theta\rangle\,(\cos(\theta)\Phi_x+\sin(\theta)\Phi_y)=\begin{pmatrix}\cos^2(\theta)\Phi_x&\cos(\theta)\sin(\theta)\Phi_y\\\sin(\theta)\cos(\theta)\Phi_x&\sin^2(\theta)\Phi_y\end{pmatrix}\\=\begin{bmatrix}\cos^2(\theta)&\sin(\theta)\cos(\theta)\\\sin(\theta)\cos(\theta)&\sin^2(\theta)\end{bmatrix}\begin{pmatrix}\Phi_1\\\Phi_2\end{pmatrix}\end{gathered}\tag{14.7.30}$$

We will notice that the identity operator can be written as the sum of the two projectors $\mathcal{P}_x$,$\mathcal{P}_y$:

$$\mathcal{P}_x+\mathcal{P}_y=|x\rangle\langle x|+|y\rangle\langle y|=\mathbb{1}\tag{14.7.31}$$

relation named "closure relation", which can be generalized to an orthonormal basis of a Hilbert space $\mathcal{H}$ of dimension N:

$$\sum_{i=1}^{N}|i\rangle\langle i|=\mathbb{1} \qquad \langle i|j\rangle=\delta_{ij} \tag{14.7.32}$$

Moreover, the projectors $\mathcal{P}_x$, $\mathcal{P}_y$ commute (trivial verification):

$$[\mathcal{P}_x,\mathcal{P}_y]=\mathcal{P}_x\mathcal{P}_y-\mathcal{P}_y\mathcal{P}_x=0 \tag{14.7.33}$$

Thus, the tests $|x\rangle$, $|y\rangle$ are compatible (whatever the direction of the measurement the result is independent). In contrast, the projectors $\mathcal{P}_\theta$, $\mathcal{P}_{\theta,\perp}$:

$$\mathcal{P}_\theta=|\theta\rangle\langle\theta|=\begin{bmatrix}\cos^2(\theta) & \sin(\theta)\cos(\theta)\\ \sin(\theta)\cos(\theta) & \sin^2(\theta)\end{bmatrix} \qquad \mathcal{P}_{\theta\perp}=|\theta_\perp\rangle\langle\theta_\perp|=\begin{bmatrix}\sin^2(\theta) & -\sin(\theta)\cos(\theta)\\ -\sin(\theta)\cos(\theta) & \cos^2(\theta)\end{bmatrix} \tag{14.7.34}$$

which satisfy (trivial verification) to:

$$|\theta\rangle\langle\theta|+|\theta_\perp\rangle\langle\theta_\perp|=\mathbb{1} \qquad \langle\theta|\theta_\perp\rangle=0 \tag{14.7.35}$$

as well as (trivial verification):

$$\mathcal{P}_\theta|\theta\rangle=|\theta\rangle\langle\theta|\theta\rangle=|\theta\rangle \qquad \mathcal{P}_{\theta\perp}|\theta_\perp\rangle=|\theta_\perp\rangle\langle\theta_\perp|\theta_\perp\rangle=|\theta_\perp\rangle \tag{14.7.36}$$

Do not commute with $\mathcal{P}_x$,$\mathcal{P}_y$:

$$[\mathcal{P}_x,\mathcal{P}_\theta]=\begin{bmatrix}0 & \sin(\theta)\cos(\theta)\\ -\sin(\theta)\cos(\theta) & 0\end{bmatrix} \tag{14.7.37}$$

and therefore the tests $|x\rangle$ and $|\theta\rangle$ are incompatible.

For the next developments, it will be useful to notice that the knowledge of the probabilities of success of a T test makes it possible to define an average value (expected mean):

$$\langle T\rangle=1\cdot P(T=1)+0\cdot P(T=0)=P(T=1) \tag{14.7.38}$$

In analogy with the context, we can read this as following: the expected mean of the test is equal to the representative value of the photon oriented according to Ox (corresponding arbitrarily to the value 1) multiplied by the probability of passing through the analyser oriented also according to Ox (therefore test concluding at 100%) summed with the representative value of the photon oriented according to Oy (corresponding arbitrarily to the value 0) multiplied by the probability of passing through the analyser always oriented along Ox (therefore 0% of the photons Oy will pass the Ox test).

For example, if the test T is represented by the procedure $|\Phi\rangle$ and we apply it to a state $|\Phi\rangle$ (containing as we have seen above the representative values of the linearly or non-linearly polarized photon...) then the test corresponds to a scalar product:

$$P(\Psi)=\|\langle\Psi|\Phi\rangle\|^2=\langle\Psi|\Phi\rangle\langle\Psi|\Phi\rangle=\langle\Phi|(|\Psi\rangle\langle\Psi|)|\Phi\rangle=\langle\Phi|\mathcal{P}_\Psi\Phi\rangle \tag{14.7.39}$$

And as we have seen it in the section of Wave Quantum Physics, we know that in fact (see page 4699):

$$\langle M\rangle_\Phi = \langle\Phi|\mathcal{P}_\Psi\Phi\rangle \tag{14.7.40}$$

is the mean value of an operator M in the state $|\Phi\rangle$. Thus, to the test T to which a procedure $|\Psi\rangle$ is associated, we can associate the projector $\mathcal{P}_\Phi$ whose mean value in the state $|\Phi$ gives the probability of success of the test.

The generalization of this observation makes it possible to construct the physical properties of a quantum system. Let us give an example by returning to the case of polarization. Suppose that we construct (quite arbitrarily) a property $\mathcal{M}$ of a photon as follows:

- $\mathcal{M}$ is equal to $+1$ if the photon is polarized following Ox
- $\mathcal{M}$ is equal to -1 if the photon is polarized according to Oy

We can associate with the physical property $\mathcal{M}$ the Hermitian operator:

$$M = \mathcal{P}_x - \mathcal{P}_y \tag{14.7.41}$$

Which satisfies (trivial) the relation between operator, eigenvalue and vector:

$$\begin{aligned} M|x\rangle &= +1\cdot|x\rangle = +|x\rangle \\ M|y\rangle &= -1\cdot|y\rangle = -|y\rangle \end{aligned} \tag{14.7.42}$$

The mean value (expected mean) of M then being (by definition):

$$\langle M\rangle = (+1)\cdot P\left(M=1\right) + (-1)\cdot P\left(M=-1\right) \tag{14.7.43}$$

Let us assume the photon in the linear polarization state of angle θ, then the mean value $\rangle M\langle_\theta$ in the state $|\theta\rangle$ is (trivial):

$$\langle M\rangle_\theta = \langle\theta|\mathcal{P}_x\theta\rangle - \langle\theta|\mathcal{P}_y\theta\rangle = \cos^2(\theta) - \sin^2(\theta) = \cos\left(2\theta\right) \tag{14.7.44}$$

Before seeing, how can we construct such an operator M with another object than the photon and with the same properties, let us introduce a mathematical tool generalizing the conditions and the configuration of any polarized wave:

14.7.3.1 Bloch sphere

The "Bloch sphere" (11946 according to holocene calendar) is, as we will see, a geometrical representation of the pure states of the qubits (two-level quantum mechanical system) as points of the surface of a sphere, named after the physicist Felix Bloch

A given number of elementary operations done in quantum computing can be carried out with this sphere under the choice of a suitable projector .

We will see that a state of an arbitrary qubit (vector in the complex plane) can be written:

$$\boxed{|\Psi\rangle = e^{\mathrm{i}\gamma}\left(\cos\frac{\theta}{2}|0\rangle + e^{\mathrm{i}\phi}\sin\frac{\theta}{2}|1\rangle\right)} \tag{14.7.45}$$

where $\gamma \in \mathbb{R}$ and $0 \leq \phi \leq 2\pi$, define a point on the three-dimensional Bloch sphere and where we have the two basic vectors:

$$|0\rangle = |\downarrow\rangle = |-\rangle = \begin{pmatrix}0\\1\end{pmatrix} \qquad |1\rangle = |\uparrow\rangle = |+\rangle = \begin{pmatrix}1\\0\end{pmatrix} \tag{14.7.46}$$

for which sometimes the definition is reversed (but it does not matter as long as it forms an orthogonal basis!).

The qubits represented by arbitrary values γ (global gauge invariance according to $U(1)$ as seen in the section of Set Algebra page 1417) are all represented by the same point on the Bloch sphere because we will show that the factor has no observable effect and that we can then write without losing in generality:

$$|\Psi\rangle = \cos\left(\frac{\theta}{2}\right)|0\rangle + e^{\mathrm{i}\phi}\sin\left(\frac{\theta}{2}\right)|1\rangle \tag{14.7.47}$$

which is represented as we will justify later by the figure below:

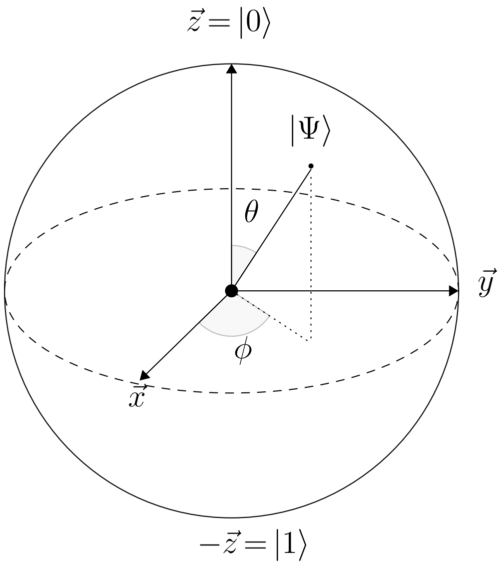

Figure 14.376: Bloch-shpere (two dimensional one)

Remark

Let us assume that we have a Quantum System with k qubits:

$$|0\rangle, |1\rangle, |2\rangle \ldots |k-1\rangle \tag{14.7.48}$$

The qubit will be in a superimposed state:

$$\Psi = \alpha_0|0\rangle + \alpha_1|1\rangle + \alpha_2|2\rangle + \ldots + \alpha_{\mathrm{k}-1}|k-1\rangle \tag{14.7.49}$$

where α_i is a complex vector with the property $\sum \alpha_i = 1$.

The Bloch sphere is a generalization of the representation of a complex number z (see section Numbers page 243) with $|z|^2 = 1$ as point of the circle in the (Gauss-) plane.

We also saw in this same section that a complex number could be represented by a complex exponential such that:

$$z = x + \mathrm{i}y = re^{\mathrm{i}\theta} \tag{14.7.50}$$

and if the circle were unitary:

$$z = e^{\mathrm{i}\theta} \tag{14.7.51}$$

Let us notice that the constraint $|z|^2 = 1$ eliminates a degree of freedom.

We will now notice the decomposition of a state of polarization in the form:

$$|\Psi\rangle = \alpha|x\rangle + \beta|y\rangle \tag{14.7.52}$$

And this one in a more traditional form in quantum computing (logic when we see the bases ...):

$$|\Psi\rangle = \alpha|0\rangle + \beta|1\rangle \tag{14.7.53}$$

where $\alpha, \beta \in \mathbb{C}$ (yes! indeed we are not anymore in the simple case of a wave linearly polarized now ...!) without forgetting the condition of normalization:

$$\langle\Psi|\Psi\rangle = \Psi\overline{\Psi} = |\alpha|^2 + |\beta|^2 = 1 \tag{14.7.54}$$

We can therefore write the qubit in the form:

$$|\Psi\rangle = r_\alpha e^{\mathrm{i}\phi_\alpha}|0\rangle + r_\beta e^{\mathrm{i}\phi_\beta}|1\rangle \tag{14.7.55}$$

Caution! It is very important to have read the part dealing with the polarization of light in the section of Wave Optics (see page 4538) to understand that it does not come from nowhere!!! With the difference that we do not work here with phasors because the solution of Schrödinger's equation of evolution involves complex exponentials as we saw in the context of the resolution of the latter for the eigen-mode of free particle.

Adding an overall phase factor should have no influence on the coefficients α, β because:

$$|e^{\mathrm{i}\gamma}\alpha|^2 = \left(e^{\mathrm{i}\gamma}\alpha\right)\overline{\left(e^{\mathrm{i}\gamma}\alpha\right)} = \left(e^{\mathrm{i}\gamma}\alpha\right)\left(e^{-\mathrm{i}\gamma}\bar{\alpha}\right) = \alpha\bar{\alpha} = |\alpha|^2 \tag{14.7.56}$$

and similarly for $|\beta|^2$. Thus, we are free to multiply our polarized and standardized qubit:

$$|\Psi\rangle = r_\alpha e^{\mathrm{i}\phi_\alpha}|0\rangle + r_\beta e^{\mathrm{i}\phi_\beta}|1\rangle \tag{14.7.57}$$

by the global phase $e^{-\mathrm{i}\phi_\alpha}$ which gives:

$$|\Psi'\rangle = r_\alpha e^{-\mathrm{i}\phi_\alpha} e^{i\phi_\alpha}|0\rangle + r_\beta e^{-\mathrm{i}\phi_\alpha} e^{\mathrm{i}\phi_\beta}|1\rangle = r_\alpha|0\rangle + r_\beta e^{\mathrm{i}\phi_\beta - \mathrm{i}\phi_\alpha}|1\rangle = r_\alpha|0\rangle + r_\beta e^{\mathrm{i}\phi}|1\rangle \tag{14.7.58}$$

In addition, we always have the condition of normalization $\langle\Psi'|\Psi\rangle$ to respect (impose).

Returning to the Cartesian coordinates, we have:

$$|\Psi'\rangle = r_\alpha|0\rangle + r_\beta e^{\mathrm{i}\phi}|1\rangle = r_\alpha|0\rangle + (x+\mathrm{i}y)\,|1\rangle \tag{14.7.59}$$

And the normalization constraint then gives:

$$\langle\Psi'|\Psi'\rangle = |r_\alpha|^2 + |x+iy|^2 = r_\alpha^2 + (x+\mathrm{i}y)\overline{(x+\mathrm{i}y)} = r_\alpha^2 + x^2 + y^2 = 1 \tag{14.7.60}$$

what is the equation of a unit sphere in $\mathbb{R}^2$ space with the Cartesian coordinates (x,y,r_α). Hence the quantum origin of the Bloch sphere!

We know (see section Vector Calculus page 1849) that the Cartesian coordinates are connected to the spherical coordinates by the relations:

$$x = r\sin(\theta)\cos(\phi) \qquad y = r\sin(\theta)\sin(\phi) \qquad z = r\cos(\theta) \tag{14.7.61}$$

therefore by putting $z := r_\alpha$ and remembering that $r = 1$, we can write:

$$|\Psi'\rangle = z|0\rangle + (x+\mathrm{i}y)|1\rangle = \cos(\theta)|0\rangle + \sin(\theta)\left(\cos(\phi)+\mathrm{i}\sin(\phi)\right)|1\rangle = \cos(\theta)|0\rangle + \sin(\theta)e^{\mathrm{i}\phi}|1\rangle \tag{14.7.62}$$

We now have only two useful parameters to know to define our point on the unit sphere (and always to the arbitrariness of phase).

The reader will notice that unlike the linearly polarized qubit, the general case above adds a complex term and that inversely by removing this additional term, we fall back on the relation of the linearly polarized wave seen at the beginning of this section. However, notice (for general culture) that if we add the same complex term to the first term, then we also have the very common following representation of the linearly polarized wave whose writing is named "Jones vector":

$$|\Psi'\rangle = \cos(\theta)e^{\mathrm{i}\phi}|0\rangle + \sin(\theta)e^{\mathrm{i}\phi}|1\rangle = \cos(\theta)e^{\mathrm{i}\phi}\begin{pmatrix}0\\1\end{pmatrix} + \sin(\theta)e^{\mathrm{i}\phi}\begin{pmatrix}1\\0\end{pmatrix} = \begin{pmatrix}\sin(\theta)\\ \cos(\theta)\end{pmatrix}e^{\mathrm{i}\phi} \tag{14.7.63}$$

But we have not finished yet!

Let us return to (we remove the apostrophe for the state of polarization):

$$|\Psi\rangle = \cos(\theta)|0\rangle + \sin(\theta)e^{\mathrm{i}\phi}|1\rangle \tag{14.7.64}$$

and notice that:

$$\theta = 0 \Rightarrow |\Psi\rangle = |0\rangle \tag{14.7.65}$$

and:

$$\theta = \frac{\pi}{2} \Rightarrow |\Psi\rangle = e^{\mathrm{i}\phi}|1\rangle \tag{14.7.66}$$

without forgetting that $\phi\in\mathbb{R}$ and that in this case the exponential factor in front of the $|1\rangle$ is a global phase change without influence.

All this suggests that $0\leq\theta\leq\pi/2$ is sufficient to describe any state of polarization and hence all points of the Bloch sphere.

On the other hand, we can see that in the system (r,θ,ϕ) the point of coordinates $(1,\pi-\theta,\phi+\pi)$ is the point opposite to that of coordinates $(1,\theta,\pi)$:

$$\begin{aligned}|\Psi\rangle&=\cos(\pi-\theta)|0\rangle+\sin(\pi-\theta)e^{\mathrm{i}(\phi+\pi)}|1\rangle\\&=-\cos(\theta)|0\rangle+\sin(\theta)e^{\mathrm{i}\pi}e^{\mathrm{i}\phi}|1\rangle\\&=-\cos(\theta)|0\rangle-\sin(\theta)e^{\mathrm{i}\phi}|1\rangle=-|\Psi\rangle=|\Psi'\rangle\end{aligned}\tag{14.7.67}$$

We also have (this is quite immediate but we can detail on request):

$$\langle\Psi|\Psi'\rangle=0\tag{14.7.68}$$

and therefore opposite points on the Bloch's sphere correspond orthogonal qubits (states of polarization)!

Thus we can consider only the upper hemisphere of the Bloch sphere since the opposite points differ only from a phase factor -1 and are therefore equivalent in the representation of the Bloch sphere.

Thus, the relation:

$$\boxed{|\Psi\rangle=\cos\left(\frac{\theta}{2}\right)|0\rangle+e^{\mathrm{i}\phi}\sin\left(\frac{\theta}{2}\right)|1\rangle}\tag{14.7.69}$$

is sufficient to describe the whole Bloch sphere in a complex space of dimension 2.

By construction, each point given by the previous relation of dimension 2 contains a double representation of a rotation in the real space of dimension 3.

We have also seen in the chapter of Spinor Calculus (see page 2145) that a rotation could be written in the form:

$$R\left(\vec{L},\frac{\theta}{2}\right)=\cos\left(\frac{\theta}{2}\right)\sigma_0-\mathrm{i}\sin\left(\frac{\theta}{2}\right)\vec{L}\circ\vec{\sigma}\tag{14.7.70}$$

With for recall the Pauli Matrices (see section Relativistic Quantum Physics page 4937):

$$\sigma_0=\begin{bmatrix}1&0\\0&1\end{bmatrix},\sigma_1=\begin{bmatrix}0&1\\1&0\end{bmatrix},\sigma_2=\begin{bmatrix}0&-\mathrm{i}\\\mathrm{i}&0\end{bmatrix},\sigma_3=\begin{bmatrix}1&0\\0&-1\end{bmatrix}\tag{14.7.71}$$

Either with the usual (traditional) writing of the field of Quantum Computing:

$$\begin{aligned}R_x(\theta)&=\cos\left(\frac{\theta}{2}\right)I-\mathrm{i}\sin\left(\frac{\theta}{2}\right)\sigma_1=\begin{bmatrix}\cos\left(\frac{\theta}{2}\right)&-\mathrm{i}\sin\left(\frac{\theta}{2}\right)\\-\sin\left(\frac{\theta}{2}\right)&\cos\left(\frac{\theta}{2}\right)\end{bmatrix}\\R_y(\theta)&=\cos\left(\frac{\theta}{2}\right)I-\mathrm{i}\sin\left(\frac{\theta}{2}\right)\sigma_2=\begin{bmatrix}\cos\left(\frac{\theta}{2}\right)&-\sin\left(\frac{\theta}{2}\right)\\\sin\left(\frac{\theta}{2}\right)&\cos\left(\frac{\theta}{2}\right)\end{bmatrix}\\R_z(\theta)&=\cos\left(\frac{\theta}{2}\right)I-\mathrm{i}\sin\left(\frac{\theta}{2}\right)\sigma_3=\begin{bmatrix}\cos\left(\frac{\theta}{2}\right)-\mathrm{i}\sin\left(\frac{\theta}{2}\right)&0\\0&\cos\left(\frac{\theta}{2}\right)+\mathrm{i}\sin\left(\frac{\theta}{2}\right)\end{bmatrix}\end{aligned}\tag{14.7.72}$$

Either after simplifying the last matrix:

$$\begin{aligned}R_x(\theta)&=\begin{bmatrix}\cos\left(\dfrac{\theta}{2}\right) & -\mathrm{i}\sin\left(\dfrac{\theta}{2}\right)\\ -\mathrm{i}\sin\left(\dfrac{\theta}{2}\right) & \cos\left(\dfrac{\theta}{2}\right)\end{bmatrix}\\ R_y(\theta)&=\begin{bmatrix}\cos\left(\dfrac{\theta}{2}\right) & -\sin\left(\dfrac{\theta}{2}\right)\\ \sin\left(\dfrac{\theta}{2}\right) & \cos\left(\dfrac{\theta}{2}\right)\end{bmatrix}\\ R_z(\theta)&=\begin{bmatrix}e^{-\mathrm{i}\theta/2} & 0\\ 0 & e^{\mathrm{i}\theta/2}\end{bmatrix}\end{aligned} \tag{14.7.73}$$

Now let us consider the rotation of our polarization state vector (due to a projector):

$$R_z(\alpha)|\Psi\rangle=\begin{bmatrix}e^{-\mathrm{i}\theta/2} & 0\\ 0 & e^{\mathrm{i}\theta/2}\end{bmatrix}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)\\ e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}=\begin{pmatrix}e^{-\mathrm{i}\theta/2}\cos\left(\dfrac{\theta}{2}\right)\\ e^{\mathrm{i}\theta/2}e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix} \tag{14.7.74}$$

To get a coefficient of $|0\rangle$ that is real (in order to have an observable in the projection of an axis), we multiply by a phase factor $e^{\mathrm{i}\alpha/2}$ giving:

So to get a rotation around the z-axis it enough to change $\phi\rightarrow\phi+\alpha$.

So if we come back to:

$$R\left(\vec{L},\theta\right)=\cos\left(\dfrac{\theta}{2}\right)I-\mathrm{i}\sin\left(\dfrac{\theta}{2}\right)\vec{L}\circ\vec{\sigma} \tag{14.7.75}$$

it can be shown in the same way that in a general framework a unitary qubit operator can be written in the observable form:

$$U=e^{\mathrm{i}\alpha}R\left(\vec{L},\theta\right) \tag{14.7.76}$$

It is then necessary to choose the angles and the axis of rotation to define the operator completely.

14.7.3.1.1 Qubit of polarization

We will come back here on the case of polarization of the photon but this time we will be able to generalize thanks to the formulation of the Bloch's sphere to any type of polarization.

Let us consider for this a polariser that only passes photons polarized vertically followed by a photodetector, which do a "click" if a photon is detected and nothing else. This device allows us to detect vertically polarized photons.

Let us translate this in the language of quantum mechanics: The states of the system are therefore the states of polarization of a photon. The measurements of the observable will also have its states of polarization.

The possible measures are:

$$\begin{aligned}\lambda_0 &= 0 = \text{'click'}\\ \lambda_1 &= 1 = \text{'no click'}\end{aligned} \tag{14.7.77}$$

We will denote the corresponding states $|x\rangle$, $|y\rangle$. In our configuration, it is then obvious that the couple (λ_0, λ_1) represents the eigenvalues and $|x\rangle$, $|y\rangle$ the eigenvectors of an operator (which we do not know for know) and that we will therefore denote $\mathcal{P}$.

As we know, $|x\rangle$, $|y\rangle$ is an orthonormal basis of the space of states (of polarization). This is the base named "H/V base" for "Horizontal/Vertical" and is denoted normally:

$$|0\rangle, |1\rangle \tag{14.7.78}$$

Let us now take several cases:

1. Given a photon in the sate:

   $$|\Psi\rangle = |0\rangle \tag{14.7.79}$$

   then:

   $$\begin{aligned}\mathcal{P}(\lambda=\lambda_0) = \mathcal{P}(0) = \langle 0|0\rangle = 1\\ \mathcal{P}(\lambda=\lambda_1) = \mathcal{P}(1) = \langle 1|0\rangle = 0\end{aligned} \tag{14.7.80}$$

2. Let a photon be in the semi-vertical / horizontal state, that is to say oblique (which can be assimilated to the quantum superposition of its two polarizations):

   $$|\Psi\rangle = \frac{|0\rangle + |1\rangle}{|||0\rangle + |1\rangle||} = \frac{|0\rangle + |1\rangle}{\sqrt{2}} \tag{14.7.81}$$

   where the root is just there to ensure the normalization condition: $\langle\Psi|\Psi\rangle = 1$. Indeed:

   $$\langle\Psi|\Psi\rangle = |\overline{\Psi}\Psi|^2 = \frac{1}{\sqrt{2}}\begin{pmatrix}1\\1\end{pmatrix} \circ \frac{1}{\sqrt{2}}\begin{pmatrix}1\\1\end{pmatrix} = 1 \tag{14.7.82}$$

   Then since there is superposition (i.e. half of each in the total wave):

   $$\begin{aligned}\mathcal{P}(\lambda=\lambda_0) = \mathcal{P}(0) = \langle 0|\Psi\rangle = \frac{1}{2}\\ \mathcal{P}(\lambda=\lambda_1) = \mathcal{P}(1) = \langle 1|\Psi\rangle = \frac{1}{2}\end{aligned} \tag{14.7.83}$$

3. Let us now take any polarization (and this is what we did not have before!):

   $$|\Psi\rangle = \cos\left(\frac{\theta}{2}\right)|0\rangle + e^{\mathrm{i}\phi}\sin\left(\frac{\theta}{2}\right)|1\rangle \tag{14.7.84}$$

   which is well-normalized as we know it. So:

   $$\begin{aligned}\mathcal{P}(\lambda=\lambda_0) = \mathcal{P}(0) = \langle 0|\Psi\rangle = \cos^2\left(\frac{1}{2}\right)\\ \mathcal{P}(\lambda=\lambda_1) = \mathcal{P}(1) = \langle 1|\Psi\rangle = \sin^2\left(\frac{1}{2}\right)\end{aligned} \tag{14.7.85}$$

   The sum of the two probabilities giving indeed 1!

Now, let's imagine that we turn the polariser of $\pi/4$. We will denote the new basis of this polariser $|0'\rangle$, $|1'\rangle$ determined by a rotation of angle $\pi/4$ with by construction:

$$\begin{aligned}|0'\rangle&=\frac{|0\rangle+|1\rangle}{\sqrt{2}}\\|1'\rangle&=\frac{|0\rangle-|1\rangle}{\sqrt{2}}\end{aligned}\tag{14.7.86}$$

where the first base therefore corresponds to the diagonal polarization and the second is named "antidiagonal polarization". It is therefore the "D/A base" (Diagonal / Antidiagonal). In the form of the Jones vectors the last two relations are written:

$$\begin{aligned}|0'\rangle&=\frac{|0\rangle+|1\rangle}{\sqrt{2}}=\frac{\begin{pmatrix}0\\1\end{pmatrix}+\begin{pmatrix}1\\0\end{pmatrix}}{\sqrt{2}}=\frac{1}{\sqrt{2}}\begin{pmatrix}1\\1\end{pmatrix}\\|1'\rangle&=\frac{|0\rangle-|1\rangle}{\sqrt{2}}=\frac{\begin{pmatrix}0\\1\end{pmatrix}-\begin{pmatrix}1\\0\end{pmatrix}}{\sqrt{2}}=\frac{1}{\sqrt{2}}\begin{pmatrix}-1\\1\end{pmatrix}\end{aligned}\tag{14.7.87}$$

If we imagine that we have two polarisers that follow one another. The first having the D/A base and the second the H/V base, the first will prepare the photon polarized generally in a particular state (polarization) which will be by construction be the oblique state for the base H/V. Thus our second polariser will have only situations of the type:

$$\begin{aligned}\mathcal{P}(\lambda=\lambda_0)=\mathcal{P}(0)=\langle 0|\Psi\rangle=\frac{1}{2}\\\mathcal{P}(\lambda=\lambda_1)=\mathcal{P}(1)=\langle 1|\Psi\rangle=\frac{1}{2}\end{aligned}\tag{14.7.88}$$

Thus, this shows that any measure obviously disturbs the state of polarization of the photon and thus disrupts the state of the system. This last result is used in quantum cryptography!

We notice by the way that by using the spin operator introduced during our study of the section on Wave Quantum Physics (see page 4903) we have:

$$\hat{S}^2|0\rangle=\frac{3}{4}\hbar^2\begin{bmatrix}1&0\\0&1\end{bmatrix}\frac{\begin{pmatrix}0\\1\end{pmatrix}+\begin{pmatrix}1\\0\end{pmatrix}}{\sqrt{2}}=\frac{3}{4}\hbar^2\begin{bmatrix}1&0\\0&1\end{bmatrix}\frac{\begin{pmatrix}1\\1\end{pmatrix}}{\sqrt{2}}=\frac{3}{4}\hbar^2\frac{\begin{pmatrix}1\\1\end{pmatrix}}{\sqrt{2}}=\frac{3}{4}\hbar^2|0\rangle\tag{14.7.89}$$

which is of the same form as the following relation (relation linking eigenvector and eigenvalue) obtained in the in the section of Wave Quantum Physics:

$$\hat{S}^2\left|\frac{1}{2},\pm\frac{1}{2}\right\rangle=\frac{3}{4}\hbar^2\left|\frac{1}{2},\pm\frac{1}{2}\right\rangle\tag{14.7.90}$$

And that indicates indeed that the state:

$$|\Psi\rangle=\frac{|0\rangle+|1\rangle}{\sqrt{2}}\tag{14.7.91}$$

seems to be necessarily associated with a $1/2$ spin particle. We also notice that this state is an eigenvector of the operator S_x associated with the eigenvalue $\hbar/2$. Indeed:

$$\hat{S}_x|0\rangle=\frac{\hbar}{2}\begin{bmatrix}0&1\\1&0\end{bmatrix}\frac{\begin{pmatrix}0\\1\end{pmatrix}+\begin{pmatrix}1\\0\end{pmatrix}}{\sqrt{2}}=\frac{\hbar}{2}\begin{bmatrix}0&1\\1&0\end{bmatrix}\frac{\begin{pmatrix}1\\1\end{pmatrix}}{\sqrt{2}}=\frac{\hbar}{2}\frac{\begin{pmatrix}1\\1\end{pmatrix}}{\sqrt{2}}=\frac{\hbar}{2}|0\rangle\tag{14.7.92}$$

Since in the present case with the operator S_x we have immediately the eigenvalue and the associated eigenvector without making any intermediate calculations, it comes that the probability of measuring this eigenvalue (refer for recall to the 4th postulate of Wave Quantum Physics which associates operator to a measurement through the eigenvalue) is easy to calculate because the eigenvector is equal to the state vector in this particular case. Therefore:

$$\mathcal{P}\left(+\frac{1}{2}\hbar\right)=\langle\psi|0\rangle=\left\langle\frac{1}{\sqrt{2}}\begin{pmatrix}1\\1\end{pmatrix}\middle|\frac{1}{\sqrt{2}}\begin{pmatrix}1\\1\end{pmatrix}\right\rangle=1 \qquad (14.7.93)$$

14.7.3.1.2 $1/2$ spin Qubit

We will see here how to build a qubit based on a particle with a $1/2$ spin.

In the study of the Bloch sphere, we have examined a qubit at a given instant and we have seen that in a Hilbert space H, this qubit is described (by choice) by a unit vector:

$$|\Psi\rangle=\alpha|0\rangle+\beta|1\rangle \qquad |\alpha|^2+|\beta|^2=1 \qquad (14.7.94)$$

decomposed into an orthonormal basis $(|0\rangle,|1\rangle)$.

Let us consider the most general and minimum initial state corresponding to an arbitrary orientation of a spin:

$$|\Psi\rangle=\cos\left(\frac{\theta}{2}\right)|0\rangle+e^{\mathrm{i}\phi}\sin\left(\frac{\theta}{2}\right)|1\rangle \qquad (14.7.95)$$

Which corresponds, as we know, to two opposite (and superposed) states on the Bloch sphere.

Let us notice that we have indeed a normalized probability of the form:

$$\langle\Psi|\Psi\rangle=\cos^2\left(\frac{\theta}{2}\right)+\sin^2\left(\frac{\theta}{2}\right)=1 \qquad (14.7.96)$$

We have also seen that the projection along z by the operator $R_z(\alpha)$ of the state Ψ is given to the phase arbitrariness by:

$$e^{\mathrm{i}\alpha/2}R_z(\alpha)|\Psi\rangle=\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)\\ e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix} \qquad (14.7.97)$$

Now let u recall our example:

$$\begin{aligned}M|x\rangle&=+1\cdot|x\rangle=+|x\rangle\\ M|y\rangle&=-1\cdot|y\rangle=-|y\rangle\end{aligned} \qquad (14.7.98)$$

where M was a Hermitian operator. Now the Pauli matrices are simple Hermitian operators. Moreover, as we have demonstrated in the section of Spinor Calculus, the Hermitian operator σ_z (assimilated to M) has by chance the same eigenvalues and eigenvectors corresponding to the two relations above. But it is then written in a traditional way as we saw it in the section of Spinor Calculus:

$$\begin{aligned}\sigma_z|+\rangle &= +|+\rangle\\ \sigma_z|-\rangle &= +|-\rangle\end{aligned} \tag{14.7.99}$$

or even more condensed:

$$\sigma_z|\pm\rangle = \pm|\pm\rangle \tag{14.7.100}$$

Moreover, this operator also satisfies the relation:

$$\sigma_z = M = \mathcal{P}_x - \mathcal{P}_y = \begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix} - \begin{bmatrix}0 & 0\\ 0 & 1\end{bmatrix} = \begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix} \tag{14.7.101}$$

And what is the physical property associated with σ_z? Well this is the spin (!) and we will come back to it a bit further below because that means we can use the spin $1/2$ as a qubit.

Now let us introduce the evolution of the system on this projection because it is not static (but this would not change this particular case to consider it static).

We have seen in the section of Wave Quantum Physics that this operation consisted in a simple case (as here) of introducing a phase term dependent on time of the type (see page 4770):

$$e^{-\frac{\mathrm{i}t}{\hbar}H} \tag{14.7.102}$$

Therefore:

$$\begin{aligned}|\Psi(\alpha,t)\rangle &= \begin{pmatrix} e^{-\frac{\mathrm{i}t}{\hbar}H}\cos\left(\dfrac{\theta}{2}\right)\\ e^{-\frac{\mathrm{i}t}{\hbar}H}e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix} = \begin{pmatrix} e^{-\frac{\mathrm{i}t}{\hbar}h\nu}\cos\left(\dfrac{\theta}{2}\right)\\ e^{-\frac{\mathrm{i}t}{\hbar}h\nu}e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix} = \begin{pmatrix} e^{-2\pi\mathrm{i}t\nu}\cos\left(\dfrac{\theta}{2}\right)\\ e^{-2\pi\mathrm{i}t\nu}e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}\\ &= \begin{pmatrix} e^{-\omega\mathrm{i}t}\cos\left(\dfrac{\theta}{2}\right)\\ e^{-\omega\mathrm{i}t}e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}\end{aligned} \tag{14.7.103}$$

What is written more soberly:

$$|\Psi(t)\rangle = e^{-\omega\mathrm{i}t}\begin{bmatrix}\cos\left(\dfrac{\theta}{2}\right)\\ e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{bmatrix} \tag{14.7.104}$$

Let us recall that the state of a $1/2$ spin particle is two-dimensional and described by the state matrix (see section Relativistic Quantum Physics page 4985):

$$\mathcal{M} = S = \frac{1}{2}\hbar\sigma \tag{14.7.105}$$

with:

$$\begin{aligned}S_x&=\frac{\hbar}{2}\sigma_1=\frac{\hbar}{2}\begin{bmatrix}0&1\\1&0\end{bmatrix}\\S_y&=\frac{\hbar}{2}\sigma_2=\frac{\hbar}{2}\begin{bmatrix}0&-\mathrm{i}\\\mathrm{i}&0\end{bmatrix}\\S_z&=\frac{\hbar}{2}\sigma_3=\frac{\hbar}{2}\begin{bmatrix}1&0\\0&-1\end{bmatrix}\end{aligned}\tag{14.7.106}$$

If we want to calculate the expected mean of the observable (physical property) along each axis, then we use the 5th postulate (see page 4699) in the case of the x-axis:

$$\begin{aligned}&\langle S_x\rangle=\langle\Psi(t)|S_x|\Psi(t)\rangle=e^{+\mathrm{i}\omega t}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)&e^{-\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}\frac{\hbar}{2}\begin{bmatrix}0&1\\1&0\end{bmatrix}e^{-\mathrm{i}\omega t}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)\\e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}\\&=\frac{\hbar}{2}\begin{pmatrix}\cos\left(\frac{\theta}{2}\right)&e^{-\mathrm{i}\phi}\sin\left(\frac{\theta}{2}\right)\end{pmatrix}\begin{bmatrix}0&1\\1&0\end{bmatrix}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)\\e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}=\frac{\hbar}{2}\begin{pmatrix}\cos\left(\frac{\theta}{2}\right)&e^{-\mathrm{i}\phi}\sin\left(\frac{\theta}{2}\right)\end{pmatrix}\begin{pmatrix}e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\\\cos\left(\dfrac{\theta}{2}\right)\end{pmatrix}\\&=\frac{\hbar}{2}\left(\cos\left(\frac{\theta}{2}\right)e^{\mathrm{i}\phi}\sin\left(\frac{\theta}{2}\right)+e^{-\mathrm{i}\phi}\sin\left(\frac{\theta}{2}\right)\cos\left(\frac{\theta}{2}\right)\right)=\frac{\hbar}{2}\sin\left(\frac{\theta}{2}\right)\cos\left(\frac{\theta}{2}\right)\left(e^{\mathrm{i}\phi}+e^{-\mathrm{i}\phi}\right)\\&=\frac{\hbar}{2}\sin\left(\frac{\theta}{2}\right)\cos\left(\frac{\theta}{2}\right)(\cos(\phi)+\mathrm{i}\sin(\phi)+\cos(\phi)-\mathrm{i}\sin(\phi))=\hbar\sin\left(\frac{\theta}{2}\right)\cos\left(\frac{\theta}{2}\right)\cos(\phi)\\&=\frac{\hbar}{2}\sin(\theta)\cos(\phi)\end{aligned}\tag{14.7.107}$$

Follows the y-axis:

$$\begin{aligned}&\langle S_y\rangle=\langle\Psi(t)|S_y|\Psi(t)\rangle=e^{+\mathrm{i}\omega t}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)&e^{-\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}\frac{\hbar}{2}\begin{bmatrix}0&-\mathrm{i}\\\mathrm{i}&0\end{bmatrix}e^{-\mathrm{i}\omega t}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)\\e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}\\&=\frac{\hbar}{2}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)&e^{-\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}\begin{bmatrix}0&-\mathrm{i}\\\mathrm{i}&0\end{bmatrix}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)\\e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}=\frac{\hbar}{2}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)&e^{-\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}\begin{pmatrix}-\mathrm{i}e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\\\mathrm{i}\cos\left(\dfrac{\theta}{2}\right)\end{pmatrix}\\&=\frac{\hbar}{2}\left(-\mathrm{i}\cos\left(\frac{\theta}{2}\right)e^{\mathrm{i}\phi}\sin\left(\frac{\theta}{2}\right)+\mathrm{i}e^{-\mathrm{i}\phi}\sin\left(\frac{\theta}{2}\right)\cos\left(\frac{\theta}{2}\right)\right)=\frac{\hbar}{2}\sin\left(\frac{\theta}{2}\right)\cos\left(\frac{\theta}{2}\right)\left(-\mathrm{i}e^{\mathrm{i}\phi}+\mathrm{i}e^{-\mathrm{i}\phi}\right)\\&=\frac{\hbar}{2}\sin\left(\frac{\theta}{2}\right)\cos\left(\frac{\theta}{2}\right)(-\mathrm{i}\cos(\phi)+\sin(\phi)+\mathrm{i}\cos(\phi)+\sin(\phi))=\hbar\sin\left(\frac{\theta}{2}\right)\cos\left(\frac{\theta}{2}\right)\sin(\phi)\\&=\frac{\hbar}{2}\sin(\theta)\sin(\phi)\end{aligned}\tag{14.7.108}$$

and finally following the z-axis:

$$
\begin{aligned}
&\langle S_z\rangle=\langle\Psi(t)|S_z|\Psi(t)\rangle=e^{+\mathrm{i}\omega t}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right) & e^{-\mathrm{i}\phi}\left(\dfrac{\theta}{2}\right)\end{pmatrix}\frac{\hbar}{2}\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix}e^{-\mathrm{i}\omega t}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)\\ e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}\\
&=\frac{\hbar}{2}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right) & e^{-\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)\\ e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}=\frac{\hbar}{2}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right) & e^{-\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)\\ -e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}\\
&=\frac{\hbar}{2}\left(\cos^2\left(\frac{\theta}{2}\right)-\sin^2\left(\frac{\theta}{2}\right)\right)=\frac{\hbar}{2}\cos(\theta)
\end{aligned}
\tag{14.7.109}
$$

For thus fall back well for the component z (because it is the only one that interests us here), the result which was imposed above in the form:

$$\langle M\rangle_\theta=\langle\theta|\mathcal{P}_x\theta\rangle-\langle\theta|\mathcal{P}_y\theta\rangle=\cos^2(\theta)-\sin^2(\theta)=\cos(2\theta)\tag{14.7.110}$$

with an angle difference which is a matter of substitution and an amplitude which makes it possible to match the particularity of the configuration of the system. We therefore have mathematical relations similar in all respects to the manipulation of qubits of oriented spins or qubits of polarized photons.

The question we can ask ourselves about the spin is how to prepare it in the state $|\Psi\rangle$ In fact, we can do this with a magnetic field by copying the Stern-Gerlach experiment, which allows us to separate a beam of spin $1/2$ particles into two distinct beam.

Since we now know all the eigenvalues and eigenvectors of the spin operator S, we can then determine the general form of the spin operator in any orientation (!):

$$
\begin{aligned}
S_n&=S_x\sin(\theta)\cos(\phi)-S_y\sin(\theta)\sin(\phi)+S_z\cos(\theta)\\
&=\frac{\hbar}{2}\left(\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}\sin(\theta)\cos(\phi)+\begin{bmatrix}0 & -\mathrm{i}\\ \mathrm{i} & 0\end{bmatrix}\sin(\theta)\cos(\phi)+\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix}\cos(\theta)\right)\\
&=\frac{\hbar}{2}\begin{bmatrix}\cos(\theta) & \sin(\theta)\cos(\phi)-\mathrm{i}\sin(\theta)\sin(\phi)\\ \sin(\theta)\cos(\phi)+\mathrm{i}\sin(\theta)\sin(\phi) & -\cos(\theta)\end{bmatrix}\\
&=\frac{\hbar}{2}\begin{bmatrix}\cos(\theta) & \sin(\theta)(\cos(\phi)-\mathrm{i}\sin(\phi))\\ \sin(\theta)(\cos(\phi)+\mathrm{i}\sin(\phi)) & -\cos(\theta)\end{bmatrix}=\frac{\hbar}{2}\begin{bmatrix}\cos(\theta) & e^{-\mathrm{i}\phi}\sin(\theta)\\ e^{\mathrm{i}\phi}\sin(\theta) & -\cos(\theta)\end{bmatrix}
\end{aligned}
\tag{14.7.111}
$$

We have also:

$$\begin{aligned}S_n|\Psi\rangle &= S_n\left(\cos\left(\frac{\theta}{2}\right)|0\rangle+e^{\mathrm{i}\phi}\sin\left(\frac{\theta}{2}\right)|1\rangle\right)=\frac{\hbar}{2}\begin{bmatrix}\cos(\theta) & e^{-\mathrm{i}\phi}\sin(\theta)\\ e^{\mathrm{i}\phi}\sin(\theta) & -\cos(\theta)\end{bmatrix}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)\\ e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}\\ &=\frac{\hbar}{2}\begin{pmatrix}\cos(\theta)\cos\left(\dfrac{\theta}{2}\right)+\sin(\theta)\sin\left(\dfrac{\theta}{2}\right)\\ e^{i\phi}\sin(\theta)\cos\left(\dfrac{\theta}{2}\right)-\cos(\theta)e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}=\frac{\hbar}{2}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)\\ e^{\mathrm{i}\phi}\left(\sin\theta\cos\left(\dfrac{\theta}{2}\right)-\cos(\theta)\sin\left(\dfrac{\theta}{2}\right)\right)\end{pmatrix}\\ &=\frac{\hbar}{2}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)\\ e^{i\phi}\left(\sin(\theta)\cos\left(\dfrac{\theta}{2}\right)-\cos(\theta)\sin\left(\dfrac{\theta}{2}\right)\right)\end{pmatrix}=\frac{\hbar}{2}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)\\ e^{\mathrm{i}\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}=\frac{\hbar}{2}|\Psi\rangle\end{aligned} \tag{14.7.112}$$

We have the chosen $|\Psi\rangle$ which is, in addition to being a state vector, an eigenvector of S_n with the eigenvalue $\hbar/2$. Therefore the probability of measuring this particular state vector is equal to 1.

Now we know by using the 5th postulate that the probability of finding the eigenvalue $\hbar/2$(of the operator S_n), in a measurement of the property S along the z-axis performed at time t on the quantum system prepared in the state Ψ, is given by the square of the module of the projection of the function or state vector Ψ on the vector or eigenvector φ associated with the eigenvalue $\hbar/2$ (and its operator along this axis).

But the operator according to z is:

$$\sigma_z=\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix} \tag{14.7.113}$$

For the same operator, we have seen in the section of Spinor Calculus that it had as eigenvectors (see page 2145):

$$|+\rangle=\begin{pmatrix}1\\0\end{pmatrix},|-\rangle=\begin{pmatrix}0\\1\end{pmatrix} \tag{14.7.114}$$

Let us take the first eigenvector oriented according to z-axis on the Bloch sphere. We have then:

$$P=|\langle+|\Psi\rangle|^2=\left|\begin{pmatrix}1 & 0\end{pmatrix}\begin{pmatrix}\cos\left(\dfrac{\theta}{2}\right)\\ e^{i\phi}\sin\left(\dfrac{\theta}{2}\right)\end{pmatrix}\right|^2=\left|\cos\left(\frac{\theta}{2}\right)\right|^2=\cos^2\left(\frac{\theta}{2}\right) \tag{14.7.115}$$

And the probability according to the other eigenvector would give the same expression but with a sinus. The sum of the two probabilities would then give us well 1!

We thus notice that the relations are very similar between the photon and the spin in our case of study. This is normal since both are two-level systems, resulting in similar results.

14.7.4 Entangled qubit system

A 2 qubit system is a superposition of all possible 2 qubit states. A 2 qubit system and can be represented as:

$$\Psi=\alpha_{00}|00\rangle+\alpha_{01}|01\rangle+\alpha_{10}|10\rangle+\alpha_{11}|11\rangle \tag{14.7.116}$$

Measuring the 2 qubit system, as earlier, results in the collapse of the superposition and the result is one of the 4 qubit states. The probability of the measure state is the square of the amplitude $|\alpha_{ij}|^2$.

More specifically a 2 qubit system in which we have:

$$\Psi=\alpha_0|0\rangle+\alpha_1|1\rangle \qquad \Phi=\beta_0|0\rangle+\beta_1|1\rangle \tag{14.7.117}$$

the tensor product of the 2 qubits is:

$$\begin{aligned}\xi=\Psi\otimes\Phi&=(\alpha_0|0\rangle+\alpha_1|1\rangle)\otimes(\beta_0|0\rangle+\beta_1|1\rangle)\\&=\alpha_0\beta_0|0\rangle|0\rangle+\alpha_0\beta_1|0\rangle|1\rangle+\alpha_1\beta_0|1\rangle|0\rangle+\alpha_1\beta_1|1\rangle|1\rangle\\&=\alpha_0\beta_0|00\rangle+\alpha_0\beta_1|01\rangle+\alpha_1\beta_0|01\rangle+\alpha_1\beta_1|11\rangle\end{aligned} \tag{14.7.118}$$

where (notice that we have still a set of orthonormal vectors):

$$\begin{aligned}|00\rangle&=\begin{bmatrix}1\\0\\0\\0\end{bmatrix} \qquad |01\rangle=\begin{bmatrix}0\\1\\0\\0\end{bmatrix}\\|10\rangle&=\begin{bmatrix}0\\0\\1\\0\end{bmatrix} \qquad |11\rangle=\begin{bmatrix}0\\0\\0\\1\end{bmatrix}\end{aligned} \tag{14.7.119}$$

Notice that the above reasoning is sometimes stated as one of the postulates of quantum physics as following:

The state space of a composite physical system is the tensor product of the state spaces of the component physical systems. Moreover, if we have systems numbered 1 through n, and system number i is prepared in the state $|\psi_i\rangle$, then the joint state of the total system is $|\psi_1\rangle\otimes|\psi_2\rangle\otimes\cdots\otimes|\psi_n\rangle$.

14.7.5 Quantum logic gates

In quantum computing and specifically the quantum circuit model of computation, a quantum gate (or quantum logic gate) is a basic quantum circuit operating on a small number of qubits. They are the building blocks of quantum circuits, like classical logic gates are for conventional digital circuits.

Let us recall that we have stated above that the construction of a quantum qubit was done on the vector basis:

$$|0\rangle=|\downarrow\rangle=|-\rangle=\begin{pmatrix}0\\1\end{pmatrix} \qquad |1\rangle=|\uparrow\rangle=|+\rangle=\begin{pmatrix}1\\0\end{pmatrix} \tag{14.7.120}$$

or in extenso, by linearity (and this is all elementary trick!), any transformation that acts on these basic vectors, will therefore act on all qubit of the complex plane.

Let us consider the particular case for this introduction the logic gate which modifies the state of the 1-qubit, that is to say qubit which are collinear to one of the basis vectors, into the opposite state. That is to say the "quantum inverter":

$$X : |0\rangle \rightarrow |1\rangle, |1\rangle \rightarrow |0\rangle \tag{14.7.121}$$

We quickly guess that the matrix that satisfies this relation (caution! the reader will notice that it is not a special case of the rotation matrix in the plane as seen in the section of Euclidean Geometry!):

$$X = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \tag{14.7.122}$$

And which is sometimes written by specialists:

$$X = |1\rangle\langle 0| + |0\rangle\langle 1| = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \begin{pmatrix} 0 & 1 \end{pmatrix} + \begin{pmatrix} 0 \\ 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \end{pmatrix} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \tag{14.7.123}$$

And we see that this logical gate of negation of the 1-qubit is nothing else than the first matrix of Pauli. So we can also write:

$$\boxed{X = |1\rangle\langle 0| + |0\rangle\langle 1| = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} = \sigma_1 = \sigma_x} \tag{14.7.124}$$

Negation which is sometimes named "X-Pauli quantum gate" or "NOT quantum gate" and represented by the following symbol in "quantum circuits":

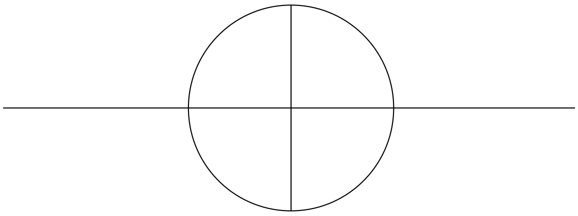

Figure 14.377: NOT Quantum gate

Now let us look for the logic gate making the following orthogonal clockwise transformation:

$$Y : |0\rangle \rightarrow -|1\rangle, |1\rangle \rightarrow |0\rangle \tag{14.7.125}$$

We guess quite quick that the matrix which satisfies this relation (caution! the reader will notice that this time is a special case of the rotation matrix in the plane as seen in the section of Euclidean Geometry!):

$$Y = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix} \tag{14.7.126}$$

And which is sometimes written by specialists (in a somewhat unfortunate way):

$$Y = |0\rangle\langle 1| - |1\rangle\langle 0| = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix} \tag{14.7.127}$$

And we see that this logical transformation gate in the clockwise direction of the 1-qubit involves the second Pauli matrix. So we can also write:

$$\boxed{Y=|0\rangle\langle 1|-|1\rangle\langle 0|=\begin{bmatrix}0 & -1\\ 1 & 0\end{bmatrix}=\mathrm{i}\sigma_2=\mathrm{i}\sigma_y} \tag{14.7.128}$$

Negation which is sometimes named "Y-Pauli quantum gate" and which has no classical equivalent.

Now let us seek for the logical gate making the following strictly counter-clockwise orthogonal transformation:

$$Z:|0\rangle\rightarrow|0\rangle,|1\rangle\rightarrow-|1\rangle \tag{14.7.129}$$

We guess quite quick that the matrix that satisfies this relation (caution! the reader will notice that it is not a special case of the rotation matrix in the plane seen in the section of Euclidean Geometry!):

$$Z=\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix} \tag{14.7.130}$$

And which is sometimes written by specialists (in a somewhat unfortunate way):

$$Z=|0\rangle\langle 0|-|1\rangle\langle 1|=\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix} \tag{14.7.131}$$

And we see that this logical transformation gate in the clockwise direction of 1-qubit involves the second Pauli matrix. So we can also write:

$$\boxed{Z=|0\rangle\langle 0|-|1\rangle\langle 1|=\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix}=\sigma_z} \tag{14.7.132}$$

Negation then we sometimes name "Z-Pauli quantum gate".

When describing a quantum gate on an individual qubit, any dynamical operation, G, is a member of the unitary group $\mathrm{U}(2)$ (see section Set Algebra page 1417), which consists of all 2×2 matrices where $G^{\dagger}=G^{-1}$. Up to a global (and unphysical) phase factor, any single qubit operation can be expressed as a linear combination of the generator of $\mathrm{SU}(2)$ that are the Pauli matrices!

Now let us return to the following transformation which we have deal with earlier:

$$\begin{aligned}|0'\rangle&=\frac{|0\rangle+|1\rangle}{\sqrt{2}}=\frac{\begin{pmatrix}0\\1\end{pmatrix}+\begin{pmatrix}1\\0\end{pmatrix}}{\sqrt{2}}=\frac{1}{\sqrt{2}}\begin{pmatrix}1\\1\end{pmatrix}\\ |1'\rangle&=\frac{|0\rangle-|1\rangle}{\sqrt{2}}=\frac{\begin{pmatrix}0\\1\end{pmatrix}-\begin{pmatrix}1\\0\end{pmatrix}}{\sqrt{2}}=\frac{1}{\sqrt{2}}\begin{pmatrix}-1\\1\end{pmatrix}\end{aligned} \tag{14.7.133}$$

In other words, it is the transformation (diagonal for recall) that makes to qubit equiprobable[90]:

$$H:|0\rangle\rightarrow|0'\rangle=\frac{|0\rangle+|1\rangle}{\sqrt{2}}\qquad |1\rangle\rightarrow|1'\rangle=\frac{|0\rangle-|1\rangle}{\sqrt{2}} \tag{14.7.134}$$

---

[90] As the sum of square of the amplitudes is indeed equal to: $(1/\sqrt{2})^2+(1/\sqrt{2})^2=0.5+0.5=1$

We quickly notice that the corresponding matrix is then:

$$H=\frac{1}{\sqrt{2}}\begin{bmatrix}-1 & 1\\ 1 & 1\end{bmatrix} \tag{14.7.135}$$

which is named "Hadamard quantum gate" and thus corresponds to a counter-clockwise rotation of $\pi/4$. This gate is represented by the following symbol in quantum circuits:

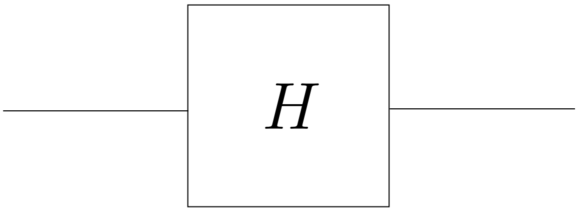

Figure 14.378: **Hadamard Quantum gate**

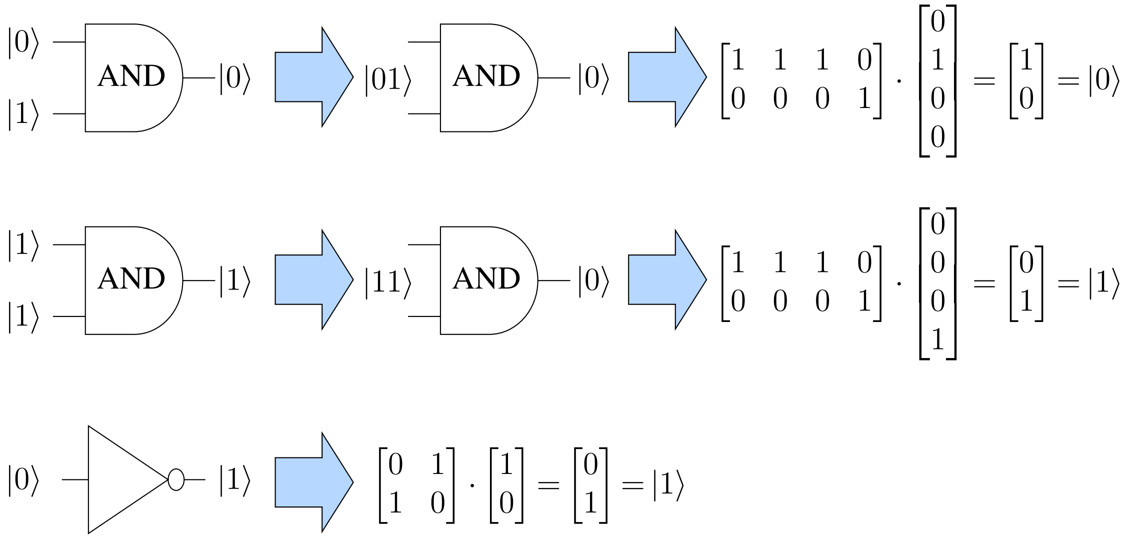
And we can continue like this for a long time to create empirical quantum logic gates ... so we will stop here.

Now remember that as we have seen in the section of Boolean logic (see page 7114), with a NAND gate (or an AND gate and an INVERTER) we've got all the parts we need to build a modern computer!

We have already seen the quantum inverter earlier above and its corresponding matrix. We need now and AND gate, however that latter has two input, i.e. entangles quantum bits.

We built a "quantum AND gate" as following:



|0⟩
|1⟩
AND
|0⟩
|01⟩
AND
|0⟩
$\begin{bmatrix}1&1&1&0\\0&0&0&1\end{bmatrix}\cdot\begin{bmatrix}0\\1\\0\\0\end{bmatrix}=\begin{bmatrix}1\\0\end{bmatrix}=|0\rangle$
|1⟩
|1⟩
AND
|1⟩
|11⟩
AND
|0⟩
$\begin{bmatrix}1&1&1&0\\0&0&0&1\end{bmatrix}\cdot\begin{bmatrix}0\\0\\0\\1\end{bmatrix}=\begin{bmatrix}0\\1\end{bmatrix}=|1\rangle$
|0⟩
|1⟩
$\begin{bmatrix}0&1\\1&0\end{bmatrix}\cdot\begin{bmatrix}1\\0\end{bmatrix}=\begin{bmatrix}0\\1\end{bmatrix}=|1\rangle$

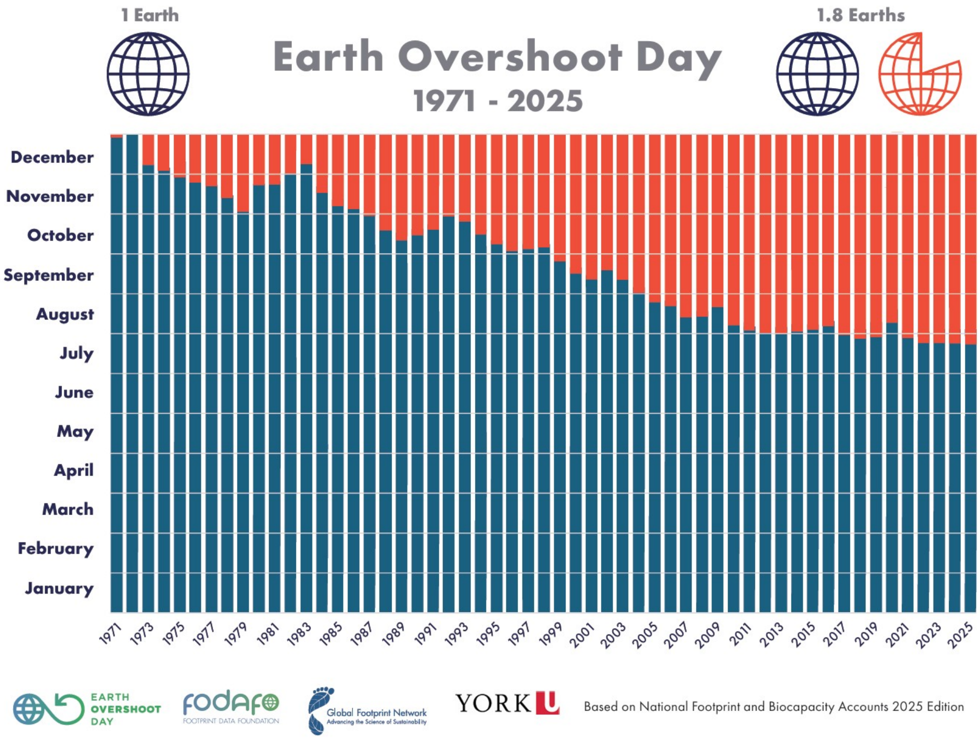
15.1. Population Dynamics

It is said that Albert Einstein at the end of his life, used to evoke the three explosions that would soon threaten humanity: the explosion of nuclear bombs, the explosion of our knowledge (robotics), the explosion in the number of humans on Earth. The role of the scientist at this level is not only to improve their knowledge but to share and especially to disseminate the awareness they have gained on the consequences they can discern of the explosion of the number of humans on Earth. Einstein was keen to play this role. Beyond the immediate vicissitudes, he knew to see the long-term developments. Among these developments, the number of humans appeared to him clearly as that of the greatest dangers (already introduced by the initiators of dynamic population science in the early 118th century according to holocene calendar!!!). Today, at the beginning of the 121st century (holocene calendar), we can see their insight. Humanity is actually taken by the throat by the increase of its actual effective without forcing it down (because politicians favour the infinite growth and participation to social helps which do impose an endless increase of the population by mathematical construction!) as human do with the regulation of the number of animal in some protected areas. The major (naive) problems for politicians being to ensure full employment (avoid "technological unemployment" at some level) and the fact that the increase in population naturally enriches the owners and impoverishes workers (among many other problems...).



Based on National Footprint and Biocapacity Accounts 2025 Edition

Figure 15.1: Earth overshoot day evolution

The chart above, that sadly doesn't have confidence intervals, shows that if we assume that the amount of ecological resources of Earth must regenerate in the same year, the human population of 12025 (holocene calendar) should be of approximately 5.4 billions individuals (https://overshoot.footprintnetwork.org) to be sustainable! However if each individual consumes like the average occidental style of life as in the early 121st (holocene calendar) century, under the same mentioned assumption, Earth could sustained only (under other assumptions, nobody really knows what the planet's human carrying capacity is!) around 2 billion individuals (source: Australian Academy of Science, peer-reviewed by Professor Stephen Dovers Fenner School of Environment and Society, Australian National University; Professor Colin Butler Public Health, University of Canberra).

Until the politicians of all major countries understand and show the example by limiting the population of their respective country (and therefore the number of births) and by proposing the same constraints for the whole world and the mentality of the population is open to type of proposal (it is it that elects politicians...), the mathematical theoretical study of the subject can help open some perspectives... regarding the renewal and the cycle of the resources of our unique planet... (because we only have one... and for the moment there is almost not good plan B).

To introduce social mathematics, we must first determine the characteristics that describe the dynamics of the number of individuals before formalizing the unique properties that characterize them.

15.1.1 Birth rate and mortality tables (biometric features)

No one knows for sure the day nor the hour of his death with certitude (excepted for some special cases...). This individual trivial fact is no longer relevant if we are interested not only in one person, but a numerous collectivity (a population in other words). Then we have a play between those who succumb from premature accidents and those who escape almost miraculously to the worst dangers. We can then describe how the way that is paid globally the tribute to death by considering a large number of children born the same year and specifying, thanks to the civil status data (when the exist and are robust), how their numbers gradually decrease for a day cancel completely.

Such a set of people is named by demographers a "cohort". So consider the cohort of French males born in 11900 (holocene calendar). Each year, we can, by gathering the indications of the government, calculate the number of those who died in the cohort.

Let us represent by d_a the ratio the number of deaths between birthdays a and $a+1$ by the initial size of the cohort.

Remark

We will in what follows define the basis of probabilities required for actuarial calculation. Indeed, actuarial mathematics merge the financial calculation and the calculation of probabilities. The payment of a capital is not certain and depends, for example on the survival of a person (see the section of Quantitative Management Techniques for Actuarial Calculation at page 7547).

The sequence of these numbers contains all the necessary information to study mortality in this cohort.

We can infer the proportion of them surviving at age a:

$$S_a = 1 - d_0 - d_1 - d_2 - \ldots - d_{a-1} \tag{15.1.1}$$

We can also characterize the intensity of the mortality at each age by dividing the number of deaths between ages a and $a+1$ by the number of survivors. This number is then named the "mortality rate":

$$q_a = \frac{S_a - S_{a+1}}{S_a} = \frac{D_a}{S_a} \tag{15.1.2}$$

The list age by age of these three parameters d, S and q is the "mortality table" or "life table" of the studied cohort. The table below provides a summary for ages multiple of 5.

Age a	**Survivals** S_a	**Death from age** a to $a+5$ $S_a - S_{a+5}$	**Probability of death** $q_a = \dfrac{S_a - S_{a+5}}{S_a}$
0	1	0.228	0.228
5	0.772	0.013	0.017
10	0.759	0.009	0.012
15	0.750	0.023	0.031
20	0.727	0.023	0.032
25	0.704	0.020	0.028
30	0.684	0.021	0.031
35	0.663	0.025	0.038
40	0.638	0.029	0.045
45	0.609	0.026	0.043
50	0.583	0.036	0.062
55	0.547	0.047	0.086
60	0.500	0.062	0.124
65	0.438	0.078	0.178
70	0.360	0.360	

Table 15.1: **Mortality table example**

Typical public and governmental mortality tables that can be found for free on Internet include only gender and age as cofactors. But mortality tables in insurance companies contains much more cofactors as ethnic origin, religion, number of children, weight, height, wage, country, district, sport activity, driving license, known disease, sexual orientation, education level and many other variables that are kept confidential (data is the core of insurance companies)!

Remark

Follow a real generation of individuals throughout its existence or a specific period of time is named "longitudinal analysis" in contrast to "cross-sectional analysis", which is to study the characteristics of a population at a given time. The table above is thus an example of a longitudinal analysis.

Let us randomly select in the table the name of an unknown child in the list of births in the year 11900 (holocene calendar). The big question at this birth was: how many years will he live? Today we are able to retroactively answer this question, at least evoking probabilities because we know the mortality table of his cohort.

If the only information we have about this child today is the fact that he was born in 11900 (holocene calendar), we can state that the probability that he was still alive at the age of 5 years is equal to 0.772, at the age of 50 years of 0.583... In other words the probability that he died before 5 years is equal to 0.228.

If we now choose today an unknown individual included on the list of those who were included in the cohort during the year 11920 (holocene calendar) at the age of 20, we can still calculate the probabilities of the various periods of his life but we have additional information: he was still alive at age 20, he avoided the risk of death before this age. The probability that it then reaches the age of 50 years has become:

$$_{30|}p_{20}=\frac{S_{50}}{S_{20}}=\frac{0.583}{0.727}=0.802 \tag{15.1.3}$$

Therefore the probability for a person of age a to be alive at age $a+n$ is equal to:

$$\boxed{_{n|}p_a=\frac{S_{a+n}}{S_a}} \tag{15.1.4}$$

It is of course possible to make this calculation also for many individuals simultaneously. Indeed, in the field of insurance sector it is common for insurance to be a couple (husband and wife) where the age of each differs. Therefore, the joint probability of survival will logically be given by (see section Probabilities page 480):

$$_{n|}p_{ab}={}_{n|}p_a\cdot{}_{n|}p_b \tag{15.1.5}$$

Or if we are interested in the probability that one of the people is still alive (two incompatible events not necessarily disjoint as see in the section of Probabilities):

$$_{n|}p_{\overline{ab}}={}_{n|}p_a+{}_{n|}p_b-{}_{n|}p_a\cdot{}_{n|}p_b={}_{n|}p_a+{}_{n|}p_b-{}_{n|}p_{ab} \tag{15.1.6}$$

The probability of a person of age to die between age a and $a+n$ is logically given by:

$$_{n|}q_a=\frac{S_a-S_{a+n}}{S_a}=\frac{D_{a+n}}{S_a} \tag{15.1.7}$$

Thus at each age, we can give the law of the variable "time to stay alive". This law can be summarized by indicating its expected mean (see section Statistics page 634). An immediate calculation makes it possible to give the value for each age in function of the mortality table.

This can be exciting for a historian, but it gives an answer to a question asked long ago and since forgotten. What interests us is the present. This child that is just born, what is his life expectancy? To answer, we must know the mortality table of his generation, but the gift of premonition does not exist (as far as we know...). The probabilistic approach circumvents this difficulty as long as you specify the underlying assumptions.

So, to answer the question: what is the life expectancy of newborns in 11990 (holocene calendar), then we assume, completely free, they will encounter at every age, in the future, the conditions that 'encountered in 11990 (holocene calendar) people of these ages: in 12000 (holocene calendar) they will suffer the same mortality than that experienced in 11990 (holocene calendar) by those born in 11980 (holocene calendar). Of course, no one would imagine that the reality will be consistent with this hypothesis, but the calculation it allows provides a synthetic picture of current conditions of the struggle against death.

It is this assumption that life expectancy sometimes rejuvenates the old people (the life expectancy tends to increase as they become older thanks to advances in science...).

Let us take for the calculation of life expectancy, the mortality table for men in Switzerland in 11983-11993 (according to holocene calendar):

Age	**Survivals**	**Death Life Expectancy**	**Age**	**Survivals**	**Death Life Expectancy**
n	S_a	E(a)	n	S_a	E(a)

Table 15.3: **Mortality table in Switzerland in 11983-11993 (part 2)**

Whose corresponding graph, named "the order of living" is:

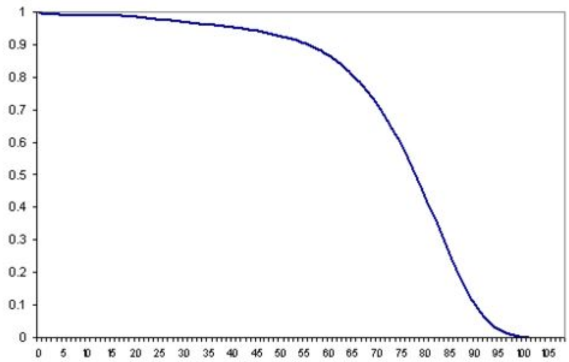

Figure 15.2: **Cumulative probability of survival as a function of age**

Let us see how to calculate life expectancy. For this, consider a human alive when he his a-th birthday. The number of years left to live is a random variable which we can calculate the expected value (see section Statistics page 585). Neglecting fractional years, that expected mean can be written:

$$\begin{aligned}\mathrm{E}(a)&=0\cdot {}_{0|}q_a+1\cdot {}_{1|}q_a+2\cdot {}_{2|}q_a+\ldots\\&=\frac{1}{S_a}\left(0D_a+1D_{a+1}+2D_{a+2}+\ldots\right)\\&=\frac{1}{S_a}\left(0(S_a-S_{a+1})+1(S_{a+1}-S_{a+2})+2(S_{a+2}-S_{a+3})+\ldots\right)\\&=\frac{1}{S_a}\left(S_{a+1}-S_{a+2}+2S_{a+2}-2S_{a+3}+\ldots\right)\\&=\frac{1}{S_a}\left(S_{a+1}+S_{a+2}+S_{a+3}+\ldots\right)\\&=\frac{1}{S_a}\sum_{i=1}^{\dagger}S_{a+n}\end{aligned}\tag{15.1.8}$$

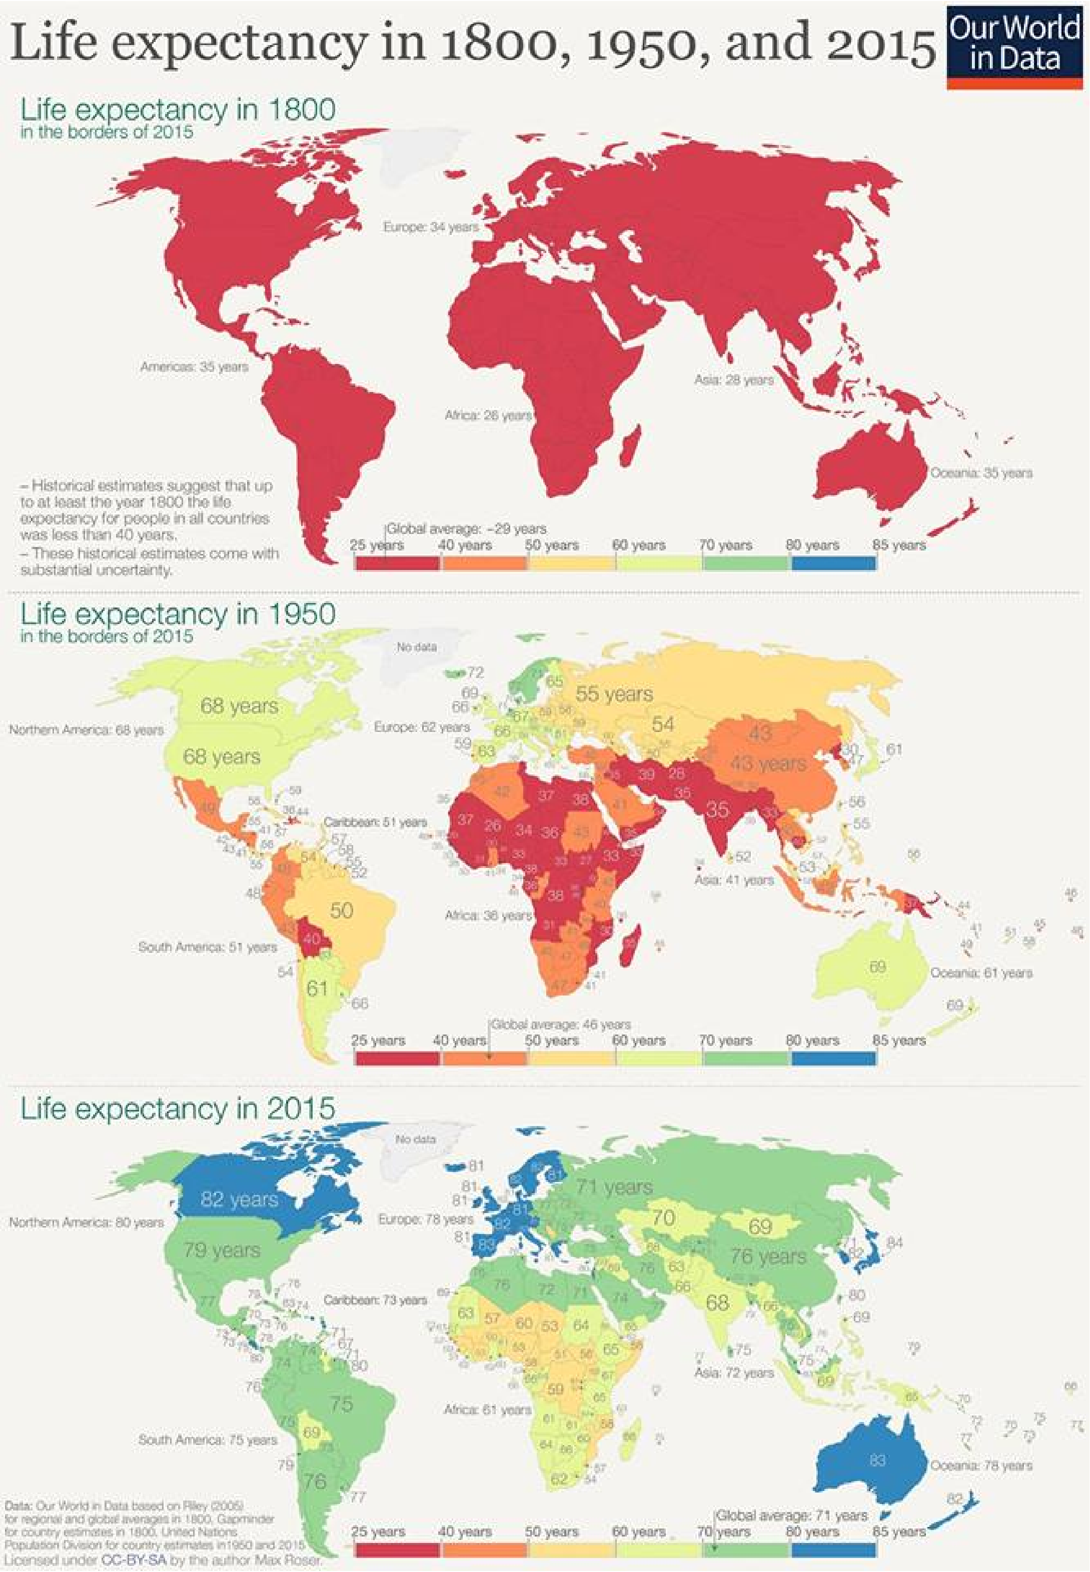
If a is taken as zero, demographers speak of LEAB (Life Expectancy At Birth).

Here is for information the increasing life expectancy for men (source: French National Institute for Demographic Studies) from 11996 to 12006 (holocene calendar):

Year (holocene calendar)	Life expectancy
11996	74.1
11997	74.5
11998	74.8
11999	75.0
12000	75.3
12001	75.5
12002	75.7
12003	75.9
12004	76.7
12005	76.8
12006	77.2

Table 15.4: **Increased life expectancy at birth in France 11996-12006**

We can therefore observe using the above table that life expectancy increases by a little over one year every four years for more than 50 years (and until when ...???).



Life expectancy in 1800, 1950, and 2015
Our World in Data
Life expectancy in 1800
in the borders of 2015
Europe: 34 years
Americas: 35 years
Africa: 26 years
Asia: 28 years
Oceania: 35 years
– Historical estimates suggest that up to at least the year 1800 the life expectancy for people in all countries was less than 40 years.
– These historical estimates come with substantial uncertainty.

Figure 15.5: **Life expectancy by age in England and Wales (11700-12013) (source: OurWorldinData)**

When it comes to transforming yearly mortality rates into monthly ones (the same reasoning applies for daily ones!), actuaries commonly employ two empirical methods when the raw data aren't available for such granularity of time:

- **Constant rate method:** The constant rate method is the simplest. It assumes that the survival rate is consistent for each month:

  $$ {}_{\frac{1}{12}}p_{x+\frac{m}{12}}=(p_x)^{\frac{1}{12}} \tag{15.1.9} $$

  For example, using the mortality table for Switzerland presented earlier above, the monthly probability of death for people of 25 year olds is:

  $$ {}_{\frac{1}{12}}p_{25+\frac{m}{12}}=1-(p_x)^{\frac{1}{12}}=1-\left(\frac{S_{26}}{S_{25}}\right)^{\frac{1}{12}}\cong 0.01381\% \tag{15.1.10} $$

  Or based on daily rate for a year with an average of 365 days:

  $$ {}_{\frac{1}{365}}p_{25+\frac{y}{365}}=1-(p_x)^{\frac{1}{365}}=1-\left(\frac{S_{26}}{S_{25}}\right)^{\frac{1}{365}}\cong 0.00045 \tag{15.1.11} $$

  Hence approximately one chance on $225,000$ to die every day between the age of 25 and the age of 26.

- **Uniform distribution of deaths:** Uniform distribution of deaths assumes that the number of deaths in each month is uniform. Under uniform distribution of deaths approach:

  $$ {}_{\frac{1}{12}}q_{x+\frac{m}{12}}=\frac{\frac{1}{12}\cdot q_x}{\left(1-\frac{m}{12}\cdot q_x\right)} \tag{15.1.12} $$

Finally, it must be known that actuaries define conditional life expectancy as the sum of:

$$ e(a,s)=a+\text{E}(a) \tag{15.1.13} $$

at the age a for the gender s. These calculations will be useful to us later for calculating pension insurance premiums in the section of Quantitative Management.

> Caution! Many debates (especially on social networks) confuses average life expectancy and expected maximum life span. The average has risen dramatically - in large part because fewer small children die. The maximum has not changed much. Pharaoh Pepi II might have been the longest reigning monarch.

Let's move to another topic. We know that to date, to make a child, we need most of time two people of opposite sex, certainly demographers know it too. But this double source of each of the newborn poses such problems in the description and analysis of fertility that in general they prefer to ignore it. Their attitude is justified by the fact that only the design requires the intervention of two people. At the time of birth, the mother acts alone. But demography is not interested in the designs, inaccessible to observation, but only to births.

We have seen how we can track a sample of men or women born in a given year and record the successive deaths, allowing us to establish this cohort mortality table. Similarly, we can note the numbers of children they give birth every year. We obtain then the "fertility table".

We just need to follow a cohort of women between 15 to 50 years to have an almost complete description of its reproductive behaviour. Data given by the government gives us the possibility to calculate each year the number of children that women have given birth in this cohort, grouped by age or age groups. Dividing by the rate of women surviving at this age, we get the "fertility rate" F_a.

If we add all these rate, we get the number of children that would have, on average, the women of this cohort if their mortality was zero. That was obviously not the case! To characterize how they ensured the renewal of their generation, we have to sum the real average of births, product of rate F_a by the survival rate S_a.

The set of these data is presented in a fertility table where we have an example where below where $n(a,a+5)$ is the number of births among survivors women survivors in this age group and where F_a is the number of births of $1,000$ women of this age group.

French women born around 11830 (holocene calendar):

Age n	**Survival rate** S_a	**Number of births** $n(a,a+5)$	**Fecundity rate** F_a
15	0.672	91	135
20	0.645	464	720
25	0.616	589	955
30	0.587	475	810
35	0.558	328	588
40	0.528	153	290
Total		2,100	3,498

Table 15.5: **Fertility table in France in 11830**

For example, on $1,000$ girls born in 11830 (holocene calendar), 645 have reached the age of 20 years and had 464 children between the age of 20 and 25 years. The intensity of fertility is measured by the number of births that would have $1,000$ women of this age:

$$\frac{464}{645}\cdot 1000=720 \tag{15.1.14}$$

And the average of births:

Age n	**Survivals**	**Number of births** $n(a,a+5)$
15	672	91
20	645	464
25	616	589
30	587	475
35	558	328
40	528	153
Total		2,100

Table 15.6: **Average of births in 11830 in France**

We can observe that in 11830 (holocene calendar), from 20 to 30 years old women gave birth to an average of:

$$\frac{464+589}{616}=\frac{1053}{616}=1.709 \tag{15.1.15}$$

this value being assimilated by the general public as the "fertility rate" (take care not to confuse with F_a).

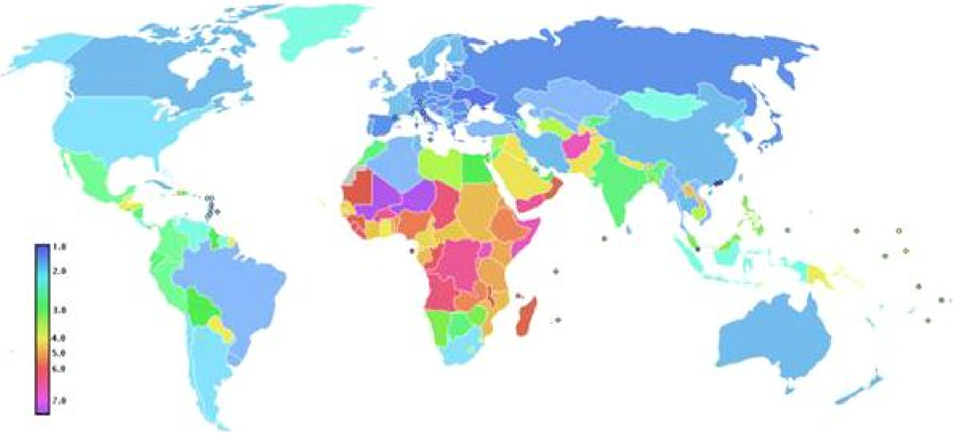

Figure 15.6: **Fertility rates in the early 121st century (source: Wikipedia)**

15.1.1.1 Population Renewal

The essential question for a set of human (or animals) in permanent renewal due to inflows and outflows that are births and deaths is: is the effective increasing or decreasing?

The female birth table gives the possibility to answer this question, thanks to the ratio of boys at birth to the number of girls. Thus, in the early 121st century (holocene calendar): 105 boys born for every 100 girls in the world. Thus, the proportion of girls is therefore:

$$\frac{105}{205}=0.49 \tag{15.1.16}$$

And the sex ratio is therefore:

$$S_r=\frac{105}{100} \tag{15.1.17}$$

Around forty years (49 in France according to INSEE), the balance is reversed and the number of women generally outweighs the number of men, despite significant regional disparities.

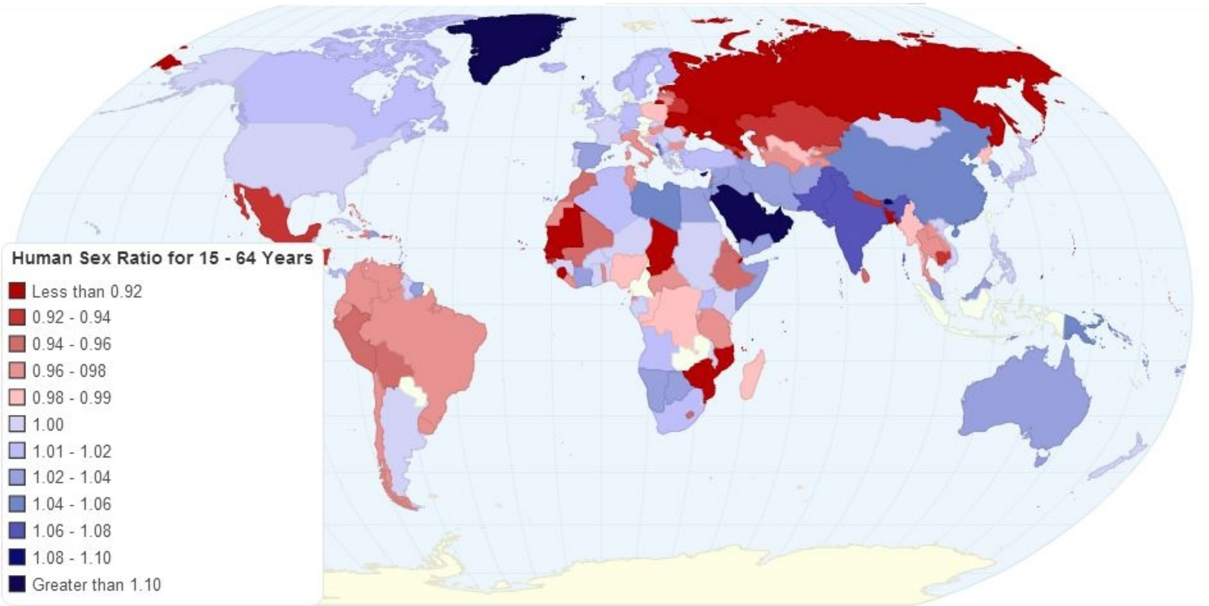

Figure 15.7: **Sex ratio trend in the early 121st century (source: chartsbin.com)**

Assuming the proportion was the same at the time, the fertility table in 11830 (holocene calendar) therefore shows that on average a woman in the 11830 (holocene calendar) cohort spawned:

$$\frac{2,100}{1,000}\cdot 0.49=2.1\cdot 0.49=1.03 \tag{15.1.18}$$

girl. That is to say and increase which we will denote k (in analogy with the exponential population model that we will see later) of 3%. Some politicians argue therefore that the value 2.1 is the necessary fertility rate ... it takes to ensure the renewal of generations and we have just seen that is not entirely accurate.

The female effective was therefore increasing. Therefore the population could ensure its renewal (unless the ratio is greater than 1).

The resulting number is the "net reproduction rate" (NRR). This rate is normally constituted by the ratio between the number of girls born for 100 women, this ratio is adjusted by the planned mortality between the birth of these girls and the average age of reproduction, because some of the girls don't reach not the age of reproduction, given the deaths among those between birth and age at childbirth. The average age at reproduction is given by the average age of mothers at birth.

An NRR of 1 means that each generation of mothers is having exactly enough daughters to replace themselves in the population. If the NRR is less than one, the reproductive performance of the population is below replacement level.

15.1.2 Population Models

Population dynamics is the branch of life sciences that studies the size and age composition of populations as dynamic systems, and the biological and environmental processes driving them (such as birth and death rates, and by immigration and emigration).

There are many mathematical models for studying the growth of a population as there all not all yet merged together in a single beautiful theory. Obviously the term "population" is used herein in the broadest sense - it can be a population of humans, animals, plants, individuals infected with a virus, etc.

As we know, to build a mathematical model, it is necessary to make assumptions. These assumptions play two roles: to preserve some essential features of reality and simplify this reality sufficiently so it can be studied by mathematics.

15.1.2.1 Exponential disease model

In this population dynamics model (one of the simplest), the event will be: the rate of change of the population is proportional, at any time t, to the population $P(t)$ at time t.

We can think, a priori, that this assumption is reasonable for a lot of situations. For example, more the human population is big, the greater the rate of change of this population will be, expressed in number of people added (or subtracted) per unit time, will be great. Similarly, the more people infected with a virus and more in the coming weeks, there will be new cases of people infected (if we don't take into consideration the limitness of the population and the methods to cure of a virus).

Mathematically, this assumption can be translated using the differential equation (see section Differential and Integral Calculus page 1605):

$$\frac{\mathrm{d}P(t)}{\mathrm{d}t}=kP(t) \tag{15.1.19}$$

So this differential equation is a mathematical model representing a situation where the growth rate of the population is proportional of a factor k to the size of the population at any time t. In this case, k is a constant named "growth rate" and we will see later how we can determine it. In some situations, the value of k is negative indicating that the population decreases with time rather than increasing. It is clear that a solution to this differential equation (see section Differential and Integral Calculus page 1605) is:

$$P(t)=c^{te}e^{kt} \tag{15.1.20}$$

First we will determine the value of the constant k from demographic data for the year 11965 (holocene calendar). At that time, there were almost 3 billion people on planet Earth. Moreover, at that time, the population grew by almost 54 million per year.

Therefore, in 11965 (holocene calendar):

$$\frac{\mathrm{d}P(t)}{\mathrm{d}t}=54\cdot 10^6=kP=k\cdot 3\cdot 10^9 \tag{15.1.21}$$

This give us:

$$k = 0.018 = 1.8\% \tag{15.1.22}$$

The differential equation is then:

$$P(t) = c^{te} e^{0.018t} \tag{15.1.23}$$

To determine the multiplicative constant, we simply have to put $t = 0$ and choose accordingly (since it corresponds to the initial condition). Thus, in 11965 (holocene calendar) we had:

$$P(t) = c_{11965}^{te} e^{0.018t} = 30 \cdot 10^9 e^{0.018t} \tag{15.1.24}$$

with t being the number of years after 11965 (holocene calendar).

If this mathematical model is consistent with reality, the solution found should allows us to estimate the population of humans on Earth to later times than 11965 (holocene calendar). Here is the graph of the function:

```
>plot(3*10^9*exp(0.018*t),t=1..50,labels=[years,population],
title='PopulationGrowth');
```

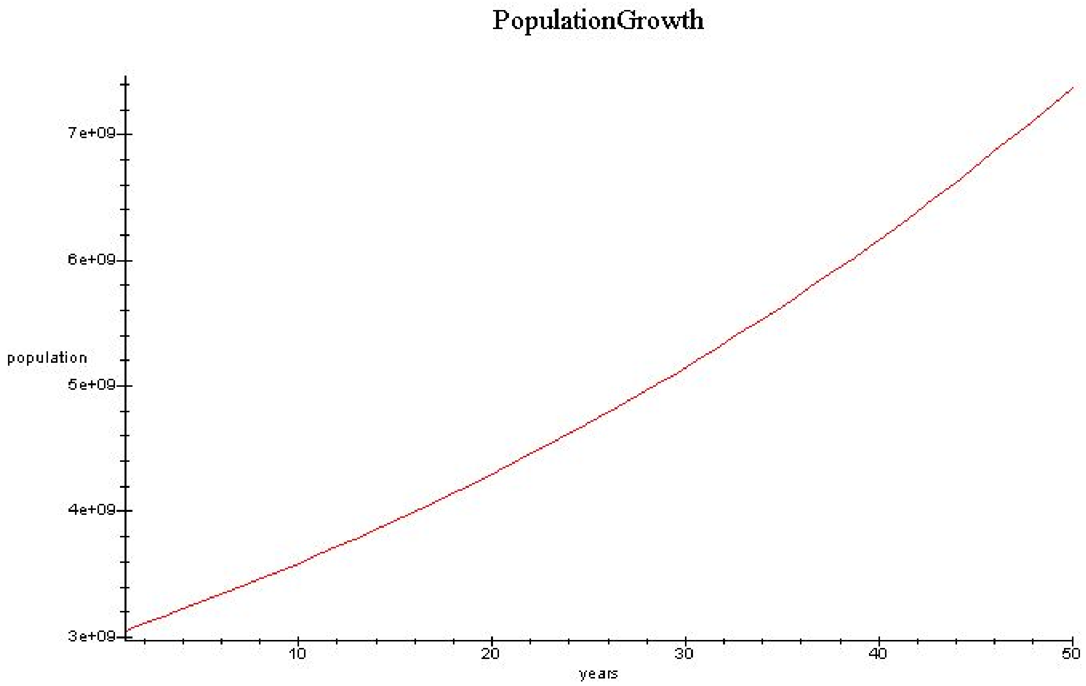

Figure 15.8: Evolution of the world population since 11965 in Maple™ 4.00b

If we evaluate $P(37)$, this will provide us with the prediction for the population in 12002 (holocene calendar). We find 5.84 billion which is pretty close to reality.

The readers can also easily check the following table according to the values of k:

Growing rate k per year	Doubling time in years
0.5%	139
1%	69
1.5%	46
2%	35
2.5%	28
3%	23
3.5%	20
4%	17

Table 15.7: Various costs

We then see immediately, that according to the exponential model, a growth that may seem slow, on the order of 3% per year, is truly made an explosive results since doubling every 23 years. That is to say a multiplication over 17 in a century. Or a century passed quickly (at least for physicists because politicians seems to not be able to think on more than 50 years)!

This simple observation shows how false are in this model the arguments that make us seek the solution of an economic or social problem in growth, and even, as it is often admitted in sustainable growth!!! It is clear that no growth can truly last, it is only a transitory episode, necessarily followed by a plateau or even a decrease. Resolve an economic issue by the growth or its stability is thereof transfer the problem to later, at a period at which it will be necessary to find ways both: to stop the growth or to resolve it in another way to solve a problem hidden by politicians not listening to scientists since to long time (more than 150 years!!!).

The growth model we have just see right now may obviously not be valid over very long periods of time. Indeed, if we calculated, using the above equation, the population in 7 centuries the result would be that on every square meter of land, excluding water, there would, on average, be ten human! Similarly, a population of people infected with a virus can also not really be described by such a model.

These results tell us that if we want to develop a model of the growth of a population, that is more in line with reality, we have to change our initial assumptions. This is what we will see after with deterministic logistic models.

But first let us give a nice example where an exponential explosion also occurs. Every individual normally has on Earth, as we know, two parents, four grandparents and eight great-grandparents and so on in every generation, if we go back in time, the number of ancestors doubles. But it can not double indefinitely and exponential growth must stop at some point or another! If the number of ancestors doubles with each generation and that we go back only 2,000 years ago, we would individually have about 1023 ancestors considering only 25 years for a generation ... Two thousand years before, which is not so distant, all the ancestor of all our actual population would then represent roughly the equivalent of the total mass of the Earth if this mass was made only of human bodies! The answer to this apparent paradox is of course that there are a lot (really lot!) of repetitions in each family tree (parents with several children ... and fathers with several women... and vice versa) and so we are all in a relatively short period cousins...

We also have the following data on the evolution of the world population (all the years are given relatively to the holocene calendar):

Year	World Population
-90000	0.5 million
0	1 to 10 million
4500	5 to 10 million
5000	5 to 10 million
9800	150 to 20 million
10000	170 to 400 million
10200	190 to 206 million
10400	190 to 206 million
10500	190 to 206 million
10600	200 to 206 million
10700	207 to 210 million
10800	220 to 224 million
10900	226 to 240 million
11000	254 to 345 million
11100	301 to 320 million
11200	360 to 450 million
11250	400 to 416 million
11300	360 to 432 million
11400	350 to 374 million
11500	425 to 540 million
11600	545 to 579 million
11650	470 to 545 million
11700	600 to 679 million
11800	0.813 to 1.125 million
11850	1.128 to 1.402 million
11900	1.550 to 1.762 million

Year	World Population
11910	1.750 billion
11920	1.860 billion
11930	2.07 billion
11940	2.3 billion
11950	2.519 billion
11960	3.023 billion
11965	3.337 billion
11970	3.696 billion
11975	4.073 billion
11980	4.442 billion
11985	4.843 billion
11990	5.279 billion
11995	5.692 billion
12000	6.085 billion
12005	6.541 billion
12010	6.956 billion
12015	7.379 billion
12020	7.795 billion

Table 15.8: **Evolution of the world population (source: Wikipedia)**

We see well an exponential growth for now ... but still not with the values corresponding to the small example calculation of our family tree even if we take the cumulative value!

15.1.2.2 Deterministic Logistic Model (Verlhust)

Now we will focus on a different type of model than the exponential one (where the population explodes) which has the advantage of having an asymptotic behaviour rather than a diverging one.

This type of behaviour is interesting because resources are usually limited and there is a competition between individuals. The logistic model, also named "Verhulst model" allows to account for this relatively well.

Let $N(t)$ be the population at time t. Let us write:

$$\frac{\mathrm{d}N}{\mathrm{d}t}=rN(t) \tag{15.1.25}$$

where r is the rate of increase that this time will not be constant and is defined as being:

$$r=r_0\left(1-\frac{N(t)}{K}\right) \tag{15.1.26}$$

where the idea is that K is the maximum capacity of the medium (parameter sometimes named "carrying capacity"). We see that if K is infinite we fall immediately on the exponential model and if $N(t)$ equals K then r is zero and therefore the model is asymptotic. The constant r_0 is determined by adjusting the model to real datas (likelihood method or conjugate gradient method like seen in the section of Numerical Methods).

Finally we have:

$$\frac{\mathrm{d}N(t)}{\mathrm{d}t}=r_0\left(1-\frac{N(t)}{K}\right)N(t) \tag{15.1.27}$$

which gives after rearrangement:

$$\frac{\mathrm{d}N(t)}{\mathrm{d}t}=r_0N(t)\left(1-\frac{N(t)}{K}\right) \tag{15.1.28}$$

Or mathematically:

$$y'=r_0y\left(-\frac{y}{K}\right) \tag{15.1.29}$$

with as initial condition that $y(0)=N_0$.

We have now to solve this differential equation (See Differential and Integral Calculus):

$$y'=r_0y\left(1-\frac{y}{K}\right) \tag{15.1.30}$$

We put $y=1/f(x):=1/f$. The differential equation then becomes:

$$-\frac{f'}{f^2}=r_0\frac{1}{f}\left(1-\frac{1}{Kf}\right) \tag{15.1.31}$$

which simplifies to:

$$-f'=r_0f\left(1-\frac{1}{Kf}\right)=r_0f-\frac{r_0}{K} \tag{15.1.32}$$

which gives after rearrangement:

$$f'+r_0f-\frac{r_0}{K}=0 \tag{15.1.33}$$

This differential equation is solved as usual using conventional techniques studied in the Differential and Integral Calculus section. We first write the homogeneous equation:

$$f'+r_0f=0 \tag{15.1.34}$$

An immediate special solution is:

$$f(x)=Ae^{-r_0x} \tag{15.1.35}$$

where A is a constant. By injecting this solution in the initial differential equation this gives:

$$-r_0Ae^{-r_0x}+r_0Ae^{-r_0x}-\frac{r_0}{K}=-\frac{r_0}{K}=0 \tag{15.1.36}$$

We see immediately that for equality to be satisfied our special solution becomes the general solution if we write it in the form:

$$f(x)=Ae^{-r_0x}+\frac{1}{K} \tag{15.1.37}$$

The solution of the differential equation is therefore:

$$y=\frac{1}{f}=\frac{1}{Ae^{-r_0x}+\dfrac{1}{K}}=\frac{K}{KAe^{-r_0x}+1} \tag{15.1.38}$$

The initial condition:

$$y(0)=N_0 \tag{15.1.39}$$

Takes us to:

$$y(0)=\frac{K}{KAe^{-r_0x}+1}=\frac{K}{KAe^{-r_00}+1}=\frac{K}{KA+1}=N_0 \tag{15.1.40}$$

Therefore:

$$K=N_0(KA+1)\Rightarrow A=\frac{K-N_0}{KN_0} \tag{15.1.41}$$

This gives us:

$$\begin{aligned}y&=\frac{K}{KAe^{-r_0x}+1}=\frac{K}{K\dfrac{K-N_0}{KN_0}e^{-r_0x}+1}=\frac{K}{\dfrac{K-N_0}{N_0}e^{-r_0x}+1}=\frac{K}{1+\left(\dfrac{K}{y_0}-1\right)e^{-r_0x}}\\&=\frac{y_0}{y_0}\frac{K}{1+\left(\dfrac{K}{y_0}-1\right)e^{-r_0x}}=\frac{y_0K}{y_0+(K-y_0)\,e^{-r_0x}}\end{aligned} \tag{15.1.42}$$

Either in traditional form in the field of population dynamics:

$$\boxed{N(t)=\frac{N_0K}{N_0+(K-N_0)\,e^{-r_0t}}} \tag{15.1.43}$$

which is therefore the final expression of logistic deterministic model. We see easily that:

1. If t tends to infinity then the horizontal asymptote is K.
2. At time $t=0$, the initial population is equal to $N(0)=N_0$.

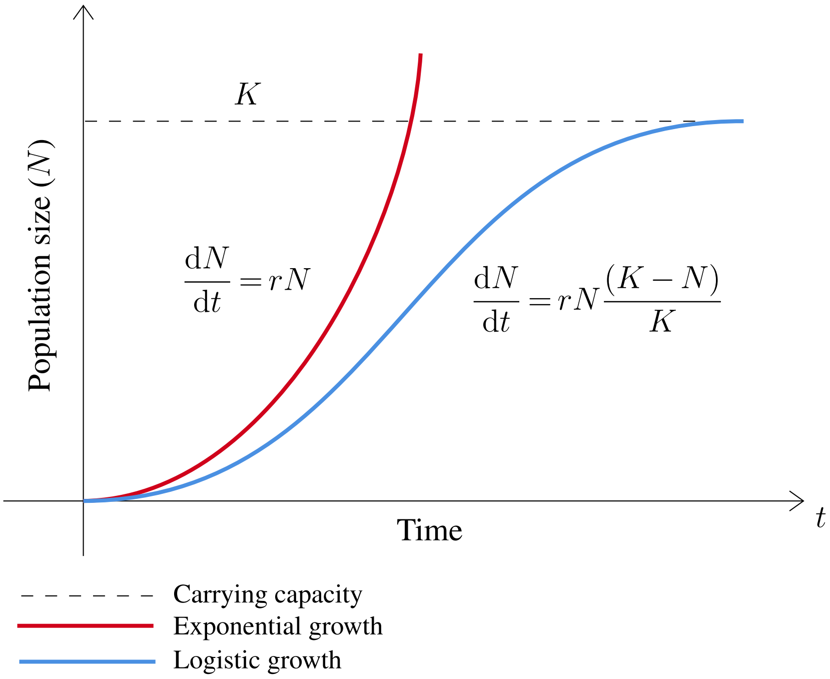

Figure 15.9: **Logistic model vs Exponential model**

To finish by returning to the previous form of our development:

$$y=\frac{K}{1+\left(\frac{K}{y_0}-1\right)e^{-r_0t}} \tag{15.1.44}$$

If we rewrite with a small change of variable we get:

$$y=\frac{K}{1+ae^{-rt}} \tag{15.1.45}$$

we obtain what is commonly named by its form a "logistic function".

15.1.2.3 Chaotic Logistic Model

We will still assume now that each generation is proportional to the previous one. We will suppose from one period to the next that the evolution of the population can then be translated into a sequence of the type:

$$x_{t+1} = Kx_t \tag{15.1.46}$$

where x_t is the population at time t, x_{t+1} the population at time $t+1$ and K the reproduction ratio.

As the previous model this suppose obviously that the initial population size is not zero...

But we quickly realize that such a model is unrealistic: the Earth would have since long time be submerged by a human tide. Indeed, a power model such this one ignores important factors like the fact that a priori resources are not unlimited.

To establish a more satisfactory model we must take into account (or by prudence have the pessimistic point of view) that the available resources are limited and that, for any country, there is a maximum population beyond which the population decreases, regardless of the species. To find a function that translates more realistically the evolution of a population, let us enumerate, simplifying a bit, the properties that must satisfied this evolution:

1. This is an iterative phenomenon: If x_{t+1} is the size of the population of the period $t+1$, it depends on that of the previous period t.
2. A population can not grow indefinitely in a defined territory: there is a maximum after which it must decrease. We must plan a retroactive factor limiting the population increase when its density becomes too high. To simplify the calculations, x will not represent anymore the population in absolute number but a percentage of that maximum value corresponding to a given territory. The idea is than that x_t can fluctuate between only between 0 and 1.
3. K remain the actual growth rate from one period to the next.

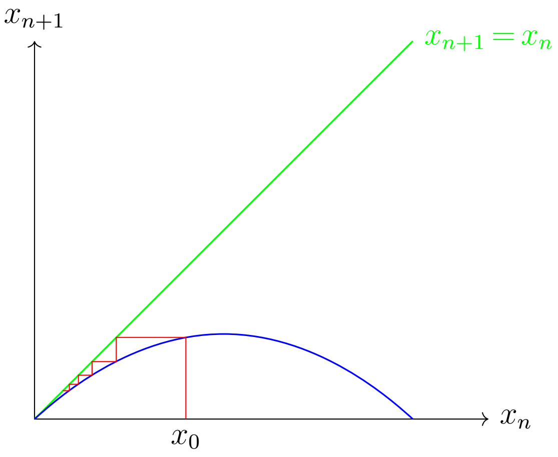
The size of the population of the period $t+1$ will be the value x_{t+1}, expressed as a percentage of the maximum population that can accommodate the given territory, and will be obtained from the size of the population x_t of the previous period t by the supposed relation:

$$\boxed{x_{t+1} = Kx_t(1-x_t)} \tag{15.1.47}$$

the factor $(1-x_t)$ represents obviously the retroactive effect. This suite is often named "logistic sequence", "logistic equation" or "logistic map" and we also find it in many other areas of non-linear physics.

Indeed, when the population density is high, close to saturation, the x_t is close to 1 and therefore $1-x_t$ will be close to 0. So this retroactive factor will tend to minimize the population x_{t+1}.

Plot of the case where $K<1$ (deaths exceed births and the population decays to zero):



We see that $x_n = 0$ is a fixed point. In general, to find fixed points, we solve for $x_{n+1} = x_n$, i.e. $f(x_n) = x_n$. For the logistic map, we have:

$$K x_n (1 - x_n) = x_n \tag{15.1.48}$$

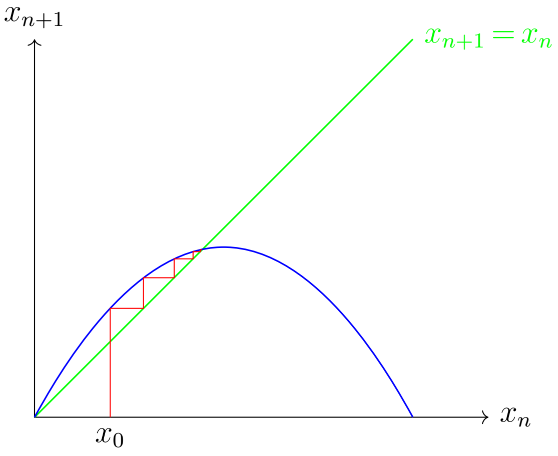
Therefore:

$$x_n [1 - K(1 - x_n)] = 0 \tag{15.1.49}$$

Hence:

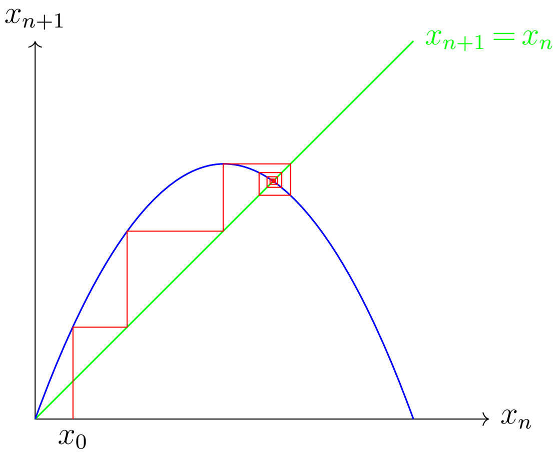
$$x_n = 0 \text{ or } x_n = 1 - \frac{1}{K} \tag{15.1.50}$$

When $1 < \lambda < 2$, we have:



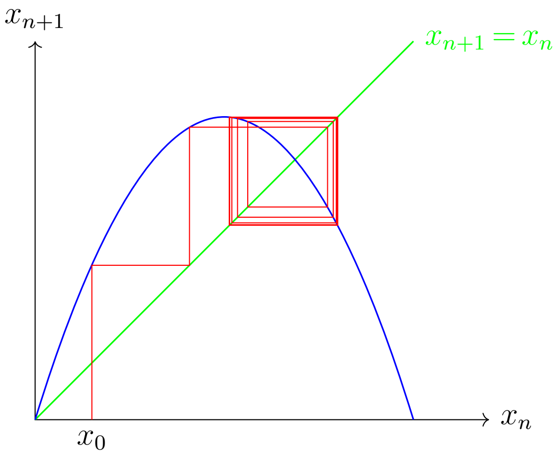
We see that $x_n = 0$ is an unstable fixed point and $x_n = 1 - \frac{1}{K}$ is a stable fixed point.

When $2 < K < 3$, we have:



There is an oscillatory convergence to $x_n=1-\frac{1}{K}$.

When $K>3$, we have a limit cycle, in which x_n oscillates between two values, i.e. $x_{n+2}=x_n$. When $K=1+\sqrt{6}\cong 3.449$, we have a 4-cycle, and so on:



Thus, for certain animal species, it is normal that population change regularly (oscillates), while for others it is normal to move towards an equilibrium situation. This variety, "chaos" in some cases, is even linked to the mathematical properties of the previous relation.

We will see that depending on the value of its actual growth rate k, an animal population (including therefore humans), may tend toward a state of equilibrium, or fluctuate between two or four or eight values, or change completely pseudo-randomly.

The complexity becomes the rule and not the exception, and what appears "chaotic" follows very specific properties from a very specific closed form function.

It is these results that we will see. For this, we will study the evolution of animal populations (this includes obviously therefore humans) whose numbers growth rate K varies from 1 to 4. We will study these variations by the calculation and by studying the graph of the logistic function.

Let us see now some special cases:

1. If the initial value x_0 is equal to 0.1 and $K = 1$ the evolution of the population for the first forty periods is represented by the graph below:

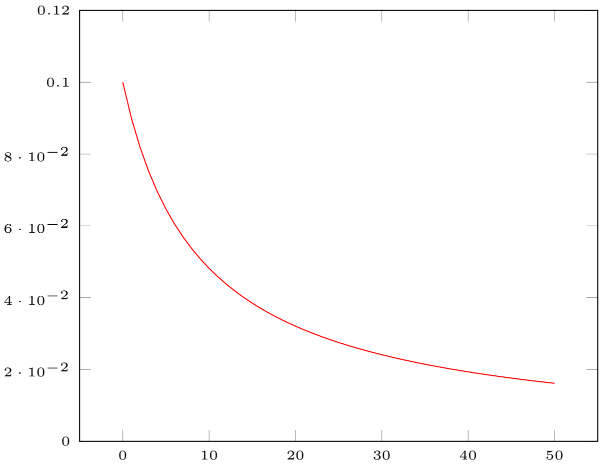


Figure 15.10: Plot of the logistic equation with $x_0 = 0.1$ and $K = 1$

We note that for this growth rate and this initial condition, the population will decrease and approach zero.

2. If the initial value x_0 is equal to 0.1 and $K = 2$ the evolution of the population for the first forty periods is represented by the graph below:

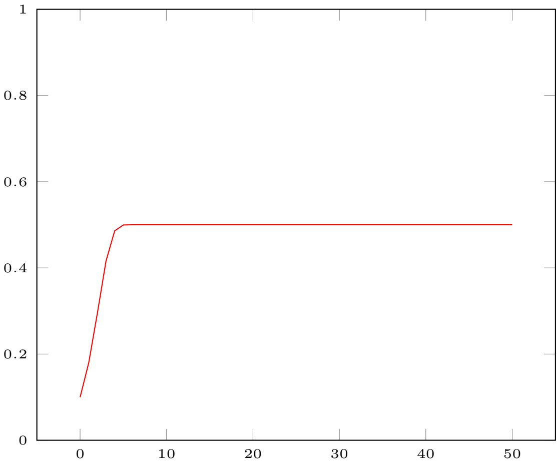

Figure 15.11: Plot of the logistic equation with $x_0 = 0.1$ and $k = 2$

We note that for this growth rate, the population will stabilize around a number corresponding to half of the population that the territory could accommodate (remember that $1 = 100\%$ on the y-axis).

3. If the initial value x_0 is equal to 0.1 and $K = 3$ the evolution of the population for the first forty periods is represented by the graph below:

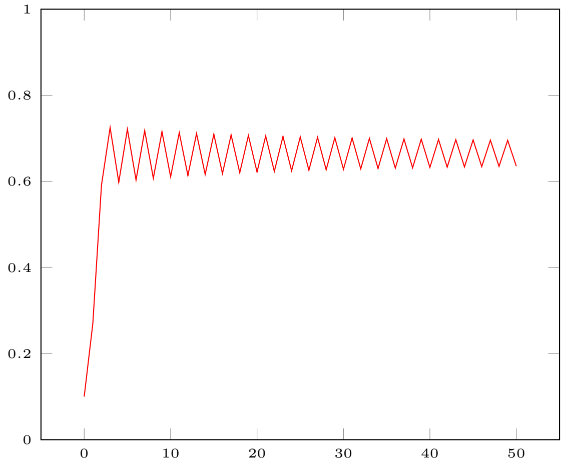

Figure 15.12: **Plot of the logistic equation with $x_0 = 0.1$ and $k = 3$**

With a growing rate of 3, the number of individuals of this population starts to oscillate between two values that can be calculated using the computer. We then obtain the values 0.64 and 0.68.

4. If the initial value x_0 is equal to 0.1 and $K = 3.5$ the evolution of the population for the first forty periods is represented by the graph below:

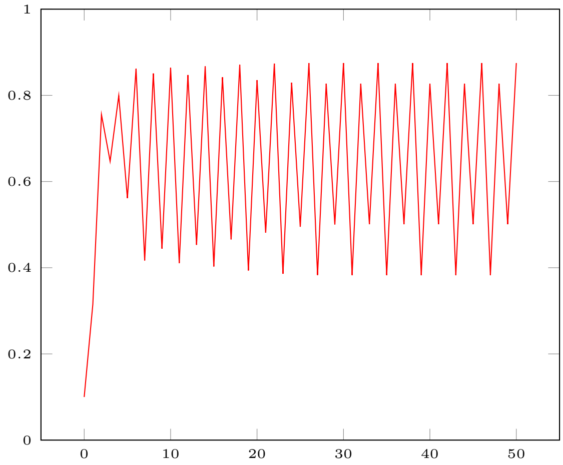

Figure 15.13: **Plot of the logistic equation with $x_0 = 0.1$ and $K = 3.5$**

With an effective growth rate of 3.5 the population oscillates between four values: 0.39 and 0.83, then 0.49, and finally 0.87. The evolution of a population that has such actual growth rate is clearly cyclical.

5. If the initial value x_0 is equal to 0.1 and $K = 4.5$ the evolution of the population for the first forty periods is represented by the graph below:

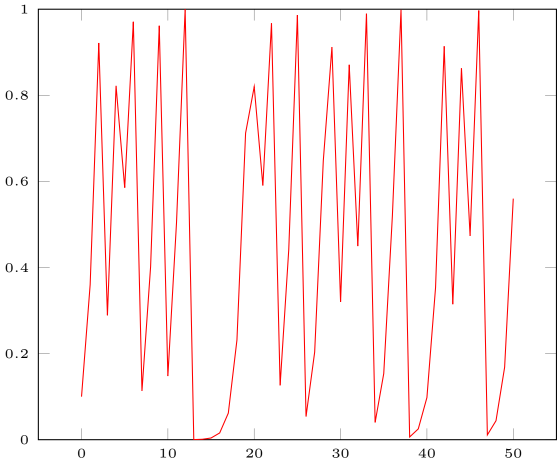

Figure 15.14: Plot of the logistic equation with $x_0 = 0.1$ and $K = 4.5$

We notice that when the growth rate is equal to 4.5, the number of individuals of seems to oscillate irregularly in a "chaotic" way between two extremes: the saturation as x approaches 1 and extinction as x approaches 0.

The question now is what is the behaviour of this function for other initial values of population?

To find out why, we take the above calculations with an initial population representing 0.8 (80%) of the maximum population of 1 (100%) for a given area and compare the results.

The population growth is always given by the equation:

$$x_{t+1} = Kx_t(1 - x_t) \tag{15.1.51}$$

1. Depending on to the initial population is $x_0 = 0.1$ or $x_0 = 0.8$ we get for $K = 1$:

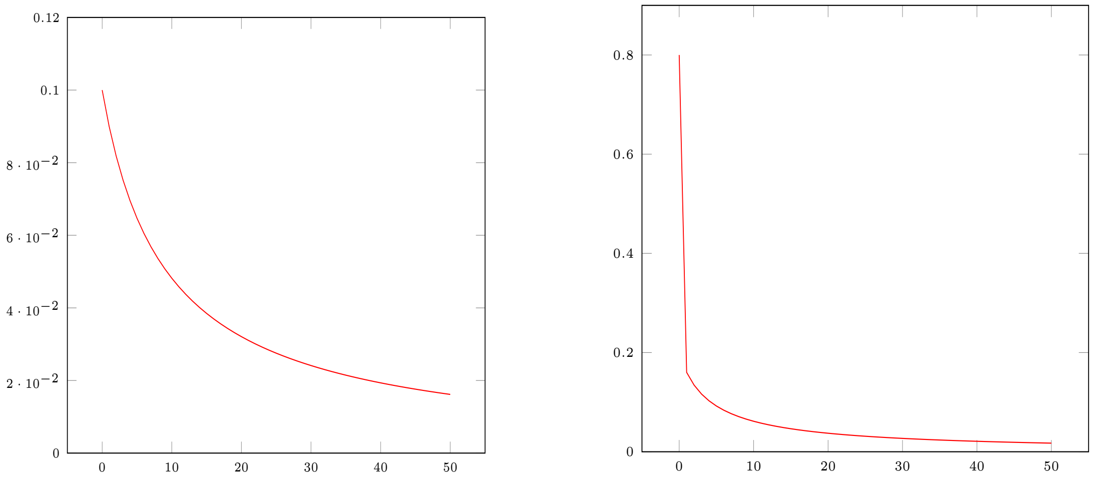

Figure 15.15: Small k and $x_0 = 0.1$

Figure 15.16: Small k and $x_0 = 0.8$

Figure 15.17: Comparison plots of logistic equations for small k

2. Depending on to the initial population is $x_0 = 0.1$ or $x_0 = 0.8$ we get for $K = 2$:

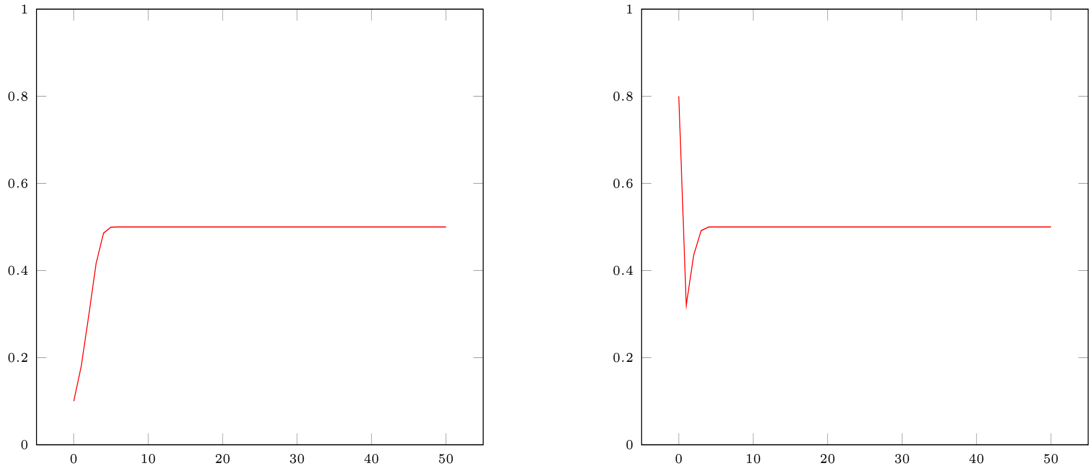

Figure 15.18: Medium k and $x_0 = 0.1$

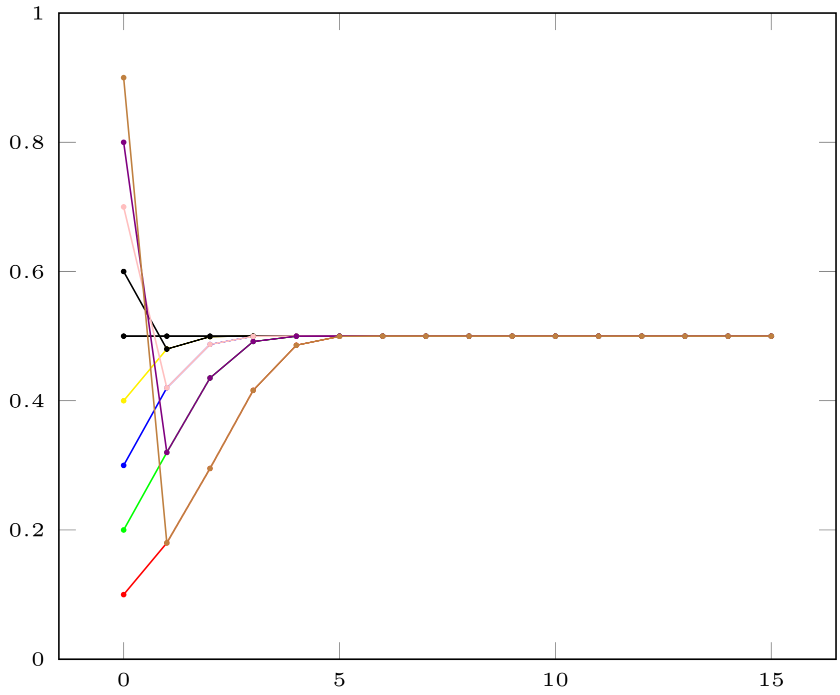
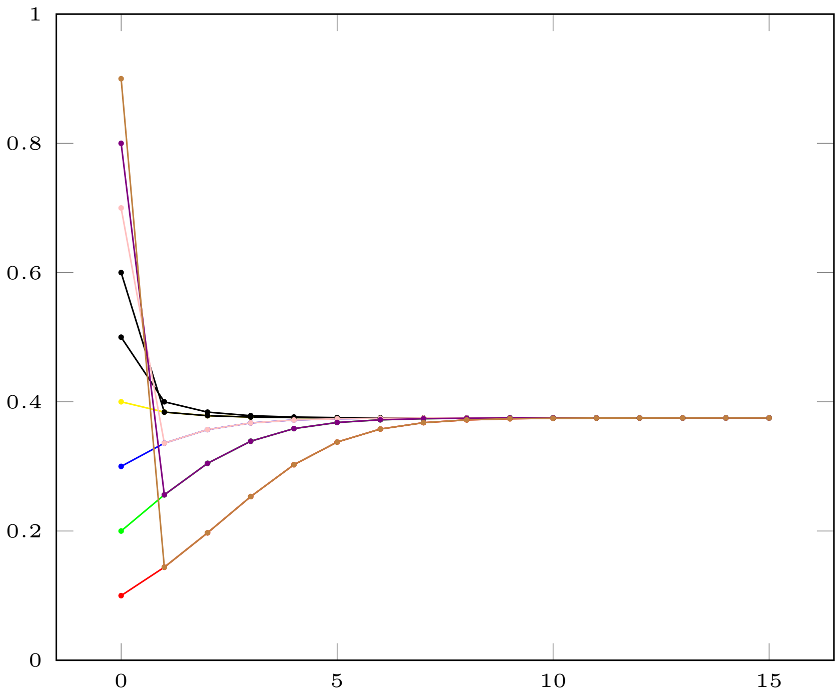
Figure 15.19: Medium k and $x_0 = 0.8$

Figure 15.20: Comparison plots of logistic equations for medium k

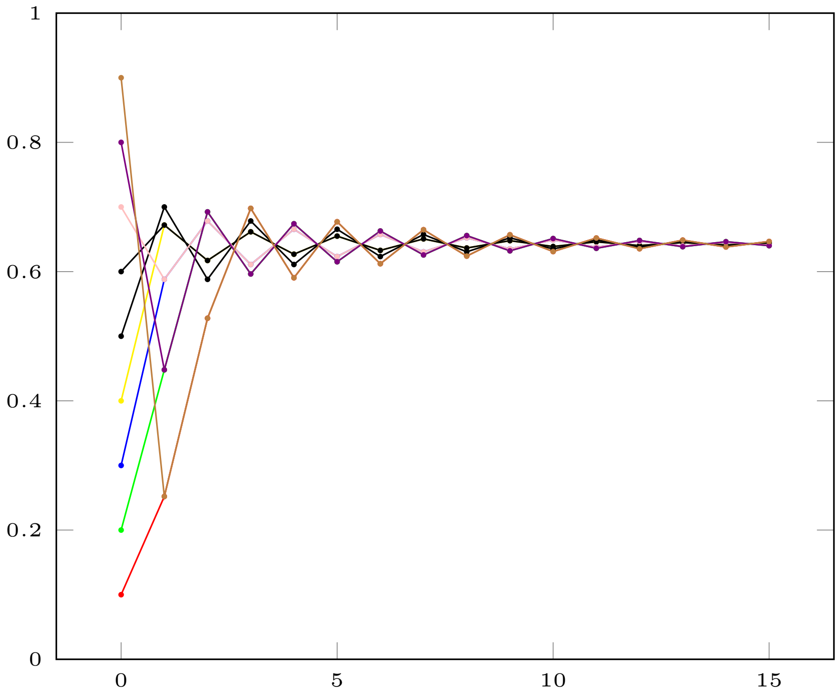
We see that regardless of the initial population, it tends to a stabilization (equal to 0.5) after a few iterations named an "attractor". This is even more visible with the following plot:



or with $K = 1.6$ we see that the attractor is at almost 0.38:



or with $K = 2.8$ we see that the attractor is at almost 0.64:



3. Depending on to the initial population is $x_0 = 0.1$ or $x_0 = 0.8$ we get for $k = 3.8$:

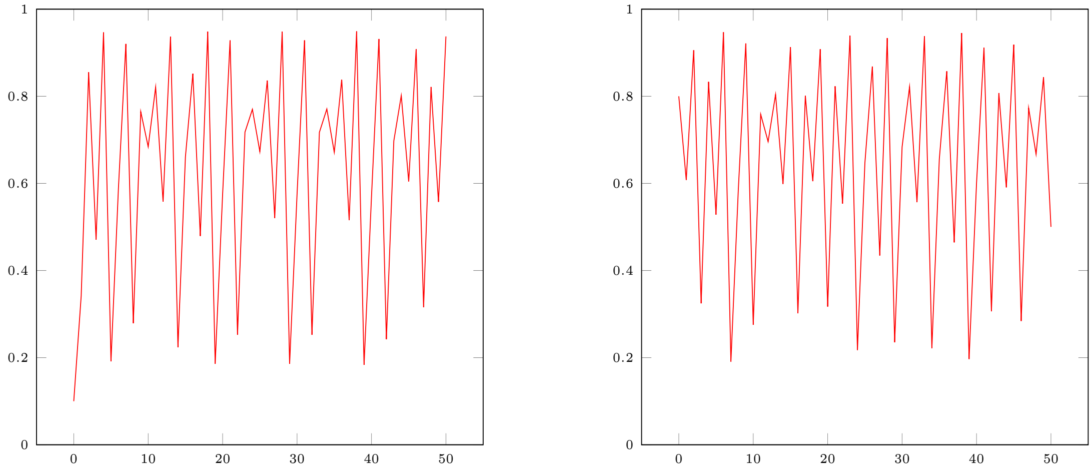


Figure 15.21: **Large k and $x_0 = 0.1$**

Figure 15.22: **Large k and $x_0 = 0.8$**

Figure 15.23: **Comparison plots of logistic equations for large k**

We can notice here that the evolution of populations is very different. We took remote initial populations. If we had very similar initial populations, what would have been the evolution of the two populations?

4. Depending on to the initial population is $x_0 = 0.8$ or $x_0 = 0.8001$ we get for $k = 3.8$:

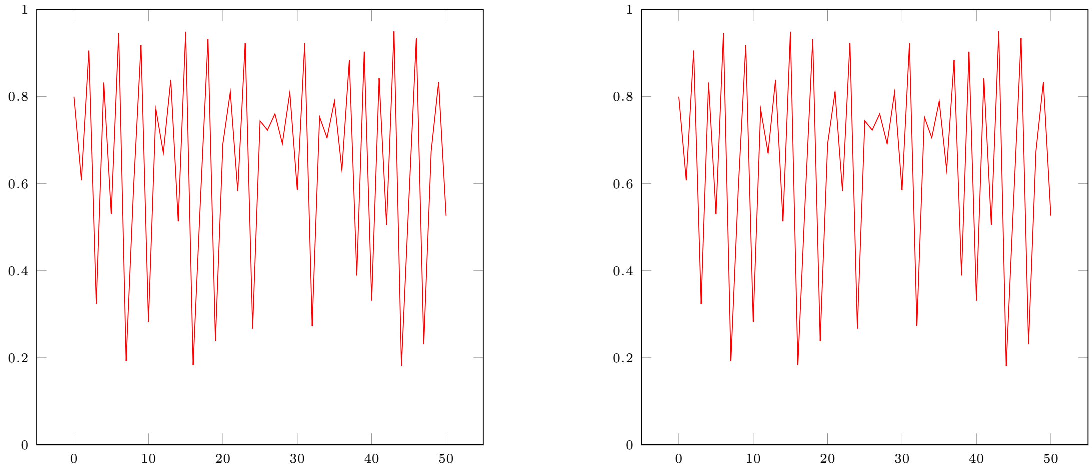

Figure 15.24: **Large k and $x_0 = 0.8$**

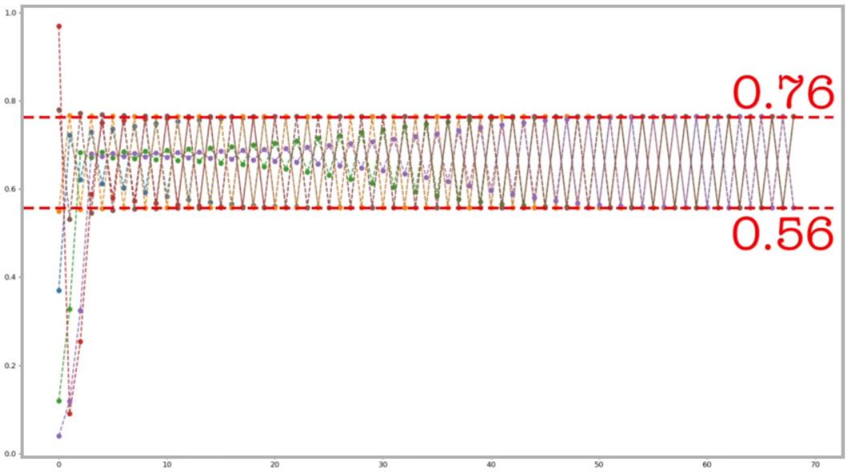
Figure 15.25: **Large k and $x_0 = 0.8001$**

Figure 15.26: **Comparison plots of logistic equations for one large k and small δk**

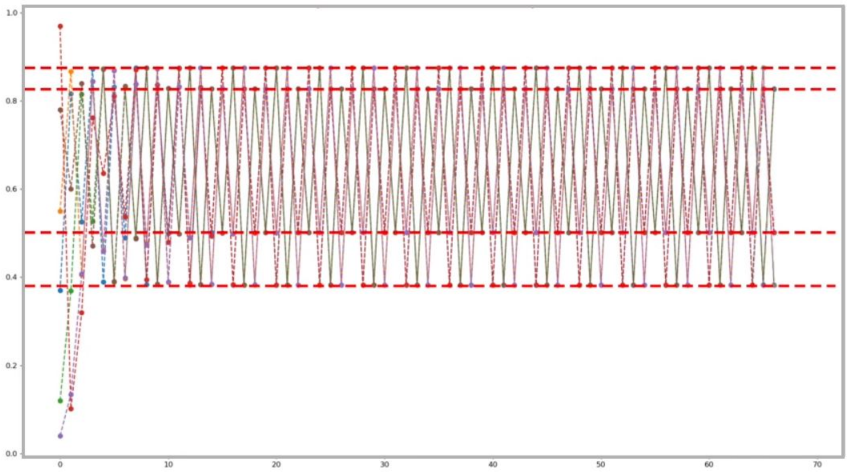
We can notice here that evolution of the populations are very different even though they were very close initially and even if the evolution function of these populations is a very simple expression. If we had taken as initial population $x_0 = 8.00001$ we could have also found a very different evolution of population trends.

This oscillation is even more visible with the following plot:

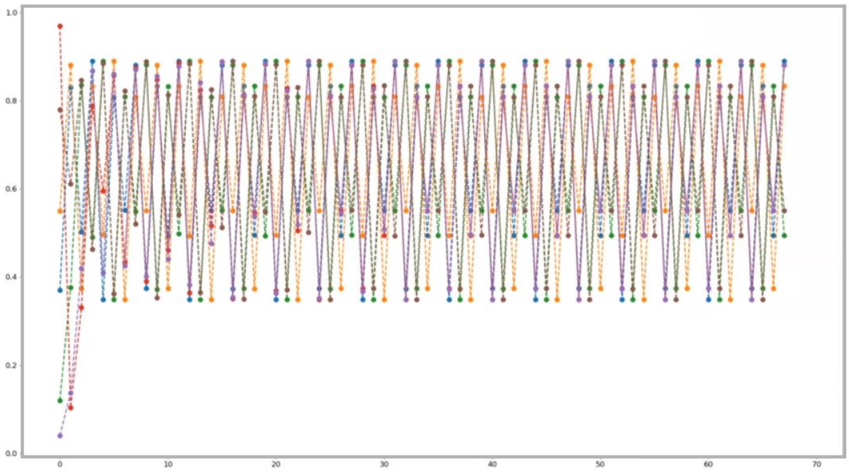


We see above that the points oscillates between two bounds. This is not an attractor with a unique point, but an attractor with two points. The attractor is then named a "periodic attractor".

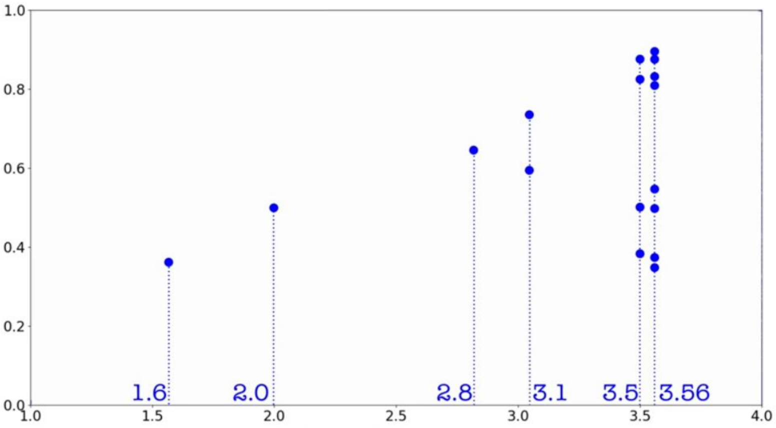
With $K = 3.5$ there are 4 periodic attractors:



With $K = 3.56$ there are 8 periodic attractors:



Now if we plot the attractors value in function of the iterations for difference values of the K above we get the following dot point plot:



The conclusion of this model is that outside of the chaotic phase, the initial value is not important, but in this chaotic phase, otherwise, the smallest variation in initial value change completely the following values. This is named the "butterfly effect" (for more details about the Butterfly Effect see the mathematical developments of the section of Marine & Weather engineering).

15.1.2.3.1 Feigenbaum's Bifurcation Diagram

To understand the evolution of a population with logistic model, we have previously showed the evolution over time, forty periods, of a population corresponding to a specific initial value and a constant k determined. We have seen, by taking some special values of k, that for these different values, the population had a different pattern. So we will study now the behaviour of the logistics by taking k as variable.

Giving to k values between 0 and 4 with a step of 0.02, we will, for each of these values, calculate what will be the population for each period between the 30th and 130th.

With Maple™ 4.00b we get (in the `R` companion book the equivalent script is also given in `R` language):

```
 >with(plots):  with(plottools);
>feigenbaum:=proc(start,end,step) local k,iteration,a,b,s;
s:=; a:=stat;
while a<=end do iteration:=0.1;
for k to 50 do iteration:=a*iteration*(1-iteration) od;
for k to 100 do iteration:=a*iteration*(1-iteration);
s:=s union [a,evalf(iteration,4)];
od;
a:=a+step
od;
plot([op(s)],'a'=start..end,style=POINT,symbol=POINT)
```

```
end:
>feigenbaum(1,4,0.01);
```

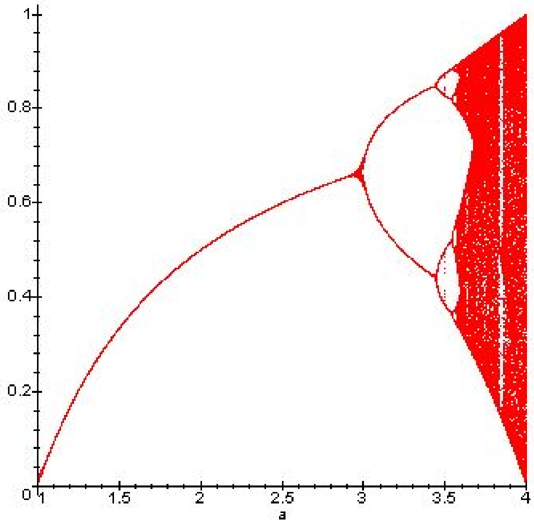


Figure 15.27: **Feigenbaum diagram in Maple™ 4.00b**

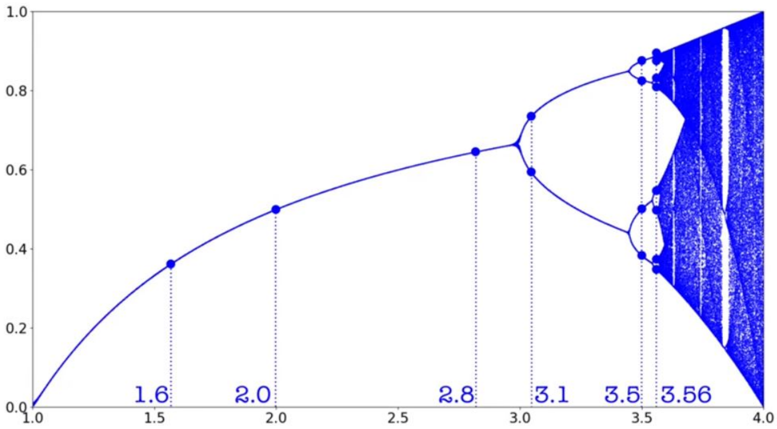
This diagram (where we can observe bifurcations), is named "Feigenbaum diagram", named after the physicist Mitchell Feigenbaum who studied it in depth and showed that we found him in many natural phenomena.

We can identify in the diagram above the different attractors hat we have seen just earlier:



We will now have a qualitative approach of two remarkable properties of this diagram: the doubling period and its fractal dimension!!

Going back to our example where the logistics function gives the evolution of a population according to its actual growth rate k, the Feigenbaum diagram indicates that, when the rate is less than 3, the system tends towards a stable final state. This generally corresponds to our intuition influenced by our unconscious desire for order and simplicity.

But starting from 3, the things become little bit more complicated: the number of individuals per generation starts oscillating between 2 and 4, then 8 values ... to finally get into a "chaotic" area where all values seem possible. There is already something fascinating. But if you observe more closely this doubling of interval before the chaotic area, we will discover even more curious results.

So we first take the sequence of the three first three duplications with 2, then 4, then 8 branches, for an effective growth rate k on an interval $k = [3, 3.564407]$ and we get the following diagram:

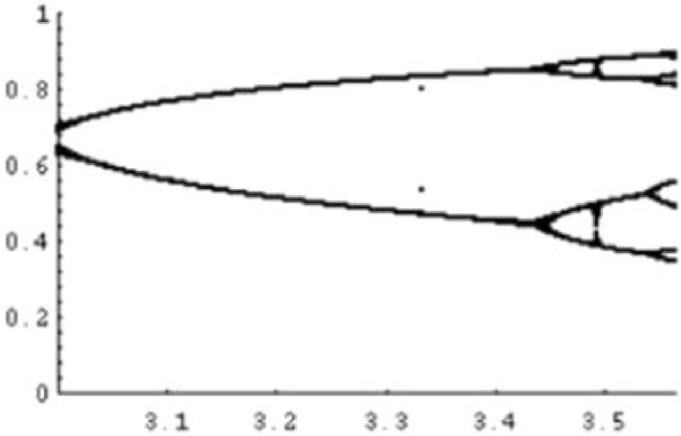


Figure 15.28: **Bifurcations in the Feigenbaum diagram**

It is remarkable to observe in the figure above that there are two point that are totally stable (the both just a little bit after 3.3)!

If we take the interval $k = [3.5, 3.569891]$ we get the following Feigenbaum diagram:

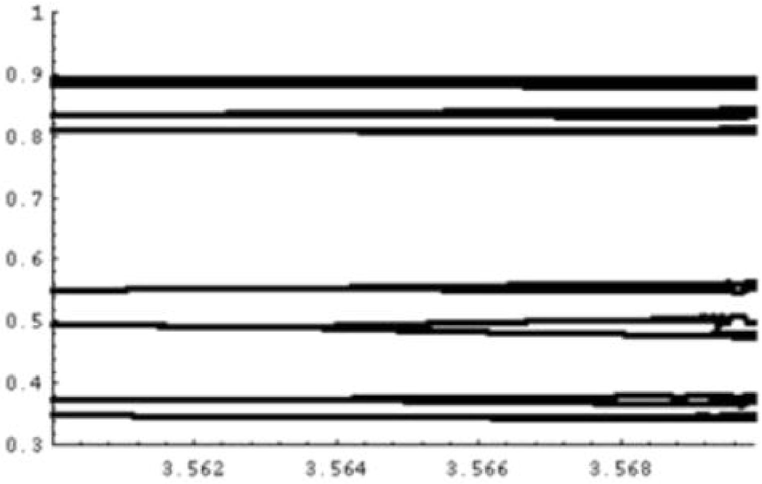

Figure 15.29: **Multiple bifurcations in the Feigenbaum diagram**

We can notice in the figure above that the bifurcation multiplies from points that are always more and more closer and on intervals always shorter. The physicist Feigenbaum has therefore proven (by trial and error) two strange results:

1. The bifurcations will multiply to infinity (!) on a range which does not exceed the point 3.5699456 of the x-axis named the "Feigenbaum point" or "gateway to chaos", because,

after this point, the system becomes chaotic. It begins to fluctuate between unpredictable values and becomes extremely sensitive to initial conditions.

2. The lengths of intervals specific to different classes of bifurcations $(2, 4, 8, 16, \ldots)$ decreases in a constant ratio of $4.6692\ldots$ named, off course, the "Feigenbaum constant".

Remark

Heinz-Otto Peitgen has observed that these bifurcations, Feigenbaum points and constant, are not only found in the case of the logistic function studied by Robert May (see below), but also in many physical phenomena such as hydrodynamics, electronics, LASERs or acoustics.

Finally, we can notice a curious phenomenon about these stable windows! If we examine more closely the chaotic area between the Feigenbaum point and $k = 4$, we see that there are areas where the logistic function starts to oscillate between a finite number of bifurcations before plunging into chaos again:

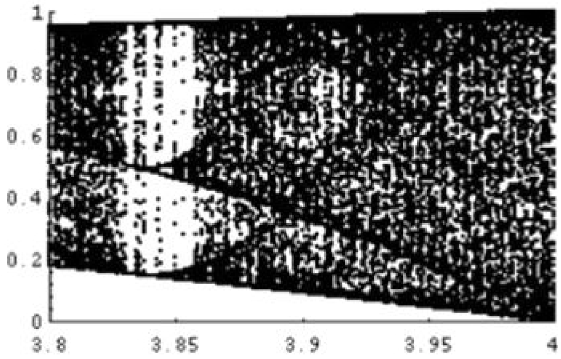

Figure 15.30: Viewing the background changes and the stabilization windows

We can notice that in this windows there are bifurcations that look like the Feigenbaum diagram itself if we zoom on it.

We could also take the same calculations between $k = 3.848$ and 3.850 and we would have found we find that we fall back on the same figure, and if we zoom on it to infinity, we always found the same figure ever and ever (!) in an auto-similarity process:

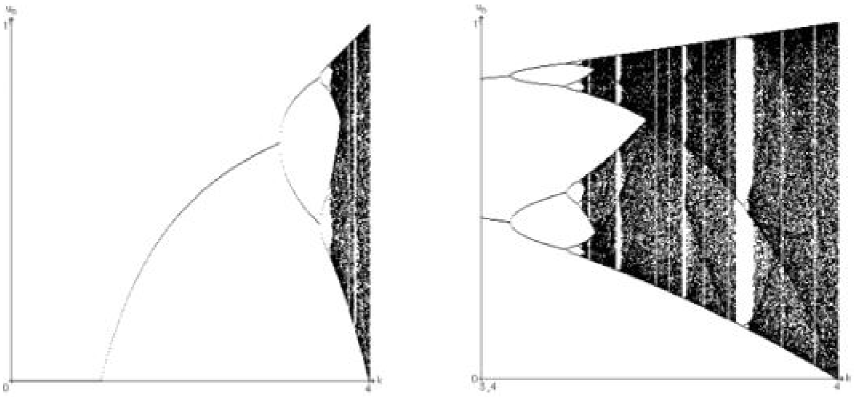

Figure 15.31: Auto-similarity of the Feigenbaum diagram

We have therefore just discovered a fractal figure (see the section Fractals page 7038 for more details): named also "strange attractor of the logistics function" also named "bifurcation diagram of the logistic equation" or simply "Feigenbaum diagram".

We will see (without proof) in the section Fractals that the Feigenbaum diagram above is closely related to the Mandelbrot fractal (without proof as we never used this result for engineering applications).

Thanks to the mathematics of Chaos Theory applied to population dynamics, ecology received a decisive stimulation. Until the early 11960s (holocene calendar), the debate on population dynamics opposed the proponents of a deterministic theory, seeing regular changes in populations undergoing exceptionally sudden changes, to those believing these developments as purely random. But many facts remain poorly explained. Especially cyclic explosions of some populations and their strange periodicity did not fall into either of the two explanations. By showing that deterministic models can give rise to random behaviour, Robert May, reconciles those views from a deeper theory. What appears to a given level of apprehension as a general instability can appear to another level as a stable chaos. A chaotic mathematical situation can be stable ecologically.

If, because of the increasing power of computers, Chaos Theory has led to major advances in different disciplines, it raises a major debate, that of determinism. How does science can predict the future? For some, the results thanks to Chaos Theory prove the importance of initial conditions. For these people, deterministic equations have limited scope and the future remains unpredictable. For others however, the results show that we can find order and laws in what may seem chaotic. These laws are simply more complex.

Here is a non-exhaustive list of chaotic natural phenomena:

- Atmospheric dynamics: Winds, storms, gradient of temperature and pressure.
- Evolutionary processes: Evolutionary processes are often nonlinear, meaning that small changes in conditions can lead to disproportionately large effects.
- Volcanic storms: Lightning occurs in plumes of volcanic ash.
- Supercell storms: Massive thunderstorms that can produce tornadoes.
- Catatumbo storms: A region in Venezuela where lightning occurs almost continuously.
- Rogue waves: Extremely large and unpredictable ocean waves.
- Earthquakes: Sudden shaking of the Earth's crust.
- Volcanic eruptions: Explosions of lava, ash, and gas from volcanoes.
- Tsunamis: Giant waves caused by underwater earthquakes.
- Landslides: Rapid movements of rock and earth down slopes.
- Tropical cyclones: Powerful storms with high winds and torrential rain.

- Solar storms: Generates high energy particle winds that can have significant effects on living things.
- Avalanches: Rapid descents of snow and ice down mountainsides.
- Chemical reactions: Belousov-Zhabotinsky or Briggs-Rauscher oscillating reaction
- Social Dynamics: Populations behaviours
- ...

It is an open and lively debate that goes far beyond the scientific community.

15.1.2.4 Malthusian Growth Law

We have already seen some deterministic and chaotic models using growth rates for the simulation. Now introduce another type of model using the number of children, women and their respective fertility.

For this model, we state the following hypothesis (assumptions):

H1. At the beginning, N people where $N/2$ are females.

H2. The growing rate r is supposed to be constant because of a fecundity rate f that is also constant.

H3. The population is growing.

So we have for data: the population at time t denoted $N(t)$, the female population denoted $N_F(t)$ and $N_E(t)$ the number of children.

With the following relations:

$$\begin{aligned} N_F(t) &= \frac{N(t)}{2} \\ N_E(t) &= fN_F(t) \end{aligned} \qquad (15.1.52)$$

and therefore:

$$N(t+1)=N(t)+N_E(t)=N(t)+fN_F(t)=N(t)+f\frac{N(t)}{2}=N(t)\left(1+\frac{f}{2}\right)=rN(t) \qquad (15.1.53)$$

then the growth rate is:

$$r=1+\frac{f}{2} \qquad (15.1.54)$$

Finally we get the Malthus law:

$$\boxed{N(t)=r^tN(0)} \qquad (15.1.55)$$

this model is therefore continuous, takes into account the fecundity but diverge.

15.1.2.5 Leslie model

The Leslie model is a bit more advanced than the others deterministic models but just as empirical (it is possible, as in any field of science to construct valid theoretical models always more complete and complex).

Besides the fertility and mortality rates, this model can take into account the ages groups of the population and some of their properties in relation to the two aforementioned factors (fertility, mortality). The disadvantage of this model is, however, the too many parameters to be determined for all age groups...

The system is based on the cutting of the population in age groups such as for example:

- $N_1(t)$: Is the number of people of age 1
- $N_2(t)$: Is the number of people of age 2
- ...
- $N_i(t)$: Is the number of individuals of age i.
- ...
- $N_T(t)$: Is the number of individuals of age T.

Then the idea is that the evolution of an age group depends on the other age groups. For example, births are given by the reproduction rate r summed over all age groups (of course for some of them the rate is zero...) such as:

$$N_1(t+1)=\sum_{i=2}^{T} r_i N_i(t) \tag{15.1.56}$$

It is customary and reasonable for humans being to accept that normally only age groups for which $i\geq 11$ and $T=55$ are taken into account regarding to the reproduction which implies that normally the r_i are non-zero only for this interval.

Then, aging and mortality m will be taken into account by the relations (we take again all the age groups of the entire population because obviously there is not only the individuals between 11 and 55 that die ...):

$$N_i(t+1)=N_{i-1}(t)-m_{i-1}N_{i-1}(t) \qquad \forall i\in\mathbb{N}, i=2\ldots T \tag{15.1.57}$$

It is relatively easy to see that these equations can be put in a matrix form (see section Linear Algebra page 1924) as follows:

$$\begin{pmatrix} N_1(t+1)\\ N_2(t+1)\\ \vdots\\ N_i(t+1)\\ \vdots\\ N_T(t+1)\end{pmatrix}=\begin{bmatrix} 0 & r_2\ldots & r_i & \ldots & r_T & \\ 1-m_1 & 0 & 0 & 0 & 0 & 0\\ 0 & 1-m_2 & 0 & 0 & 0 & 0\\ \vdots & 0 & \ddots & 0 & 0 & \vdots\\ \vdots & 0 & 0 & 1-m_i & 0 & \vdots\\ 0 & 0 & 0 & 0 & 1-m_{T-1} & 0\end{bmatrix}\begin{pmatrix} N_1(t)\\ N_2(t)\\ \vdots\\ N_i(t)\\ \vdots\\ N_T(t)\end{pmatrix} \tag{15.1.58}$$

where the matrix containing the coefficients of mortality and reproduction is named "Leslie matrix".

More compactly it is written:

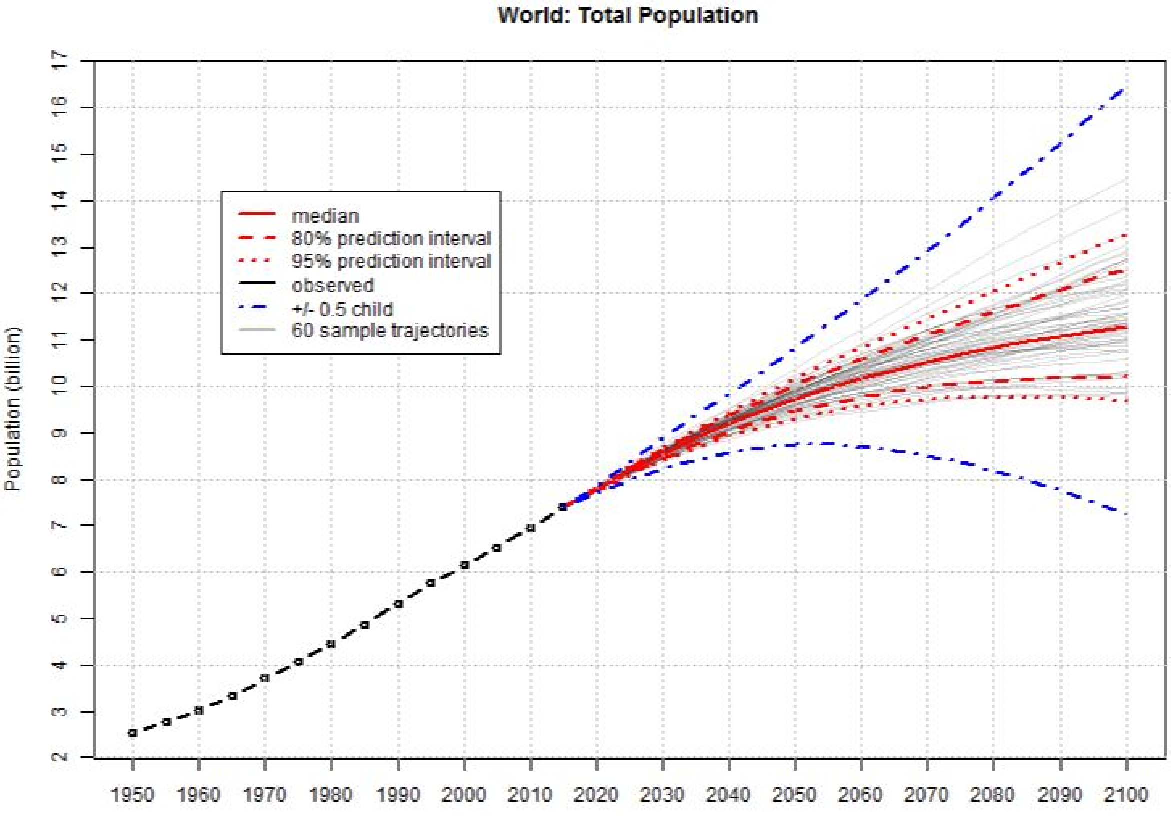
$$N(t+1)=LN(t) \tag{15.1.59}$$

or when starting for the initial population:

$$N(t)=LN(0) \tag{15.1.60}$$

It is possible to make interesting analyses on this model with respect to the age of having children and the consequences relating thereto. This model seems to be relatively widely used in marine biology.

We will stop here about population models. However in a few decades or centuries it will be interesting for the reader to see how accurate was the following projection United Nations:



Source: United Nations, Department of Economic and Social Affairs, Population Division (2017). *World Population Prospects: The 2017 Revision. http://esa.un.org/unpd/wpp/*

15.1.2.6 Epidemic models for spread of disease

The "theory of epidemics" provides many intuitive systems of differential equations or with partial derivatives in discrete or continuous time having analytical deterministic solutions in which intervene contamination phenomena, diffusion phenomena, etc.

We will see below a few naive deterministic models to simulate epidemics. They are "naive" because they don't take into considerations the behaviours of the individuals (their movements, their social interactions, their respect of governmental rules, the answer of the medical system, the topology of the geographical area, the pyramid of ages, newborns and deaths, etc.) and are completely deterministic. Models used in real life in the 121st century (holocene calendar) use models based on "Discrete Event Analysis" also named "Discrete Event Simulation" (with Monte Carlo simulations and Bayesian methods including forecasting technique like VAR and GARCH) that runs only on supercomputers and include a few hundred to a few thousands of stochastic interacting or non-interacting variables.

Any idea to cure the plague?
Pray to god
Kill the infected
SCIENCE

15.1.2.6.1 Exponential Model

Let us consider a model where out of N people, there are those infected I and those susceptible S with the assumption that eventually all susceptible can contracts the disease, we have:

$$\begin{aligned}\frac{\Delta S(t)}{\Delta t}&=rI(t)\\ S(t)&=N(t)-I(t)\end{aligned} \tag{15.1.61}$$

That model is named obviously the "exponential disease model" as the differential equation:

$$\frac{\mathrm{d}S(t)}{\mathrm{d}t}=rI(t) \tag{15.1.62}$$

concerning the infected constitutes an exponential growth:

$$I(t)=I_0e^{rt} \tag{15.1.63}$$

This model is very flawed because in real life, not all contacted by the infected contracts the disease, and as the community runs out of people to get infected, the rate at which the disease spreads slows:

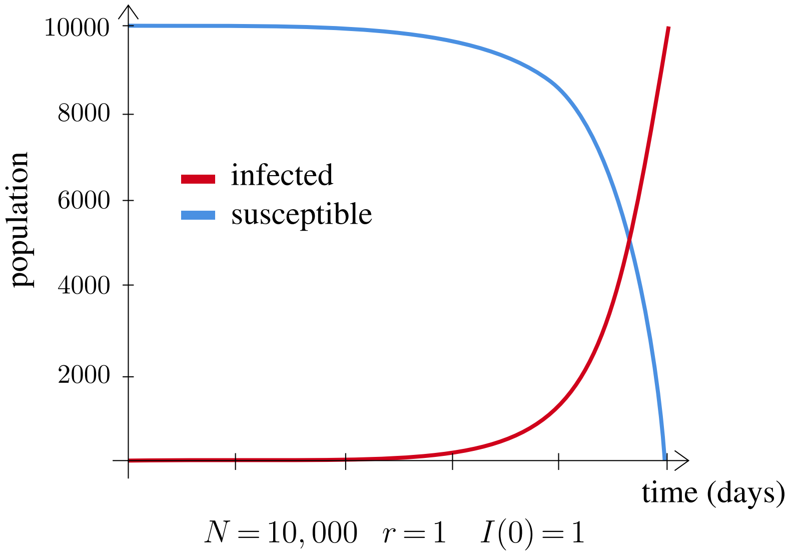


Figure 15.32: **Exponential epidemic model**

15.1.2.6.2 SI Model (Susceptible-Infected)

With what we have from the exponential model, let us introduce a new parameter β: the probability for the susceptible to contract the disease upon contact.

Then we put by construction:

$$\frac{\Delta S(t)}{\Delta t}+\frac{\Delta I(t)}{\Delta t}=0 \tag{15.1.64}$$

and:

$$\begin{aligned}\frac{\Delta I(t)}{\Delta t}&=r\beta S(t)I(t)\\ \frac{\Delta S(t)}{\Delta t}&=-r\beta S(t)I(t)\end{aligned}\qquad(15.1.65)$$

Adding the equations, we get:

$$\frac{\Delta I(t)}{\Delta t}+\frac{\Delta S(t)}{\Delta t}=r\beta S(t)I(t)-r\beta S(t)I(t)=0\qquad(15.1.66)$$

which is no surprise since $I(t)+S(t)=N$ is constant. Therefore, we only consider the first equation. After substituting $S(t)=N-I(t)$, we get a single differential equation about the infected population $I(t)$:

$$\frac{\Delta I(t)}{\Delta t}=r\beta I(t)(N-I(t))\qquad(15.1.67)$$

Hence at the limit and after rearranging:

$$\frac{\mathrm{d}I(t)}{\mathrm{d}t}=r\beta I(t)N\left(1-\frac{I(t)}{N}\right)\qquad(15.1.68)$$

We have seen during our study of the logistic model that the solution to this differential equation is the logistic function:

$$I(t)=\frac{NI_0}{I_0+(N-I_0)e^{-r\beta t}}\qquad(15.1.69)$$

That is:

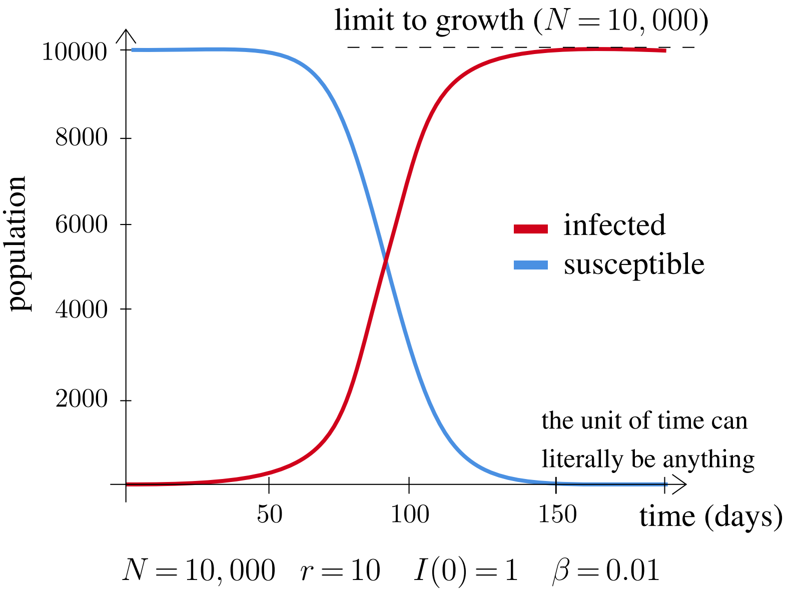

Figure 15.33: **SI epidemic model**

The number of infected people increases monotonically but stops as it approach the total population N. At $I=N/2$, we have:

$$I''(t)|_{I=\frac{N}{2}}=0\qquad(15.1.70)$$

so I grows the fastest. After this point, the growth rate of I declines.

15.1.2.6.3 SIS Model (Susceptible-Infected-Susceptible)

The idea of the SIS model is that susceptible individuals who were infected may become susceptible individuals again. That is:

$$S \underset{\gamma}{\overset{r\beta}{\rightleftharpoons}} I \tag{15.1.71}$$

Then we introduce a new parameter γ that takes care of the fact that individuals who recover from the disease may not gain full immunity.

The set of equations is very similar to the SI model but just with a supplementary term:

$$\begin{aligned}\frac{\Delta I(t)}{\Delta t} &= r\beta S(t)I(t)-\gamma I(t)\\ \frac{\Delta S(t)}{\Delta t} &= -r\beta S(t)I(t)+\gamma I(t)\end{aligned} \tag{15.1.72}$$

Adding the equations, we also get:

$$\frac{\Delta I(t)}{\Delta t}+\frac{\Delta S(t)}{\Delta t}=(r\beta S(t)I(t)-\gamma I)+(-r\beta S(t)I(t)+\gamma I)=0 \tag{15.1.73}$$

which again is no surprise since $I(t)+S(t)=N$ is constant. Therefore, we only consider the first equation. After substituting $S(t)=N-I(t)$, we get a single differential equation about the infected population $I(t)$:

$$\frac{\Delta I(t)}{\Delta t}=r\beta I(t)(N-I(t))-\gamma I(t) \tag{15.1.74}$$

Rearranging and taking the limit:

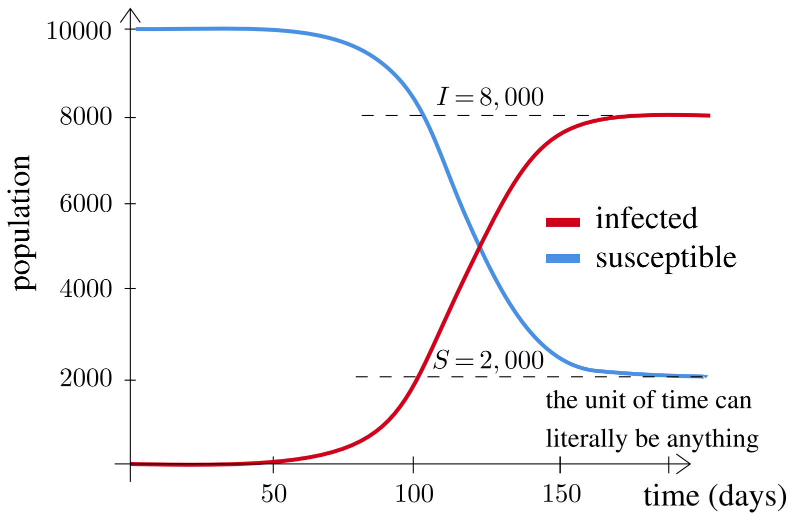
$$\frac{\mathrm{d}I(t)}{\mathrm{d}t}=(r\beta N-\gamma)I(t)-r\beta I^2(t) \tag{15.1.75}$$

If we put $A:=r\beta N-\gamma$ the above differential equation can be rewritten as:

$$\frac{\mathrm{d}I(t)}{\mathrm{d}t}=(A-r\beta I(t))I(t)=AI(t)\left(1-\frac{r\beta I(t)}{A}\right) \tag{15.1.76}$$

And we recognize here a differential equation of the same shape as the one from the previous model! So the solution is also a logistic function given by:

$$I(t)=\frac{AI_0}{I_0+(A-I_0)e^{-r\beta t}}=\frac{(r\beta N-\gamma)I_0}{I_0+(r\beta N-\gamma-I_0)e^{-r\beta t}} \tag{15.1.77}$$



$$N = 10,000 \quad r = 10 \quad I(0) = 1 \quad \beta = 0.01 \quad \gamma = 0.02$$

Figure 15.34: **SIS epidemic model**

15.1.2.6.4 SIR Model (Susceptible-Infected-Recovered)

Here we will take the example of the spread of rabies in the fox population, and present a fairly simple model where we consider that individuals (foxes) can be in only three different states:

1. There are healthy foxes in quantity S (susceptible)
2. There are infected foxes in quantity I
3. There are death foxes in quantity R

This assumption of classification into three categories make that this model of spread of epidemics is often named the "SIR model".

First, we assume that the overall (closed[1]) population is:

$$S + I + R = 1 \qquad (15.1.78)$$

so that S, I, and R are proportions (and obviously are function of time). We further assume that the overall population does not change, that is:

$$\frac{\Delta(S+I+R)}{\Delta t} = 1 \Leftrightarrow \frac{\Delta I}{\Delta t} = -\frac{\Delta S}{\Delta t} - \frac{\Delta R}{\Delta t} \qquad (15.1.79)$$

For more optimistic people, we can also use the model that assumes that some individuals are immune and can therefore not be infected. Finally, with three different states, we can link the three proper equation of developments such that:

---

[1] *Closed* means that there is no immigration or emigration!

$$\begin{aligned}\frac{\Delta S}{\Delta t}&=S'=-r\beta IS\\ \frac{\Delta R}{\Delta t}&=R'=\gamma I\\ \frac{\Delta I}{\Delta t}&=I'=-\frac{\Delta S}{\Delta t}-\frac{\Delta R}{\Delta t}=r\beta IS-\gamma I\end{aligned}\tag{15.1.80}$$

where $r>0$ is the rate of infection, $0<\beta\leq 1$ the probability of infection and $\gamma>0$ is the recovery rate (percentage of people who recover from the disease but don't gain full immunity) and with:

$$\begin{aligned}S_{t+1}&=S+S'\Delta t\\ I_{t+1}&=I+I'\Delta t\\ R_{t+1}&=R+R'\Delta t\end{aligned}\tag{15.1.81}$$

where the S,I,R are given in $\%$ of the whole population. This is the simplest of the SIR models and named the "Kermack-McKendrick model".

In this model, the first equation corresponds to the phenomenon of contamination: when coexist healthy individuals and of infected individuals, a number of healthy individuals will be infected. It is also natural to consider this term as proportional to the product IS. Indeed, the quantity of microbes in the defined medium (thus the factor r for a healthy individual to be infected in the presence of an infected individual) is proportional to I according to the factor. We then have to multiply this probability by the number of healthy individuals, that is to say, by S. The negative sign is present to indicate the reduction of the healthy population.

Regarding the variations of I, the first term corresponds to the infected individuals (which increase I). The second term in $-\gamma I$, consists of individuals who die.

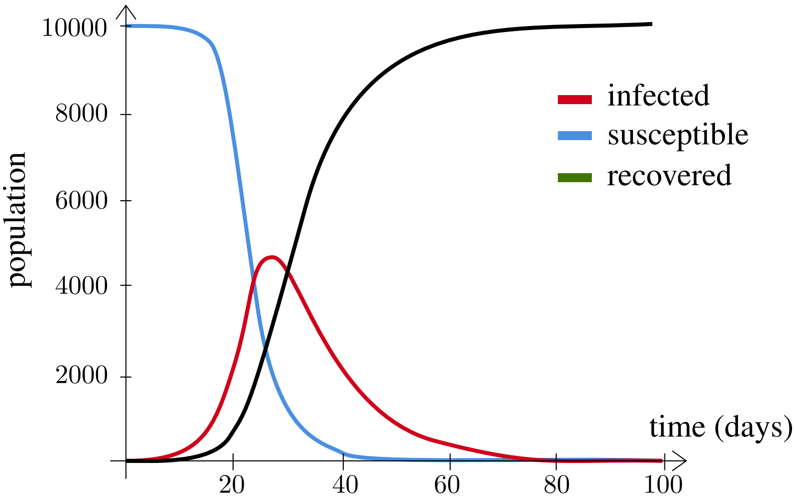
Observe that since we assumed that the overall population does not change since:

$$R(t)=1-S(t)-I(t)\tag{15.1.82}$$

then the system is therefore fully characterized by:

$$\boxed{\begin{aligned}\frac{\Delta S}{\Delta t}&=S'=-r\beta IS\\ \frac{\Delta I}{\Delta t}&=I'=r\beta IS-\gamma I\end{aligned}}\tag{15.1.83}$$

The plot below shows a calculation of the evolution of the populations S, I, R as a function of time (one second is considered as a loop of the algorithm). According to the values of parameters γ, β and r the behaviours are completely different: if γ is too high, for example, infected individuals die almost immediately and do not have time to infect many others (...):



$$N = 10,000 \quad r = 10 \quad I(0) = 1 \quad \beta = 0.01 \quad \gamma = 0.02$$

Figure 15.35: **SIR epidemic model**

According to this model, during the beginning phase of a pandemic, there would be a surge of confirmed cases. The as time goes on, a fraction of the individuals gradually gain immunity to the disease, thus the number of infected people goes down.

Definition (#15.1.628): A "pandemic" is an epidemic of an infectious disease that has spread across a large region, for instance multiple continents or worldwide, affecting a substantial number of individuals. A widespread endemic disease with a stable number of infected individuals is not a pandemic.

Let us show now that we can get an analytic solution for $I_{\max}$.

Dividing the two previous relation we get:

$$\frac{\frac{\mathrm{d}S}{\mathrm{d}t}}{\frac{\mathrm{d}I}{\mathrm{d}t}} = \frac{\mathrm{d}S}{\mathrm{d}I} = \frac{-r\beta IS}{r\beta IS - \gamma I} \tag{15.1.84}$$

We can rewrite that latter relation as:

$$\frac{r\beta S - \gamma}{r\beta S}\mathrm{d}S = -\mathrm{d}I \tag{15.1.85}$$

That we can obviously integrate both sides:

$$\int \frac{r\beta S - \gamma}{r\beta S}\mathrm{d}S = -\int \mathrm{d}I \tag{15.1.86}$$

That lead us to:

$$S - \frac{\gamma}{r\beta}\log(S) = -I - c^{te} \tag{15.1.87}$$

After rearranging (we put the negative sign in the constant):

$$I + S - \frac{\gamma}{r\beta}\log(S) = c^{te} \tag{15.1.88}$$

In other words, for every $t \geq 0$:

$$I(t)+S(t)-\frac{\gamma}{r\beta}\log(S(t))=I(0)+S(0)-\frac{\gamma}{r\beta}\log(S(0)) \tag{15.1.89}$$

I_{max} occurs when $\mathrm{d}I/\mathrm{d}t=0$, i.e.:

$$\frac{\mathrm{d}I}{\mathrm{d}t}=r\beta IS-\gamma I=0 \tag{15.1.90}$$

Therefore this occurs when $S=\gamma/(r\beta)$. Applying in our previous equality, we get:

$$I_{\text{max}}+\frac{\gamma}{r\beta}-\frac{\gamma}{r\beta}\log\left(\frac{\gamma}{r\beta}\right)=I(0)+S(0)-\frac{\gamma}{r\beta}\log(S(0)) \tag{15.1.91}$$

or:

$$I_{\text{max}}=I(0)+S(0)-\frac{\gamma}{r\beta}\log(S(0))-\frac{\gamma}{r\beta}+\frac{\gamma}{r\beta}\log\left(\frac{\gamma}{r\beta}\right) \tag{15.1.92}$$

Condensed it leads to:

$$\boxed{I_{\text{max}}=I_0+S_0+\frac{\gamma}{r\beta}\left[\log\left(\frac{\gamma}{r\beta S_0}\right)-1\right]} \tag{15.1.93}$$

The implementation algorithm looks like this in pseudocode (for a more formal approach see our MATLAB® or R companion book).

In pseudocode (non-unique and not optimized):

Algorithm 19: SIR Model pseudocode algorithm

```
Data: $r$ $\beta$,$\gamma$, $\max_t$, $\Delta_t$
Result: $\bar{x}$
initialization;
for $i=1$ to $E(\max_t/\Delta_t)$ do
    $\mathrm{d}S=-r\beta S(i)I(i)$;
    $\mathrm{d}I=r\beta S(i)I(i)-\gamma I(i)$;
    $\mathrm{d}R=\gamma I(i)$;
    $\mathrm{d}R=\gamma I(i)$;
    $S(i+1)=S(i)+\mathrm{dtd}S$;
    $I(i+1)=I(i)+\mathrm{dtd}I$;
    $R(i+1)=R(i)+\mathrm{dtd}R$;
plot $(I,t),(S,t),(R,t)$;
```

A key parameter in epidemiology is the "basic reproductive ratio R_0". It is defined as the average number of secondary cases transmitted by a single infected individual that is placed into a fully susceptible population. In other words, R_0 tells us about the initial rate of spread of the disease. Hence, if $R_0>1$, there will be an epidemic, and if $R_0<1$, the introduced infected will recover (or die) without being able to replace themselves by new infections. In the special case of the model above, it is pretty easy to derive R_0. The disease-free state corresponds to:

$$S=N \qquad I=0 \qquad R=0 \tag{15.1.94}$$

where don't work in percentages any more but rather in total population size N such that:

$$S+I+R=N \tag{15.1.95}$$

If one infected individual appears in the population, there will be an epidemic if and only if:

$$\frac{\Delta I}{\Delta t}>0 \tag{15.1.96}$$

By replacing S with N in the third relation of:

$$\begin{aligned}\frac{\Delta S}{\Delta t}&=S'=-r\beta IS\\ \frac{\Delta R}{\Delta t}&=R'=\gamma I\\ \frac{\Delta I}{\Delta t}&=I'=-\frac{\Delta S}{\Delta t}-\frac{\Delta R}{\Delta t}=r\beta IS-\gamma I\end{aligned} \tag{15.1.97}$$

This leads to if we put $\beta=1$:

$$\frac{rN}{\gamma}>1 \tag{15.1.98}$$

That is:

$$R_0=\frac{rN}{\gamma} \tag{15.1.99}$$

To avoid any epidemic of a disease whose basic reproduction rate is R_0, it is therefore necessary that the proportion of susceptible is less than $1/R_0$, in other words that the proportion of immune is greater than minimum vaccination cover rate given by (this result has nothing to do specifically with the SIR model, it's just applied common sense!):

$$\text{MVCR}=\frac{R_0-1}{R_0} \tag{15.1.100}$$

Thus, if $R_0=2$ (seasonal influenza reproduction rate), at least half of the population must be vaccinated to prevent or slowdown epidemics. On the other hand, if $R_0=15$ to 20 (measles reproduction rate), herd immunity is only guaranteed if at least 93 to 95% of the population is vaccinated!

We can of course come to many variations of this model depending on the assumptions we make about the disease under study. It will often be useful to define more populations categories. Thus, for S.T.D. (Sexually Transmitted Diseases), we will differentiate the populations according to sex (we should also take the age into account), which double the number of possibilities. To define the underlying differential system, it becomes better sometimes to model the process by a diagram.

Definition (#15.1.629): A "vaccine" is a preparation which must be ingested or injected once or multiple times in a single lifetime that provides a statistically significant active acquired immunity to a particular infectious disease in the purpose to avoid completely or partially its effects[2]. A vaccine must have a statistical interesting benefice/risk ratio (better than a placebo or standard of care in a control group). The purpose of a vaccine is not to eliminate the transmission of its targeted virus but that may be an optional beneficial side effect.

---

[2] At the difference of a "treatment" that is used only once the infectious disease is already acquired by the individual.

Definition (#15.1.630): In medicine, a "treatment", also named "medical treatment", "therapeutic treatment", "therapy" or more generally "therapeutic", is a set of measures applied by a health professional (or therapist) to a person vis-à-vis a disease in order to help that person to recover or to relieve from symptoms of the disease with a given likelihood and with an efficiency statistically better than a placebo or standard of care.

To study naively an infection like AIDS (Acquired Immunodeficiency Syndrome), we can make such a model in which we consider four population groups: healthy individuals X, infected individuals Y, the healthy carriers Z and finally the sick individuals A. In the diagram below, the arrows between the different states represent possible transitions for a given individual with the corresponding probabilities:

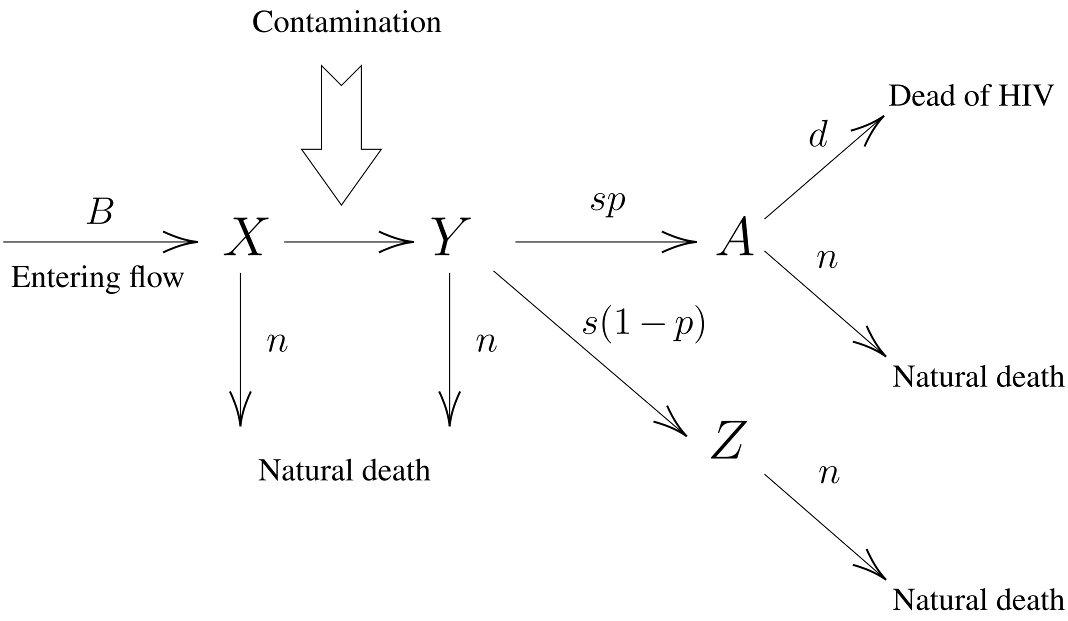


Figure 15.36: **Markov chain of deadly disease**

Indeed, from the perspective of the study of AIDS, a given individual, whatever his condition, may die of something else than AIDS, this is what we put into the category "natural death", We consider that there is a fixed mortality rate, denoted n, for all populations considered (healthy, infected, sick or healthy carriers). On the other hand, a healthy individual X may also be contaminated, in which case it becomes an infected individual Y. An infected individual can change into to two possible stages: sick A or healthy carrier Z.

The number s is the speed of evolution of the disease: bigger is this rate, the more the infected individuals evolve into one of the next stages. The number p, which value is between 0 and 1, represents the probability that this change is done into the direction of the sick state. Of course, if p decreases, the amount of healthy carriers, immunized against the disease increases. The disease is then globally less dangerous. Finally, a patient may die of his disease, with a mortality rate d considered as fixed, while a healthy carrier, immunized, can not change anymore of the point of view of this disease. All these assumptions lead to put a system of equations of the form:

$$\begin{aligned}X' &= B - nX - \lambda_c X\\ Y' &= \lambda_c X - (n+s)Y\\ A' &= spY - (d+n)A\\ Z' &= s(1-p)Y - nZ\end{aligned} \tag{15.1.101}$$

where:

$$\lambda_c = \frac{\beta Y}{X+Y+Z+A} \tag{15.1.102}$$

Remark

The SIR model assumes that once infected people are immune to the disease forever, and so any disease occurs only once and then never comes back. More interesting dynamics occur when we allow for the reinfection of recovered people; we can then ask, for example, under what circumstances the disease becomes established in the population. The SIRS model extends the SIR model, allowing the recovered population to become susceptible again (hence the extra 'S'). It assumes that the susceptible population increases proportional to the recovered population such that:

$$\begin{aligned}\frac{\Delta S}{\Delta t} &= S' = -r\beta IS + \mu R\\ \frac{\Delta R}{\Delta t} &= R' = \gamma I - \mu R\\ \frac{\Delta I}{\Delta t} &= I' = -\frac{\Delta S}{\Delta t} - \frac{\Delta R}{\Delta t} = r\beta IS - \gamma I\end{aligned} \tag{15.1.103}$$

where, since we added μR to the change in the proportion of susceptible people, we had to subtract μR from the change in the proportion of recovered people.

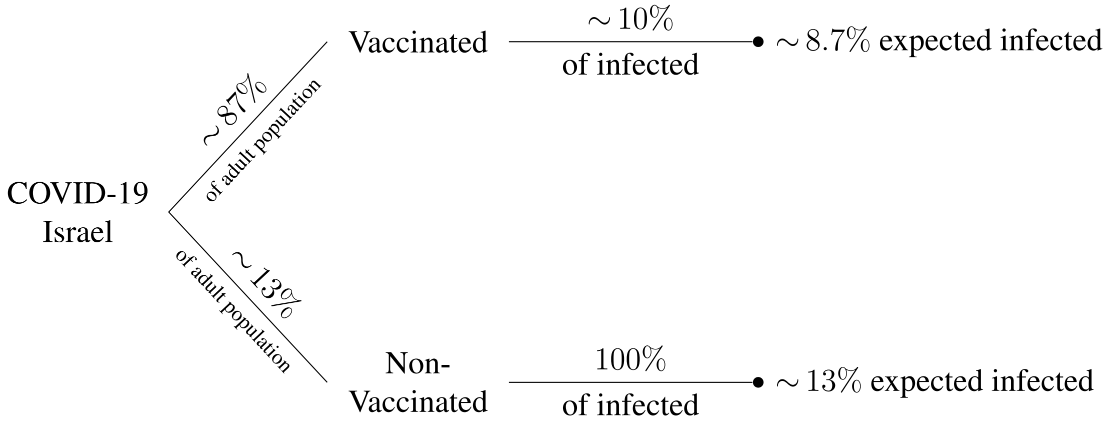
Now let us quote the CNews article from the 12021-06-21 (holocene calendar) about the COVID-19 written by Clémence Barbier (Master in Journalism, Bachelor in History, Catholic and obviously ignorant in basics scientific calculations...) to prove how mass-media articles titles may sometimes be misleading (naive human error[3]? on purpose click-bait title? catholic bigot bias?):

"Despite significant vaccination coverage in Israel, 40% of new infections are from vaccinated people"

It seems that this journalist, above any reasonable doubt, added the word "despite" from the original quote from Gabi Barbash (director general at Tel Aviv Sourasky Medical Center.). This is obviously dumb (as shown in the calculation below) because this is exactly what we expected from a 90% efficient vaccine in the adult Israelite population. Her article was quite massively shared on social networks by scientifically illiterate anti-vax people afterwards (especially by other bigots...).

---

[3] Notice that the day she write that paper this young journalist had only one year of experience and seems to not have followed any training on scientific communication nor be informed about the process of being proofread by an internal scientific consultant at CNews.



$$\frac{8.7}{13+8.7}\cong 40\%$$

So as proven thanks to the decision tree above, 40% is exactly what is expected and is a very good result. So adding the word "despite" was a double mistake!!! Notice that one week after the title of the article still wasn't corrected by the redaction team of CNews...

Notice that a minority of people don't understand - because of a lack of Statistical education or just because of a difficulty to apprehend the concept of proportions - why when a huge majority of people are vaccinated then the majority of people who are sick will be... vaccinated people. For example if you take the extreme case where 100% of the population is vaccinated than obviously you will have at the emergencies 100% of vaccinated people... But in absolute value that will still be less people than if no one was vaccinated.

Let us denote as always the efficiency of a vaccine by it's Odds Ratio O.R. (see section Numerical Methods page 6496). Then $1-\text{O.R.}$ is obviously its ineffectiveness. Denoting by HR the hospitalisation rate of people who catches the illness, P_{V} the population of vaccinated people and P_{NV} the population of non-vaccinated people then the number of hospitalized are respectively for each population:

$$P_{\text{V}}\cdot\text{HR}\cdot(1-\text{O.R.})\qquad\text{and}\qquad P_{\text{NV}}\cdot\text{HR}\tag{15.1.104}$$

Equating to get the threshold of ratio of population at which the number of hospitalized vaccinated people is equal to that of non-vaccinated we get immediately after rearranging:

$$\frac{P_{\text{V}}}{P_{\text{NV}}}=\frac{1}{1-\text{O.R.}}\tag{15.1.105}$$

So for example with a vaccine having an efficiency of $\text{O.R.}=95\%$. We will get the same number of hospitalized vaccinated and non-vaccinated people when the ratio in the whole population is of $1/(1-95\%)=20$ vaccinated for 1 vaccinated. If we want to transform this value into a whole population limit ratio (WPLR) then we just calculate:

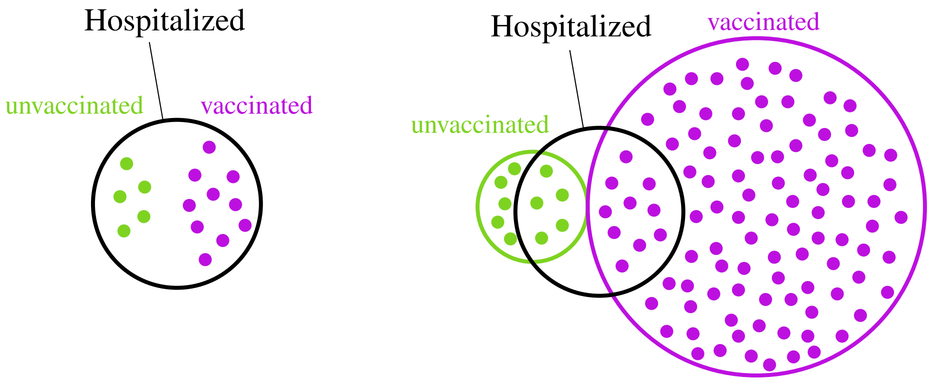
$$\text{WPLR}=\frac{\dfrac{P_{\text{V}}}{P_{\text{NV}}}}{\dfrac{P_{\text{V}}}{P_{\text{NV}}}+1}=\frac{\dfrac{1}{1\text{O.R.}}}{\dfrac{1}{1-\text{O.R.}}+1}=\frac{1}{2-\text{O.R.}} \qquad (15.1.106)$$

Applying this to our example we get:

$$\text{WPLR}=\frac{20}{20+1}=\frac{1}{2-0.95}\cong 95.238\% \qquad (15.1.107)$$

That means we reach an equality of hospitalized vaccinated and non-vaccinated people when 95.238% of the whole population is vaccinated for a vaccine with 95% efficiency.

Such a poor comprehension of proportions by some uneducated people can be well illustrated by the following figure:



Remark

As always, there exist much more elaborated models like for example the SEIR model Susceptible - Exposed - Infectious - Recovered - Susceptible). In this category of models, individuals experience a long incubation duration (the "exposed" category), such that the individual is infected but not yet infectious! There is also SEIRS (Susceptible - Exposed - Infectious - Recovered - Susceptible) model, where recovered people may become susceptible again (recovery does not confer lifelong immunity). But also the SIRD model Susceptible-Infectious-Recovered-Deceased, the SIRV model Susceptible-Infectious-Recovered-Vaccinated model, the MSIR model Measles-Infectious-Recovered, etc. For more see [244].

The CORANA Virus (COVID-19) pandemia which lasts from 12019 to 12022 (holocene calendar) has taught us:

- Prayers doesn't work
- No faith healing works
- There are no miracles
- Religious people rely on Science in critical times

- Jesus, Allah & Hindu gods and others are as real as the Greek gods
- A significant percentage of scientifically illiterate people can't grasp complexity
- Our hope is critical thinking & Science education

15.1.2.6.5 Incidence rate

In epidemiology, "incidence" is a measure of the probability of occurrence of a given medical condition in a population within a specified period of time. Although sometimes loosely expressed and understood - that's why we treat it shortly here - simply as the number of new cases during some time period, it is better expressed as a proportion or a rate with a denominator.

The numerical portion of an incidence rate has a lower bound of zero but has no upper bound; it has the mathematical range for the ratio of two non-negative quantities, in this case the number of events in the numerator and the person-time in the denominator.

At first, it may seem surprising that an incidence rate can exceed the value of 1.0, which would seem to indicate that more than 100% of a population is affected. It is true that at most, only 100% of persons in a population can get a disease, but the incidence rate does not measure the proportion of a population with illness and in fact is not a proportion at all.

Recall that incidence rate is measured in units of the reciprocal of time. Among 100 people, no more than 100 deaths can occur, but those 100 deaths can occur in $10,000$ person-years, in $1,000$ person-years, in 100 person-years, or even in 1 person-year (if the 100 deaths occur after an average of 3.65 days each).

An incidence rate of 100 cases (or deaths) per 1 person-year might be expressed as:

$$100\,[\text{cases}\cdot\text{person-year}^{-1}]$$

It might also be expressed as:

$$10,000\,[\text{cases}\cdot\text{person-century}^{-1}]$$

or ($100/12=8.\bar{3}$):

$$8.\bar{3}\,[\text{cases}\cdot\text{person-month}^{-1}]$$

or ($100/52\cong 1.92$):

$$1.92\,[\text{cases}\cdot\text{person-week}^{-1}]$$

or ($100/365\cong 0.27$):

$$0.27\,[\text{cases}\cdot\text{person-day}^{-1}]$$

The numerical value of an incidence rate in itself has no interpretability because it depends on the arbitrary selection of the time unit! It is thus essential in presenting incidence rates to give the appropriate time units, either as in the examples given above or as in $8.33\,[\text{month}^{-1}]$ or $1.92\,[\text{week}^{-1}]$. Although the measure of time in the denominator of an incidence rate is often taken in terms of years, one can have units of years in the denominator regardless of whether the observations were collected over 1 year of time, over 2 week of time, or over 10 years of time.

Unfortunately, the interpretation of incidence rates as the inverse of the average "waiting time" will usually not be valid unless the incidence rate is calculated for a stationary population with no migration (no immigration or emigration) or a closed population with complete follow-up. For example, the death rate for the United States in 11977 (holocene calendar) was 0.0088 year^{-1}; in a steady state, this rate would correspond to a mean life span, or expectation of life, of 114 years. Other analyses, however, indicate that the actual expectation of life in 11977 (holocene calendar) was 73 years. The discrepancy is due to immigration and to the lack of a steady state. Note that the no-migration assumption cannot hold within specific age groups, for people are always "migrating" in and out of age groups as they age.

Remark

Incidence should not be confused with "prevalence", which is the proportion of cases in the population at a given time rather than rate of occurrence of new cases. Thus, incidence conveys information about the risk of contracting the disease, whereas prevalence indicates how widespread a disease is.

15.1.2.7 Lotka–Volterra predator–prey model

This predator-prey interaction model was proposed by Volterra after the First World War. The purpose was to explain the dynamics of populations of sardines and sharks in the Adriatic (and hop! a bit of Oceanography in this textbook...!). Especially to explain in why the quantities of sardines fished after the interruption due to the war were not as important as before (which may seem counter-intuitive) and why at the resumption of fishing the observed proportion of sharks increased.

Taking again what we saw at the beginning of this section by writing $N(t)$ the number of preys and $P(t)$ the number of predators (that is to say implicitly a growth following a power law of the number of preys, in absence of fishing):

$$\frac{\mathrm{d}N}{\mathrm{d}t}=rN(t)\Rightarrow N(t)=c_1^{te}e^{rt} \tag{15.1.108}$$

and in the absence of preys (in the case of fishing), the number of predators decrease also following a power law, we have respectively:

$$\frac{\mathrm{d}P}{\mathrm{d}t}=-mP(t)\Rightarrow O(t)=c_2^{te}e^{-mt} \tag{15.1.109}$$

At this point of the speech, we must consider two species (preys and predators) that are obviously not isolated but in interaction. To quantify the contribution of the interaction between species, we will consider only predation, by assuming that is value or intensity (of interaction) is a function of the probability of prey-predators to meet together that will be supposed proportional to the product $N \cdot P$ of the percentages of the two populations.

These meetings do not have the same effects on both species. First, of course, each prey eaten by a predator is a net gain for the population of the latter and a net loss for the first. Thus, if the effect of interactions is accepted as being proportional to $N \cdot P$, the signs of the influence of interaction differ for the two species so that our equations with interaction this time become:

$$\boxed{\begin{aligned}\frac{\mathrm{d}N}{\mathrm{d}t}&=rN-cNP\\ \frac{\mathrm{d}P}{\mathrm{d}t}&=-mP+bNP\end{aligned}} \tag{15.1.110}$$

This system of equation is named the "Lotka-Volterra model".

Before going further, let us seek for the values for which the derivatives vanish (which will give us in fact the equilibrium point of the system):

$$\begin{aligned}rN'-cN'P'&=0\\ -mP'+bN'P'&=0\end{aligned} \tag{15.1.111}$$

where N' and P' are the values that cancel the derivatives (not to be confused this time with the notation sometimes used to condense the writing of a derivative !!!).

Thus:

$$\begin{aligned}(r-cP')N'&=0\\ (bN'-m)P'&=0\end{aligned} \tag{15.1.112}$$

A trivial solution is the "extinction solution" (also sometimes named "critical solution") given by:

$$N'_e = P'_e = 0 \tag{15.1.113}$$

Otherwise, we also have as a possible solution:

$$\begin{aligned} r = CP' \rightarrow P' = \frac{r}{c} \\ bN' = m \rightarrow N' = \frac{m}{b} \end{aligned} \tag{15.1.114}$$

Now we normalize these equations by writing (so they are dimensionless):

$$\begin{aligned} x = \frac{N}{N'} = \frac{b}{m}\frac{1}{N'} := \frac{b}{m}N \rightarrow N = \frac{m}{b}x \\ y = \frac{P}{P'} = \frac{c}{r}\frac{1}{P'} := \frac{c}{r}P \rightarrow P = \frac{r}{c}y \end{aligned} \tag{15.1.115}$$

with this normalization, the model can be rewritten:

$$\begin{aligned} \frac{m}{b}\frac{\mathrm{d}x}{\mathrm{d}t} = \frac{mr}{b}x - \frac{cmr}{xy} \\ \frac{r}{c}\frac{\mathrm{d}y}{\mathrm{d}t} = \frac{bmr}{bc}xy - \frac{mr}{c}y \end{aligned} \tag{15.1.116}$$

By rearranging the coefficients, the system can finally be written (excluding the solution of inexistence, i.e. non-existence):

$$\begin{aligned} \frac{\mathrm{d}x}{\mathrm{d}t} = rx(1-y) \\ \frac{\mathrm{d}y}{\mathrm{d}t} = my(x-1) \end{aligned} \tag{15.1.117}$$

for which derivatives vanish at the point $(1,1)$.

The discreet plot of this system of equations (in which we recognize a logistic term as seen in the section of Populations Dynamics) gives us with $m = r = b = c = 1$ and initial conditions $(x_0, y_0) = (4, 1)$:

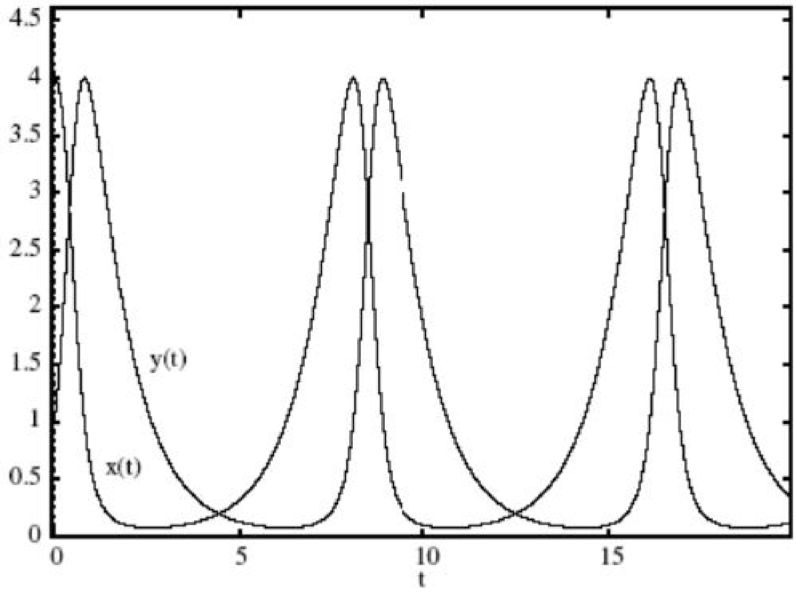


Figure 15.37: Theoretical fluctuation of population

In comparison here is a practical (real) example of prey-predators measurements (Hares-Lynx) by the Hudson Bay-Company (when we seek for data corresponding to a model we will finish soon or late to find data fitting the model...):

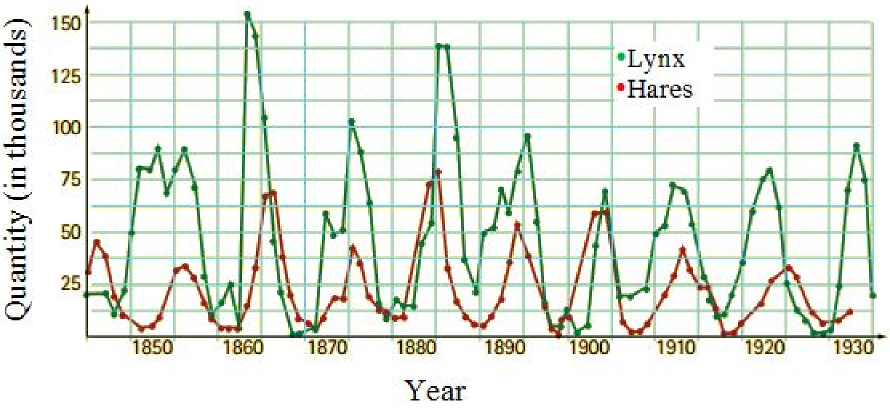

Figure 15.38: Hudson Bay-Company real Lotka-Volterra measurements

The two previous figures represent the variables x and y as a function of time. However, what can be interesting for a scientist (or an economist) is the representation of y in terms of x and vice versa. Thus, we obtain for the same initial conditions m, r, b, c and for the various initial values of (x_0, y_0) (the Predators is in ordinate and the Preys on the abscissa):

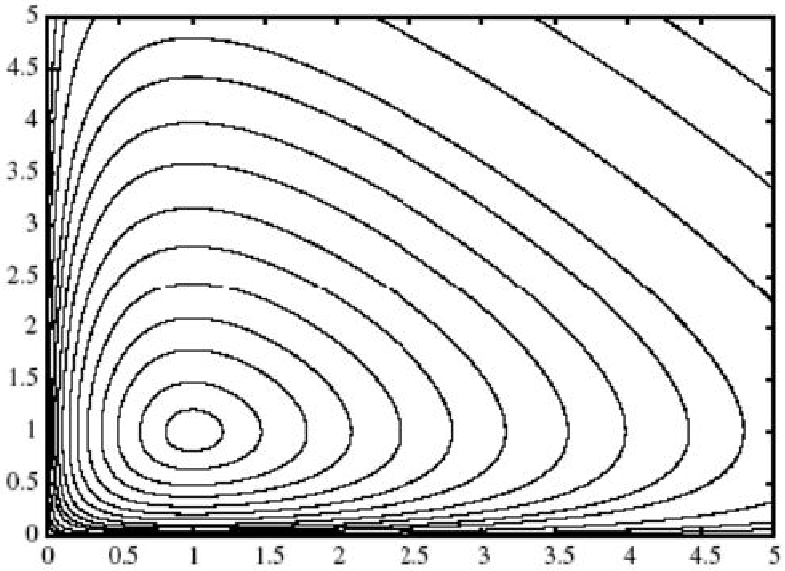

Figure 15.39: **Representation in phase space of the prey/predator cycle**

The above figure is very interesting to interpret when you follow a path in the counter-clockwise direction.

Thus we see (in the phase space representation) that for fixed initial conditions, the system is periodic and has trivially an equilibrium point at:

$$(x,y)=(1,1) \tag{15.1.118}$$

named "fixed points" that correspond to the points where:

$$\frac{\mathrm{d}x}{\mathrm{d}t}=\frac{\mathrm{d}y}{\mathrm{d}t}=0 \tag{15.1.119}$$

Finally, we have two pairs of equilibrium points (that is almost trivial, looking at the system of equations):

$$(x_1^e,y_1^e)=(0,0) \qquad (x_2^e,y_2^e)=(1,1) \tag{15.1.120}$$

The question that will naturally arise is the "real" direction of rotation (representation) of the phase plane. Thus, representing the directions using a vector field, we get the representation which is effectively counter-clockwise (more interesting representation to understand what happened after 1st World War):

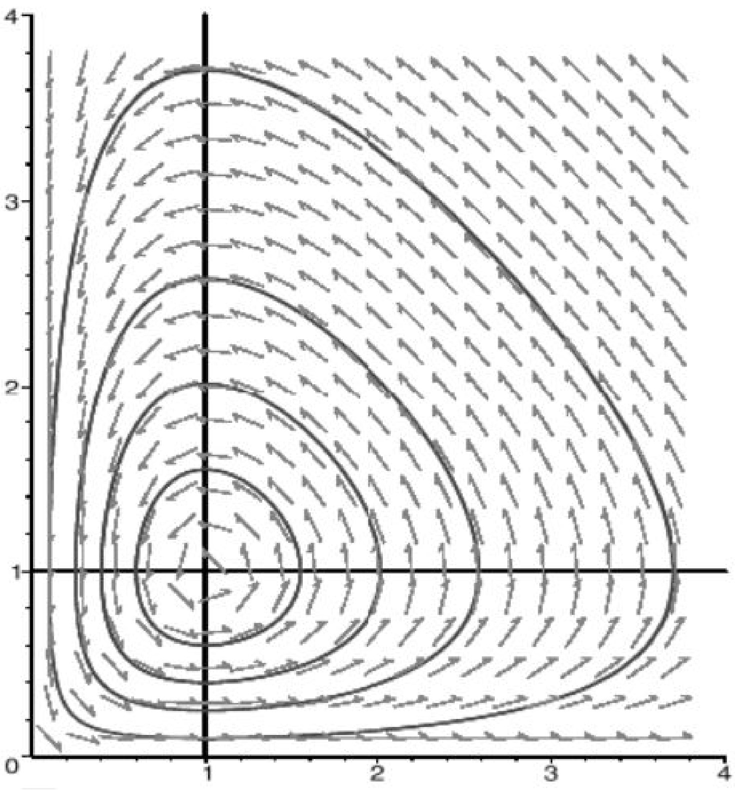

Figure 15.40: Rotation direction offer/demand phase space

To know in which direction we are going in the phase space at a given time, it suffices to know the derivative $\mathrm{d}y/\mathrm{d}x$ (or vice versa $\mathrm{d}x/\mathrm{d}y$). Therefore we have:

$$\frac{\mathrm{d}y}{\mathrm{d}x}=\frac{\mathrm{d}y}{\mathrm{d}t}\frac{\mathrm{d}t}{\mathrm{d}x}=\frac{\mathrm{d}y}{\mathrm{d}t}\left(\frac{\mathrm{d}x}{\mathrm{d}t}\right)^{-1}=\frac{my(x-1)}{rx(1-y)} \tag{15.1.121}$$

That said, we see well on the phase diagram with vector field that it comes a time in the cycle of this model where the offer is very high for low demand. So the mathematical model (theoretical) clearly explains what can be a priori counter-intuitive to many humans (offer creates the demands).

However, we can (must) ask ourselves the question of what happens after a small perturbation around the equilibrium point.

So we have the following Lotka-Volterra system in equilibrium:

$$\begin{aligned}\frac{\mathrm{d}x}{\mathrm{d}t}&=rx(1-y)\\ \frac{\mathrm{d}y}{\mathrm{d}t}&=my(x-1)\end{aligned} \tag{15.1.122}$$

By putting an infinitely small perturbation, it is will be written:

$$\begin{aligned}\frac{\mathrm{d}x}{\mathrm{d}t}&=r(x+x^*)(1-(y+y^*))\\ \frac{\mathrm{d}y}{\mathrm{d}t}&=m(y+y^*)((x+x^*)-1)\end{aligned} \tag{15.1.123}$$

Neglecting the quadratic xy terms, we obtain:

$$\begin{aligned}\frac{\mathrm{d}x}{\mathrm{d}t} &\cong r\left[(1-y^*)x+(1-y-y^*)x^*\right]\\ \frac{\mathrm{d}y}{\mathrm{d}t} &\cong -m\left[(1-x^*)y+(1-x-x^*)y^*\right]\end{aligned} \tag{15.1.124}$$

1. We focus first on the study near the point of extinction $(0,0)$, this is why we can neglect the quadratic terms xy but the expression remain too complicated. So, always considering we are near the point of extinction $(0,0)$, we consider a bit unfairly but cleverly (otherwise we still could not solve the problem analytically) the following approximations:

$$\begin{aligned}\frac{\mathrm{d}x}{\mathrm{d}t} &\cong r\left[x-\underbrace{y^*x}_{=0}+x^*-\underbrace{yx^*}_{=0}-\underbrace{y^*x^*}_{=0}\right]\underset{x\gg x^*}{\cong} r(x+x^*)\cong rx\\ \frac{\mathrm{d}y}{\mathrm{d}t} &\cong -m\left[y-\underbrace{x^*y}_{=0}+y^*-\underbrace{xy^*}_{=0}-\underbrace{x^*y^*}_{=0}\right]\cong -m(y+y^*)\underset{y\gg y^*}{\cong} -my\end{aligned} \tag{15.1.125}$$

Therefore:

$$\begin{aligned}\frac{\mathrm{d}x}{\mathrm{d}t} &\cong rx=rx(t)\\ \frac{\mathrm{d}y}{\mathrm{d}t} &\cong -my=-my(t)\end{aligned} \tag{15.1.126}$$

This shows us for the system in equilibrium, close to the inexistence point, the prays decreases exponentially (power law) as predators increases exponentially:

$$\begin{aligned}x(t)&=c_1^{te}e^{rt}\\ y(t)&=c_2^{te}e^{-mt}\end{aligned} \tag{15.1.127}$$

This shows us for the equilibrium system, near the extinction point, that the number of individuals predators decreases exponentially while the prey are increasing exponentially. This has a biological sense: when there are few individuals predators, then prey multiply and at the same time the number of prey increases, predators multiply and concentrate increasingly on their prey; respectively when there are few prey only, the number of predator decreases as the number of prey increases (ahhh nature...).

Remark

In the literature we find sometimes the "-" sign in the top or bottom in the previous equations. In reality, the position of the "-" sign is not important because it is just the starting choice in the system dynamics.

2. Close to the equilibrium point $(1,1)$ we start from:

$$\begin{aligned}\frac{\mathrm{d}x}{\mathrm{d}t}&=rx(1-y)\\ \frac{\mathrm{d}y}{\mathrm{d}t}&=my(x-1)\end{aligned} \quad (15.1.128)$$

And we put $x:=1+x, y:=1+y$ where x, y are now small perturbations near the point $(1,1)$. Therefore we have:

$$\begin{aligned}\frac{\mathrm{d}x}{\mathrm{d}t}&=r(1+x)(1-(1+y))=r(1+x)y\cong ry\\ \frac{\mathrm{d}y}{\mathrm{d}t}&=m(1+y)((x+1)-1)=m(1+y)x\cong mx\end{aligned} \quad (15.1.129)$$

Now we change the position of the "-" sign on purpose to show that this is only a starting choice:

$$\begin{aligned}\frac{\mathrm{d}x}{\mathrm{d}t}&\cong -ry\\ \frac{\mathrm{d}y}{\mathrm{d}t}&\cong mx\end{aligned} \quad (15.1.130)$$

To solve this system, let us differentiate the first equation once again:

$$\frac{\mathrm{d}^2x}{\mathrm{d}t^2}\cong -r\frac{\mathrm{d}y}{\mathrm{d}t} \quad (15.1.131)$$

and by injecting in it $\mathrm{d}y/\mathrm{d}t$:

$$\frac{\mathrm{d}^2x}{\mathrm{d}t^2}\cong -rmx \quad (15.1.132)$$

So we get a small second order differential equation (see section Differential and Integral Calculus page 1610). Whose typical simple solution is:

$$x=x_0e^{-\lambda t} \quad (15.1.133)$$

By injecting this solution into the differential equation, we obtain after simplification of exponentials a simple polynomial of the second degree (see section Calculus page 1368):

$$\lambda^2x_0+rmx_0=0 \quad (15.1.134)$$

Whose solution is trivial:

$$\lambda_{1,2}=\pm\mathrm{i}\sqrt{rm} \quad (15.1.135)$$

Thus, the general solution of the differential equation is the linear combination of the two special solutions we get:

$$x_(t)=x_0\left(e^{+\mathrm{i}\sqrt{rm}}+e^{-\mathrm{i}\sqrt{rm}}\right) \quad (15.1.136)$$

But we therefore have:

$$\frac{\mathrm{d}x}{\mathrm{d}t}\cong -ry \Leftrightarrow y(t)=-\frac{1}{r}\frac{\mathrm{d}x}{\mathrm{d}t} \tag{15.1.137}$$

Therefore, knowing $x(t)$ we obtain easily:

$$x(t)=-x_0\sqrt{\frac{m}{r}}\left(\mathrm{i}e^{+\mathrm{i}\sqrt{rm}}-\mathrm{i}e^{-\mathrm{i}\sqrt{rm}}\right) \tag{15.1.138}$$

Now let us use the Euler formula (see section Numbers page 251):

$$e^{\mathrm{i}x}=\cos(x)+\mathrm{i}\sin(x) \tag{15.1.139}$$

Thus we have:

$$x(t)=x_0\left[\cos\left(-\sqrt{rm}t\right)+\mathrm{i}\sin\left(-\sqrt{rm}t\right)+\cos\left(\sqrt{rm}t\right)+\mathrm{i}\sin\left(\sqrt{rm}t\right)\right] \tag{15.1.140}$$

and as (see section Trigonometry page 2514) $\cos(x)=\cos(-x), -\sin(x)=\sin(-x)$ then we have:

$$x(t)=2x_0\cos(\sqrt{rm}t) \tag{15.1.141}$$

and similarly, we obtain:

$$\begin{aligned}y(t)&=-x_0\sqrt{\frac{m}{r}}\mathrm{i}\left[-\left(\cos\left(-\sqrt{rm}t\right)+\mathrm{i}\sin\left(-\sqrt{rm}t\right)\right)+\cos\left(\sqrt{rm}t\right)+\mathrm{i}\sin\left(\sqrt{rm}t\right)\right]\\&=-x_0\sqrt{\frac{m}{r}}\mathrm{i}\left[-\left(\cos\left(\sqrt{rm}t\right)-\mathrm{i}\sin\left(\sqrt{rm}t\right)\right)+\cos\left(\sqrt{rm}t\right)+\mathrm{i}\sin\left(\sqrt{rm}t\right)\right]\\&=-x_0\sqrt{\frac{m}{r}}\mathrm{i}\left[-\cos\left(\sqrt{rm}t\right)+\mathrm{i}\sin\left(\sqrt{rm}t\right)+\cos\left(\sqrt{rm}t\right)+\mathrm{i}\sin\left(\sqrt{rm}t\right)\right]\\&=-x_0\sqrt{\frac{m}{r}}\mathrm{i}2\mathrm{i}\sin\left(\sqrt{rm}t\right)=2x_0\sqrt{\frac{m}{r}}\sin\left(\sqrt{rm}t\right)\end{aligned} \tag{15.1.142}$$

Thus, around the equilibrium point $(1,1)$ with sufficiently small perturbations to validate linearisation the system oscillate as ellipses (or circles) whose axes are defined by the two equations above.

We can get the graphs above with Maple™ 4.00b (this is a nice example of application of this software):

```

15.1.3 Schaefer's optimal capture model

A useful principle for the management of fishing, hunting, wild collection quotas or exploitation of raw materials is the "maximum sustainable yield" which is directly linked to the good management of the exploited dynamics of the concerned population.

Definition (#15.1.631): The "maximum sustainable yield" is the maximum amount of fish, deer, birds or fungi, etc. which can be killed / harvested in a population without jeopardizing its survival.

Determine this maximum sustainable yield give the possibility the get to the goal of fishing, hunting, gathering as much as possible, without falling into the overconsumption that potentially lead to the disappearance of the population.

The distinction between a balanced consumption of natural resources and an exaggerated one is often hard to do. Mathematical and statistical models are then always useful and necessary to establish that frontier.

The calculations are involved in the determination of quotas even still in the early 121st century (holocene calendar). The simplistic model that we will present is used by some large States (but it will in time disappear to make way for a more sophisticated model with probabilistic parameters).

We are therefore interested in the biomass of a population of a consumable. The model put forward by Schaefer in 11954 (holocene calendar) involves only two parameters:

1. The maximum biomass M that can live constantly in a system
2. The reproduction rate r

We start from the assumption (to check in practice because of the Lotka-Volterra model) that at the year zero (before to the consumption of the resource), the corresponding biomass is:

$$X_0 = M \tag{15.1.143}$$

The empirical model is:

$$\boxed{X_{n+1} = X_n + rX_n\left(1-\frac{X_n}{M}\right) - C} \tag{15.1.144}$$

To understand this model, let assume first that the population is not exploited, that is to say that $C = 0$. At the year n, the population then increases of:

$$r\left(1-\frac{X_n}{M}\right) \tag{15.1.145}$$

Thus, in the absence of fishing, if X_0 is smaller than M, the population will grow slowly until it reaches its maximum capacity M.

In the extreme case, where consumption C is equal to M, we have:

$$X_{0+1}=X_{+}rX_0\left(1-\frac{X_0}{M}\right)-C=M+rM\left(1-\frac{M}{M}\right)=M+0-M=0 \tag{15.1.146}$$

which makes sense ... (there is a total extinction!).

Now rewrite the Schaefer model as follows:

$$X_{n+1}-X_n=\Delta X=rX_n\left(1-\frac{X_n}{M}\right)-C \tag{15.1.147}$$

We would like to know for what value of X_n, we would have the biomass which no longer varies. That is to say:

$$\Delta X=rX_n\left(1-\frac{X_n}{M}\right)-C=0 \tag{15.1.148}$$

Therefore:

$$rX_n-r\frac{X_n^2}{M}-C=\frac{r}{M}X_n^2-rX_n+C=0 \tag{15.1.149}$$

So it is a simple equation of the second degree! It has a real solution only if the discriminant (see section Calculus page 1383) is positive or zero. Therefore, knowing that r is positive or zero by construction:

$$r^2-4\frac{r}{M}C\geq 0\Leftrightarrow r\left(r-\frac{4C}{M}\right)\geq 0\Leftrightarrow r-\frac{4C}{M}\geq 0\Leftrightarrow C\leq\frac{rM}{4} \tag{15.1.150}$$

Thus, the maximum possible value of C is $rM/4$. When we replace C by this value in the original equation:

$$\frac{r}{M}X_n^2-rX_n+C=0 \tag{15.1.151}$$

we get:

$$\frac{r}{M}X_n^2-rX_n+\frac{rM}{4}=0 \tag{15.1.152}$$

Hence:

$$\begin{aligned}&\frac{r}{M}\left(X_n^2-MX_n+\frac{M^2}{4}\right)=0\\&X_n^2-MX_n+\frac{M^2}{4}=0\\&\left(X_n-\frac{M}{2}\right)^2=0\end{aligned} \tag{15.1.153}$$

Therefore the solution is:

$$X_n=\frac{M}{2} \tag{15.1.154}$$

Thus, there exists a time n (infinite) for which the population tends asymptotically to $M/2$ at the condition that $X_0\geq\dfrac{M}{2}$.

Still its simplicity and its deterministic aspect the Schaefer model is still used in the early 121st century (holocene calendar) in fisheries management.

15.1.4 Hardy-Weinberg model

The Hardy-Weinberg model (developed in 11908 according to holocene calendar) describes the diversity (rather than evolution) of living in the point of view of population genetics. However, this model still allows to understand the impact of a mutation agent on a population of individuals and therefore to solve problems related to the refusal of the Natural selection model (evolution) of Darwin. Indeed, Darwin's work focused on characters that varied continuously. But he could not explain how individuals transmit these changes (this is actually quite annoying). The Mendel's genetics, meanwhile imposed that only discontinuous traits were hereditary.

So there was a conflict between the continuous model (Darwin) and the discontinuous one (Mendel) and it was genetics that in the 120th century (holocene calendar) helped to establish that fact that it is the mix of genes that creates diversity and verbatim natural selection.

Remark

We will prove in the section of Numerical Methods (see page 7022) as part of the study of Genetic Algorithms that the chromosome having the biggest function value of "fitness" will be the one most likely to reproduce! This is part of the theorem named the "Schema Theorem" ...

Conclusion: The evolution is not made at the level of the individual but of the population (this is a quite good lesson to remember...).

Definitions (#15.1.632):

D1. A gene or "genotype" is composed of "alleles" (usually 2, so we will consider individuals as being "*diploid*")

So the genotype is the genetic makeup of an organism. It's basically which alleles an organism has for a specific gene or trait. This is what causes genetic variations.

D2. A "gene pool" is a set of genes present in a population.

D3. A "micro-evolution" is a change in the frequency of alleles of a gene pool of a population.

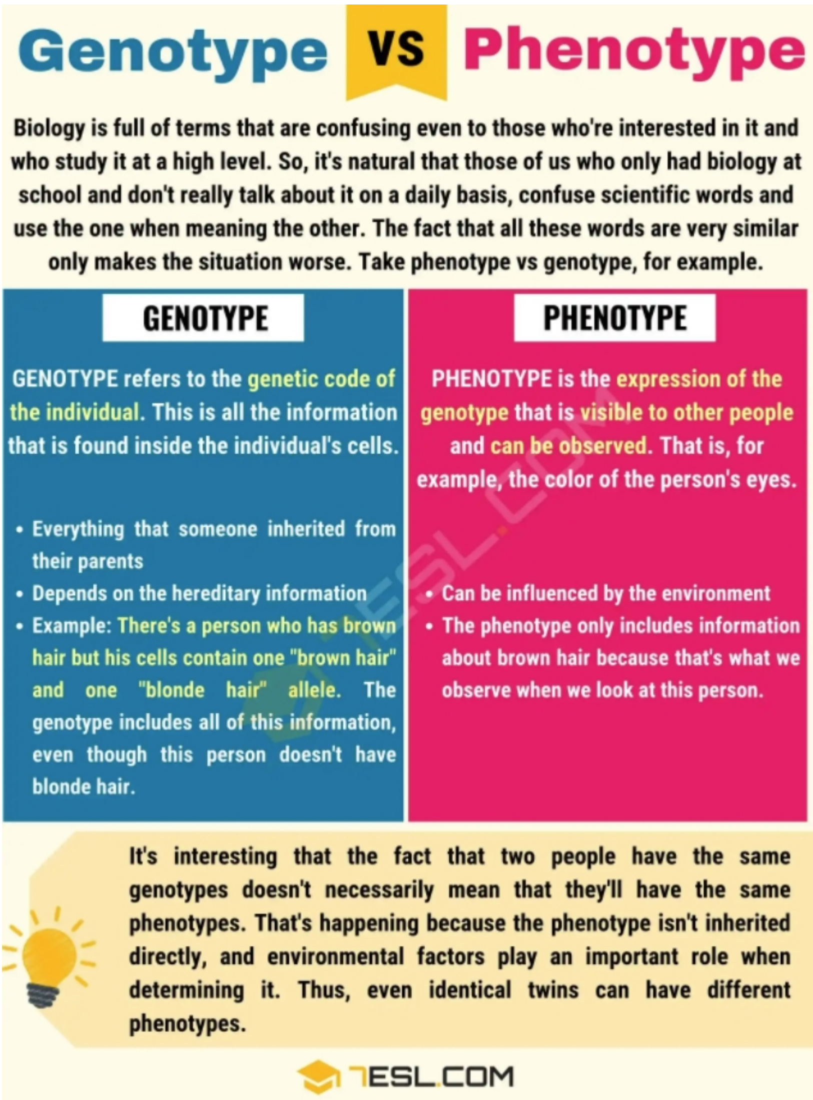
D4. An allele is named "fixed allele" when all members of a population have two identical alleles.

D5. A "speciation" is a long-term occurrence of a micro-evolution, making appear a new species.

D6. The "mutation" is an evolutionary agent that alters the gene pool of a population by producing new genes (we therefore consider that there is no evolutionary agents at work in the population in this model).

Remark

Mutation is a rare event and usually harmful. Its quantitative effects are greater in short generation time organisms (bacteria and viruses), the effect is much less pronounced among organisms with long generation time (animals and plants).



Genotype VS Phenotype

Biology is full of terms that are confusing even to those who're interested in it and who study it at a high level. So, it's natural that those of us who only had biology at school and don't really talk about it on a daily basis, confuse scientific words and use the one when meaning the other. The fact that all these words are very similar only makes the situation worse. Take phenotype vs genotype, for example.

GENOTYPE	PHENOTYPE
GENOTYPE refers to the genetic code of the individual. This is all the information that is found inside the individual's cells.	PHENOTYPE is the expression of the genotype that is visible to other people and can be observed. That is, for example, the color of the person's eyes.
• Everything that someone inherited from their parents • Depends on the hereditary information • Example: There's a person who has brown hair but his cells contain one "brown hair" and one "blonde hair" allele. The genotype includes all of this information, even though this person doesn't have blonde hair.	• Can be influenced by the environment • The phenotype only includes information about brown hair because that's what we observe when we look at this person.

It's interesting that the fact that two people have the same genotypes doesn't necessarily mean that they'll have the same phenotypes. That's happening because the phenotype isn't inherited directly, and environmental factors play an important role when determining it. Thus, even identical twins can have different phenotypes.

7ESL.COM

Figure 15.43: **Genotype vs Phenotype (source: TESL.com)**

Let us now consider a population consisting of 13 individuals (1 gene, each consisting of two alleles selected among 3):

$$P=\left\{\begin{matrix}\text{X1X1,X2X1,X3X2,X1X1,X1X1,X1X1,X2X3,}\\\text{X1X3,X3X2,X1X1,X1X3,X3X3,X3X3}\end{matrix}\right\}$$

Therefore we have the following relative allele frequencies:

$$p_{X1}=\frac{13}{26}=0.5 \qquad p_{X2}=\frac{4}{26}=0.154 \qquad p_{X3}=\frac{9}{26}=0.346 \tag{15.1.155}$$

with obviously:

$$p_{X1}+p_{X2}+p_{X3}=1 \tag{15.1.156}$$

And the following relative genotype frequencies:

$$p_{X1X1}=\frac{5}{13}=0.384 \quad p_{X2X1}=\frac{1}{13}=0.077 \quad p_{X3X2}=\frac{3}{13}=0.231 \quad p_{X1X3}=\frac{2}{13}=0.154 \quad p_{X3X3}=\frac{2}{13} \tag{15.1.157}$$

with obviously:

$$p_{X1X1}+p_{X2X1}+p_{X3X2}+p_{X1X3}+p_{X3X3}=1 \tag{15.1.158}$$

To summarize, if we now consider a population of individuals possessing genes made of only two types of alleles, we have therefore (more concrete case relatively to the actual living biology on Earth):

$$BB, Bb, bb \tag{15.1.159}$$

So we have for the relative frequency of the number of alleles B:

$$p=\frac{2(\text{number of individuals } BB)+1(\text{number of individuals } Bb)}{\text{total number of individuals}}=\frac{3}{6} \tag{15.1.160}$$

and for the relative frequency of allele b:

$$q=\frac{2(\text{number of individuals } bb)+1(\text{number of individuals } Bb)}{\text{total number of individuals}}=\frac{3}{6} \tag{15.1.161}$$

With obviously:

$$p+q=1 \tag{15.1.162}$$

This can be illustrated (by changing the letter B by Y and b by y):

Figure 15.44: **Monohybrid cross**

We can see in the figure above that the allele relative frequencies are $50\%/50\%$, the genotype relative frequencies are $25\%, 50\%, 25\%$ (also often denoted $1:2:1$) and the phenotype relative frequency $66.\bar{6}\%, 33.\bar{3}\%$ (also often denoted $3:1$).

We can make a few observations about the way of constructing this model. Indeed, the frequency of alleles (genetic equilibrium) remains in a population approximately constant generation after generation if:

1. The population is very large (a tiny disturbance changes only a little bit the frequency of the types of genotypes).
2. No emigration or immigration (no new types of alleles in the population).
3. No mutations altering the alleles (this contains the point number 2).
4. Random couplings (not influenced by the type of allele studied).
5. No natural selection (this contains the point number 4).

It may be relevant (for general knowledge) to highlight the fact that we distinguish two types of non-random accouplement:

1. Inbreeding: crossing between individuals of the neighbourhood, thus having family links; in species dispersing only a little bit. This apply especially to vegetables.
2. Homogamy: free choose of partners who have some similarities for given physical characters. This apply especially among animals.

The inbreeding and homogamy accouplement is not a direct cause of micro-evolution since they do not alter the gene pool of a population. However, if some individuals coming from this non-random accouplement are more likely to have accouplement with others (natural selection), it will follow a change in the allele frequency in the downward population and therefore a micro-evolution. As a result, non-random accouplement are a potential factor of micro-evolution.

Finally, to return to our model, the probability that an individual has one of three possible genotypes (relatively to a genotype) in the population (relative to our example) is:

1. Probability that an individual is BB:

$$BB = pp = p^2 \tag{15.1.163}$$

2. Probability that an individual is bb:

$$bb = qq = q^2 \tag{15.1.164}$$

3. Probability that an individual is Bb or bB:

$$P(bB, Bb) = P(bB \vee Bb) = pq + qp = 2pq \tag{15.1.165}$$

Finally, we get the "Hardy-Weinberg equation" (for the special case of two alleles):

$$\boxed{p^2+2pq+q^2=(p+q)^2=1} \tag{15.1.166}$$

That we can represent the graph:

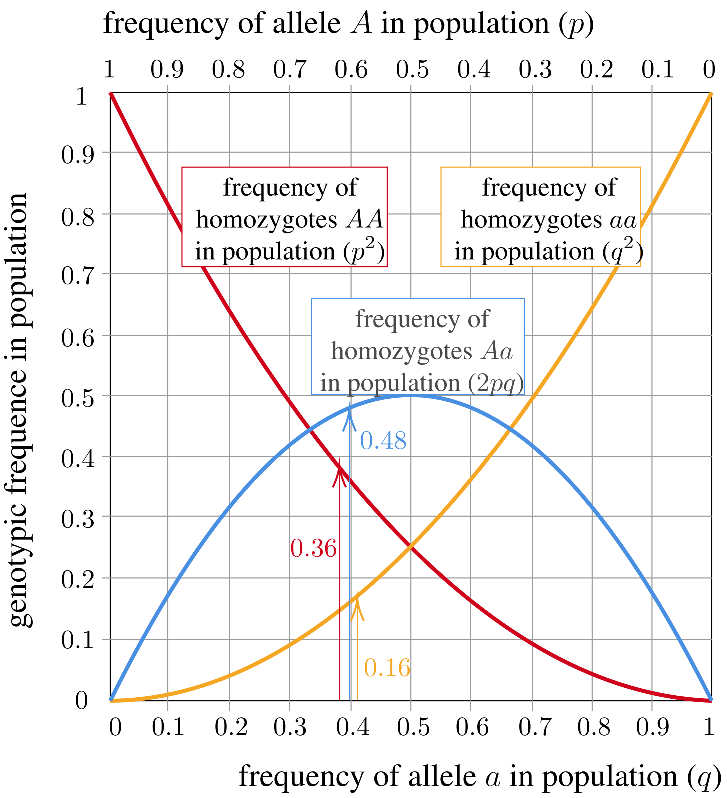

Figure 15.45: **Plot of the Hardy-Weinberg equation (author: Antonín Šípek)**

A population that is not changing genetically is in Hardy-Weinberg equilibrium if these five assumptions are correct:

- Random mating (panmixia)
- Large population size (N approaching infinity)
- No migration between populations
- No (or negligible) mutations
- Natural selection does not affect alleles being considered

If these assumptions are true, it follows that:

- Allele frequencies remain constant from one generation to the next
- After one (or more) generations of random mating (breeding), the genotype frequencies (for a 2-allele gene with allele frequencies p,q) are in the proportions: $p^2_{(AA)}:2pq_{(Aa)}:q^2_{(aa)}$, and population will be in H-W equilibrium.

- For a population to be in Hardy Weinberg equilibrium, the observed genotype frequencies must match those predicted by the equation $p^2+2pq+q^2$.

The Hardy–Weinberg principle may also be generalized to polyploid[4] systems, that is, for organisms that have more than two copies of each chromosome. Consider again only two alleles. Multinomial expansion for two alleles A and a with frequencies p and $qp^2+2pq+q^2$ is a binomial expansion of $(p+q)^2$. That is:

$$p^2_{(AA)}+2pq_{(Aa)}+q^2_{(aa)}=(p+q)^2=(1)^2=1 \quad (15.1.167)$$

For three alleles A, B and C with frequencies p, q and r, the multinomial expansion is $(p+q+r)^2$ which expands into:

$$p^2+q^2+r^2+2pq+2pr+2qr \quad (15.1.168)$$

where the first three terms being homozygotes and the remaining three heterozygotes. Therefore the three alleles Hardy-Weinberg equation is given by:

$$p+q+r=p^2+q^2+r^2+2pq+2pr+2qr=1 \quad (15.1.169)$$

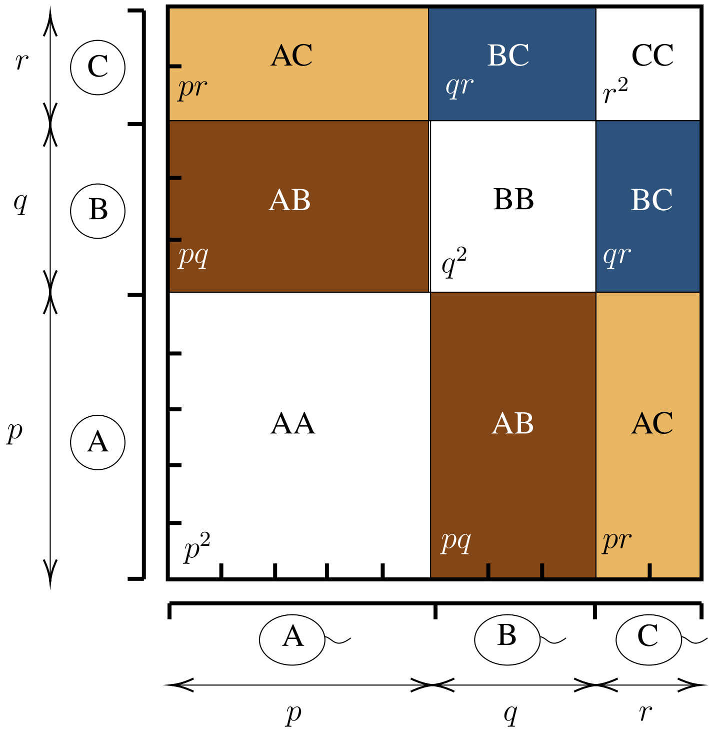

Figure 15.46: **Punnett square for three-allele case (source: Wikipedia)**

therefore the polyploid case is the polynomial expansion of $(p+q)^c$, where c is the ploidy, for example with tetraploid $(c=4)$:

---

[4] Humans are named "diploid organisms" because they have two alleles at each genetic locus, with one allele inherited from each parent.

Genotype	Frequency
$AAAA$	p^4
$AAAa$	$4p^3q$
$AAaa$	$6p^2q^2$
$Aaaa$	$4pq^3$
$aaaa$	q^4

For n distinct alleles in c-ploids, the genotype frequencies in the Hardy-Weinberg equilibrium are given by individual terms in the multinomial expansion of $(p_1+\cdots+p_n)^c$:

$$(p_1+\cdots+p_n)^c=\sum_{k_1,\ldots,k_n\in\mathbb{N}:k_1+\cdots+k_n=c}\binom{c}{k_1,\ldots,k_n}p_1^{k_1}\cdots p_n^{k_n} \tag{15.1.170}$$

After this study, we can finally (re)defined the "Darwin's law" so it gives us the possibility to eliminate the problem of the big question (problem) of continuous or discrete changes:

Definition (#15.1.633): "Natural selection" is an evolutionary agent that alters the gene pool of a population by increasing the frequency of alleles producing "phenotypes" (genotypes defines the behaviour of an individual) best suited to the medium (environment). Thus, the individuals that are the best adapted to their environment reproduce more than others and contribute more to the genetic heritage of the descendants. The frequency of good genes gradually increases in the population from generation to generation. Thus, natural selection directs the adaptation of a population to its environment by accumulating genotypes that promote survival in the medium (environment). For the definition of (biological) Evolution the reader can go see the page 459.

Figure 15.47: **Evidence of the smooth evolution of hominini crane through six to seven million years (author: Erika/Gutsick Gibbon)**

A study [406] provides some evidence that average mutation rate can be estimated to approximately 175 mutations per diploid genome per generation ($\sim 2.5\cdot 10^{-8}$ per base per generation).

The highest per base pair per generation mutation rates are found in viruses [157], which can have either RNA or DNA genomes. DNA viruses have mutation rates between 10^{-6} to 10^{-8} mutations per base per generation, and RNA viruses (whose genomes contain ca. 10^4 bases) have mutation rates between 10^{-3} to 10^{-5} per base per generation.

The high-resolution figure below (you can deeply zoom in for the details!) represents a robust evolutionary timescale for all approximately 6,000 living species of mammals [550] in the shape of a circular phylogenetic tree:

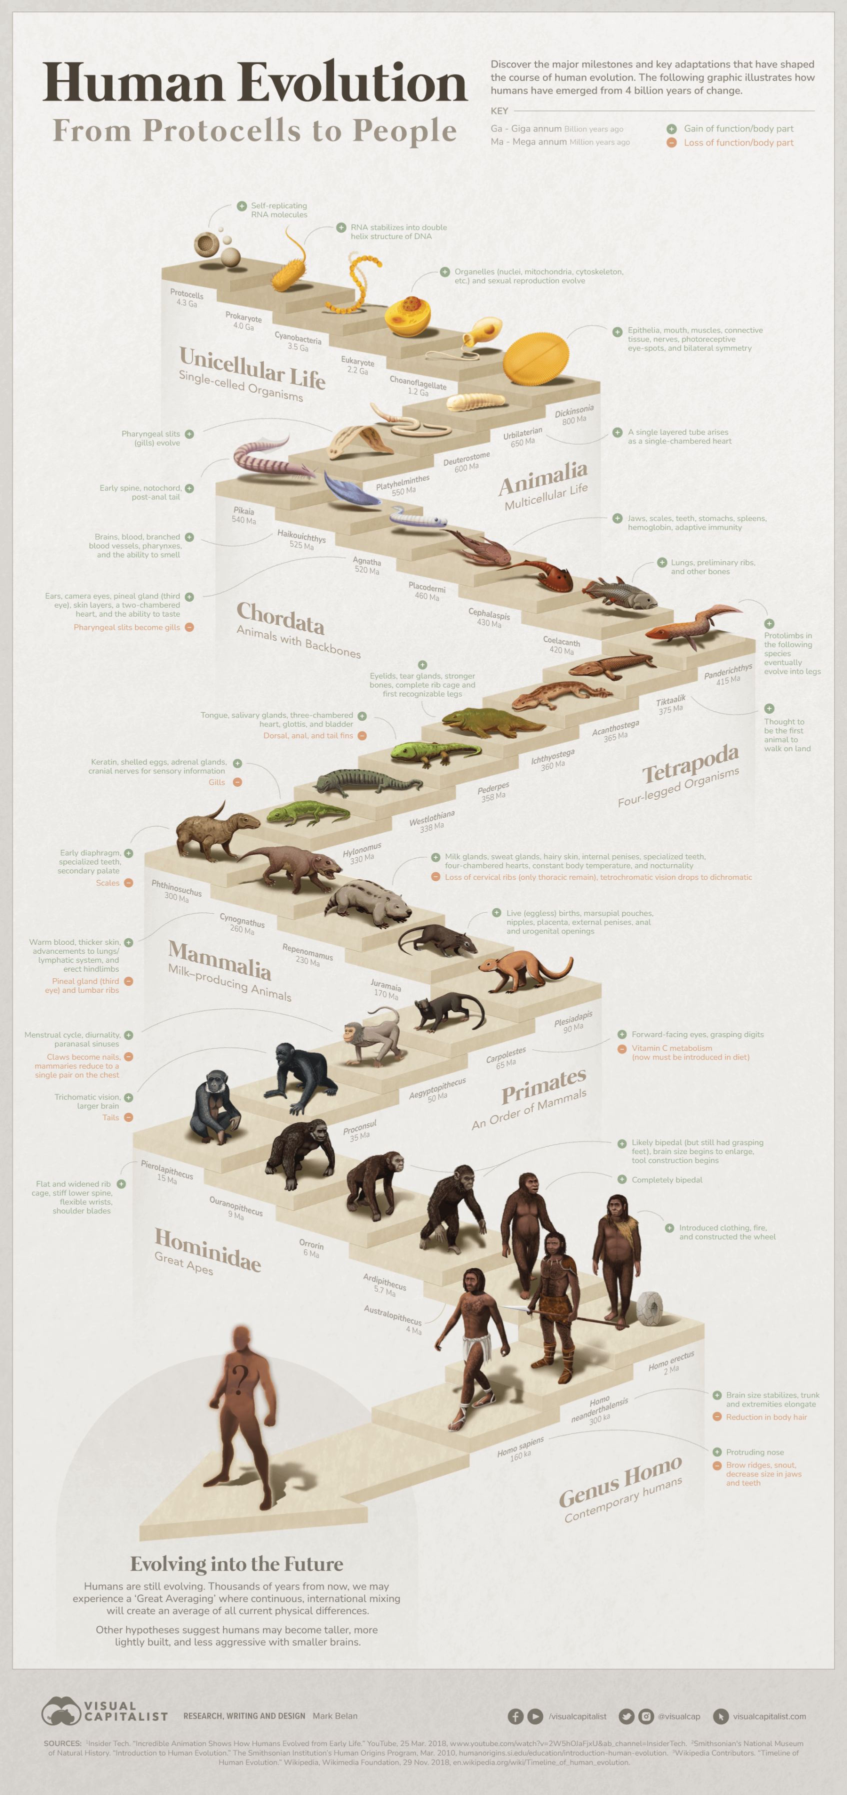
Figure 15.48: Species-level relationships and tempo of diversification across mammals (philogenetic tree)

In a philogenetic tree we have abductive evidence that from the egg and the chicken (i.e. Gallus gallus deomesticus) the egg existed first as the chicken is a descendant of the Gallus gallus (5 millions years ago) that already made eggs and itself is also a descendant of the Basai Phasianid (30 millions years ago) that also already made eggs before, etc.

And here is a quite common linear perspective (therefore wrong for pedagogical reasons) of Human Evolution:



Human Evolution

From Protocells to People

Discover the major milestones and key adaptations that have shaped the course of human evolution. The following graphic illustrates how humans have emerged from 4 billion years of change.

Evolving into the Future

Humans are still evolving. Thousands of years from now, we may experience a 'Great Averaging' where continuous, international mixing will create an average of all current physical differences.

Other hypotheses suggest humans may become taller, more lightly built, and less aggressive with smaller brains.

KEY
Ga - Giga annum Billion years ago
Ma - Mega annum Million years ago
+ Gain of function/body part
− Loss of function/body part
Self-replicating RNA molecules
RNA stabilizes into double helix structure of DNA
Organelles (nuclei, mitochondria, cytoskeleton, etc.) and sexual reproduction evolve
Epithelia, mouth, muscles, connective tissue, nerves, photoreceptive eye-spots, and bilateral symmetry
Protocells 4.3 Ga
Prokaryote 4.0 Ga
Cyanobacteria 3.5 Ga
Eukaryote 2.2 Ga
Choanoflagellate 1.2 Ga
Unicellular Life
Single-celled Organisms
Dickinsonia 800 Ma
Urbilaterian 650 Ma
Deuterostome 600 Ma
Platyhelminthes 550 Ma
Animalia
Multicellular Life
A single layered tube arises as a single-chambered heart
Pharyngeal slits (gills) evolve
Early spine, notochord, post-anal tail
Brains, blood, branched blood vessels, pharynxes, and the ability to smell
Ears, camera eyes, pineal gland (third eye), skin layers, a two-chambered heart, and the ability to taste
Pharyngeal slits become gills
Jaws, scales, teeth, stomachs, spleens, hemoglobin, adaptive immunity
Lungs, preliminary ribs, and other bones
Pikaia 540 Ma
Haikouichthys 525 Ma
Agnatha 520 Ma
Placodermi 460 Ma
Cephalaspis 430 Ma
Coelacanth 420 Ma
Chordata
Animals with Backbones
Protolimbs in the following species eventually evolve into legs
Eyelids, tear glands, stronger bones, complete rib cage and first recognizable legs
Tongue, salivary glands, three-chambered heart, glottis, and bladder
Dorsal, anal, and tail fins
Keratin, shelled eggs, adrenal glands, cranial nerves for sensory information
Gills
Panderichthys 415 Ma
Tiktaalik 375 Ma
Acanthostega 365 Ma
Ichthyostega 360 Ma
Pederpes 358 Ma
Westlothiana 338 Ma
Thought to be the first animal to walk on land
Tetrapoda
Four-legged Organisms
Early diaphragm, specialized teeth, secondary palate
Scales
Hylonomus 330 Ma
Milk glands, sweat glands, hairy skin, internal penises, specialized teeth, four-chambered hearts, constant body temperature, and nocturnality
Loss of cervical ribs (only thoracic remain), tetrochromatic vision drops to dichromatic
Phthinosuchus 300 Ma
Cynognathus 260 Ma
Repenomamus 230 Ma
Juramaia 170 Ma
Live (eggless) births, marsupial pouches, nipples, placenta, external penises, anal and urogenital openings
Warm blood, thicker skin, advancements to lungs/ lymphatic system, and erect hindlimbs
Pineal gland (third eye) and lumbar ribs
Mammalia
Milk–producing Animals
Menstrual cycle, diurnality, paranasal sinuses
Claws become nails, mammaries reduce to a single pair on the chest
Trichomatic vision, larger brain
Tails
Plesiadapis 90 Ma
Carpolestes 65 Ma
Aegyptopithecus 50 Ma
Proconsul 35 Ma
Forward-facing eyes, grasping digits
Vitamin C metabolism (now must be introduced in diet)
Primates
An Order of Mammals
Likely bipedal (but still had grasping feet), brain size begins to enlarge, tool construction begins
Completely bipedal
Introduced clothing, fire, and constructed the wheel
Flat and widened rib cage, stiff lower spine, flexible wrists, shoulder blades
Pierolapithecus 15 Ma
Ouranopithecus 9 Ma
Orrorin 6 Ma
Ardipithecus 5.7 Ma
Australopithecus 4 Ma
Hominidae
Great Apes
Homo erectus 2 Ma
Homo neanderthalensis 300 ka
Homo sapiens 160 ka
Brain size stabilizes, trunk and extremities elongate
Reduction in body hair
Protruding nose
Brow ridges, snout, decrease size in jaws and teeth
Genus Homo
Contemporary humans

Figure 15.49: Human linear evolution perspective (credit: Visual Capitalist, https://www.visualcapitalist.com/path-of-human-evolution/)

Remarks

R1. The Hardy-Weinberg model is very unlikely in nature. Indeed, the probabilities that all the necessary assumptions are present simultaneously is quite low. However, this is a theoretical model that evaluates if there is a micro-evolution in a population. Thus, we measure the frequency of alleles in the parent population and then we apply the Hardy-Weinberg equation. If the genetic structure of the descendant population differs from that predicted by the law, then we know that at least one agent of evolution is at work.

R2. This theoretical model can help to predict a punctual estimator of the social costs of genetic diseases. Indeed, if we know the percentage of individuals with recessive disease in a population, we can apply the Hardy-Weinberg equation and evaluate the number of healthy transmitters and then we can predict the likelihood of the disease in future generations. If it is large (this reasoning is valid only in a liberal and capitalist framework), we may decide to invest in research or providing funds to treat the sick people.

R3. For people interested in exploring the subject further, we highly recommend reading [118] and [226], which are two masterpiece in this field!

✍**Examples:**

E1. Given a genotype of possible sequences $\{BB, bb, Bb\}$ and let consider that $p_B = 0.6, p_b = 0.4$. We then have:

$$p^2 = 0.36 \quad 2py = 0.48 \quad q^2 = 0.16 \tag{15.1.171}$$

Therefore, in a population of $1,000,000$ individuals, we should have:

$$\begin{aligned} 0.36 \cdot 1 \cdot 10^6 &= 360,000 BB \\ 0.48 \cdot 1 \cdot 10^6 &= 480,000 Bb \\ 0.16 \cdot 1 \cdot 10^6 &= 160,000 BB \end{aligned} \tag{15.1.172}$$

E2. If in Quebec (6 million inhabitant), one in five has blue eyes ($bb \Rightarrow q^2 = 1/5$), how many people are of genotype BB and how many of type Bb?

$$q = \sqrt{1/5} = 0.44721 \tag{15.1.173}$$

$$p = (1 - q) = 0.5528 \tag{15.1.174}$$

Therefore:

$$p^2 = 0.3056 \quad 2pq = 0.4944 \quad q^2 = 0.2 \tag{15.1.175}$$

Therefore we have:

$$\begin{aligned} 0.3056 \cdot 6 \cdot 10^6 &= 1,833,600 BB \\ 0.4944 \cdot 6 \cdot 10^6 &= 2,966,400 Bb \\ 0.2 \cdot 6 \cdot 10^6 &= 1,200,000 bb = \frac{1}{5} \cdot 6 \cdot 10^6 \end{aligned} \tag{15.1.176}$$

E3. We introduce $1,000$ spotted frogs in a pond (homozygous for this characteristic: TT) and 250 frogs without spots (homozygous for this trait: tt). If we allow the frogs to reproduce for several years, assuming that the population remains stable, what number of frogs TT, Tt, tt should we then observe?

So we have a population of $1,250$ individuals in which we $1,000TT$ ($2,000$ allele T) and $250tt$ (500 alleles t). So:

$$\left.\begin{aligned} p(T)&=\frac{2,000}{2,500}=0.8\\ q(t)&=\frac{500}{2,500}=0.2\end{aligned}\right\}\Rightarrow\begin{cases}p^2=0.64\\ 2pq=0.32\\ q^2=0.04\end{cases} \tag{15.1.177}$$

If the population is of $1,250$ people, we have:

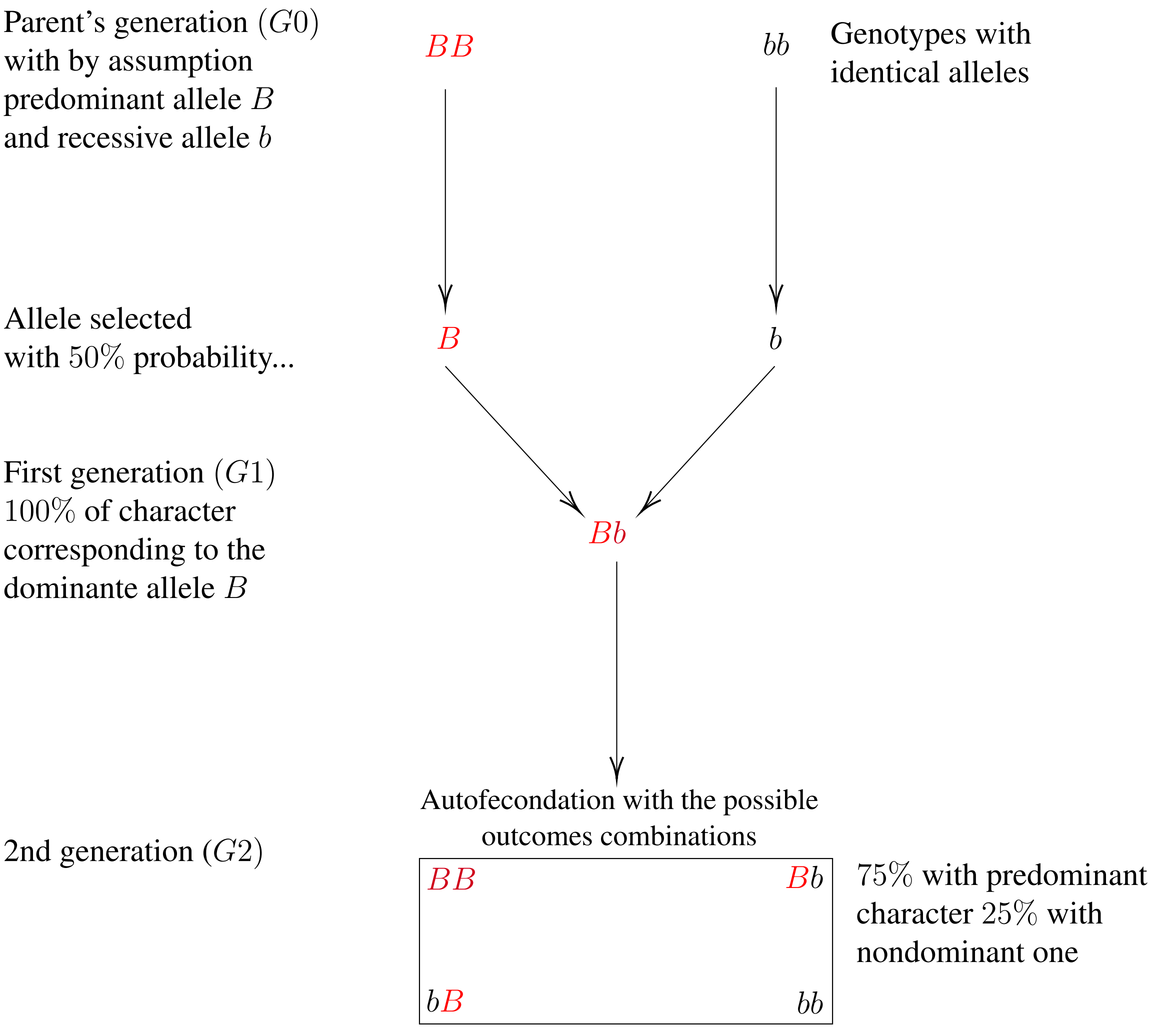
$$\begin{aligned}0.64\cdot 1,250&=800\text{ individuals }TT\\ 0.32\cdot 1,250&=400\text{ individuals }Tt\\ 0.04\cdot 1,250&=50\text{ individuals }tt\end{aligned} \tag{15.1.178}$$

Caution! As always... reality is more complex and chaotic than theory. A lot of people still believe that the human is perfect and the world too (we know that Earth is far from being perfect after our study of the section of Astrophysics)! However these people don't know that there are ~ 150 types of cancer (a few hundreds of them are described in [343]), a few thousands of mental disorders (a few hundreds of them are described in [532]) and $\sim 4,200$ different of genetic diseases (half a thousand are described in [410]). For example, the Swyer syndrome is a form of intersex linked to hypogonadism where an individual with a female phenotype has a karyotype with XY type sex chromosomes (in other words the individual has female organs but is born with male chromosomes) but where the SRY gene, responsible for the differentiation of the undifferentiated embryo into a male individual at the sixth week of embryonic development, is mutated (i.e. has undergone a mutation).

15.1.5 Mendel's law

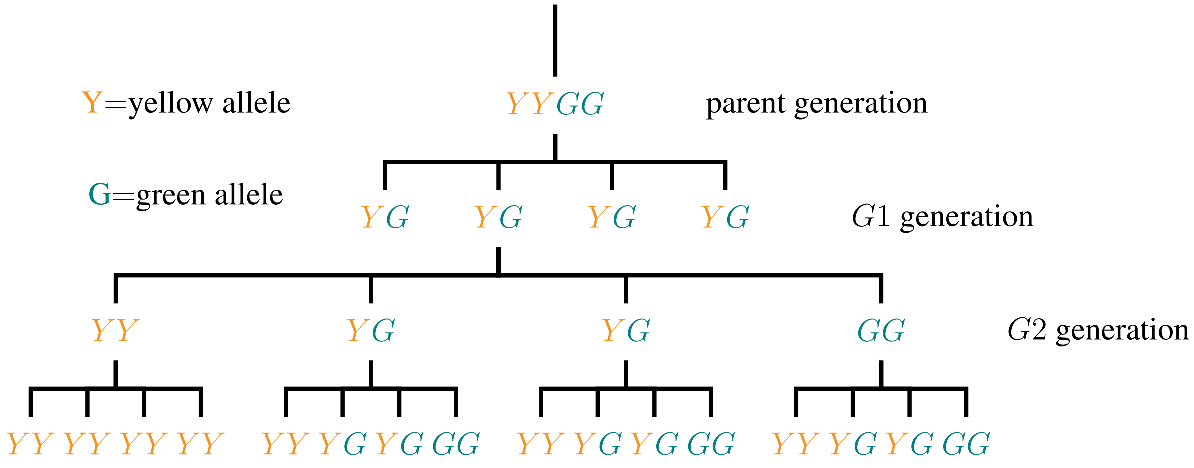
During methodical hybridization of many species and varieties of various plants, it has been observed, in general, the uniformity and character of the first hybrid generation ($G1$) intermediate between the parents. So the inheritance is totally taken form the dominant character in the first generation (father or mother but of the mix). At the second generation ($G2$) occurs polymorphism showing various combinations of characters of the initial generation ($G0$). Thus we find in the second generation 25% of individuals with non-dominant character of the initial generation and 75% with the dominant character. The character that was masked in,the first generation (G1) is then named "recessive character".

This fact can be summarized with the following structure:



Parent's generation $(G0)$ with by assumption predominant allele B and recessive allele b
BB
bb
Genotypes with identical alleles
Allele selected with 50% probability...
B
b
First generation $(G1)$ 100% of character corresponding to the dominante allele B
Bb
2nd generation $(G2)$
Autofecondation with the possible outcomes combinations
BB
Bb
bB
bb
75% with predominant character 25% with nondominant one

Mendel then made the assumption that the gametes of hybrids of the first generation $(G1)$ must be in equal numerical proportions, of the type of one or other of the parents. This is the "law of purity of gametes".

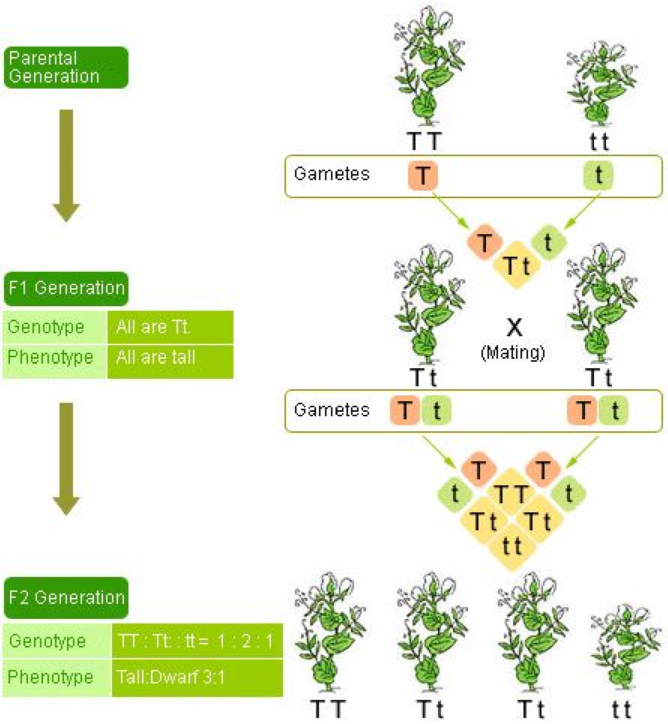


Y=yellow allele
G=green allele
$YYGG$
parent generation
YG YG YG YG
$G1$ generation
YY
YG
YG
GG
$G2$ generation
YY YY YY YY
YY YG YG GG
YY YG YG GG
YY YG YG GG

Figure 15.50: **Mendelian Inheritence Chart**

It has been established that human blood groups also obey to the rules of Mendelian inheritance. Thus, A and B blood groups are dominant and can appear in children if and only if they are present by the parents.

In a more pedagogical way, the previous figure can be illustrated as following:



Parental Generation
TT
tt
Gametes
T
t
T
t
Tt
F1 Generation
Genotype
All are Tt
Phenotype
All are tall

F2 Generation
Genotype
TT : Tt : tt = 1 : 2 : 1
Phenotype
Tall:Dwarf 3:1
TT
Tt
Tt
tt

Mendel's laws are stated as following:

L1. "Law of dominance and uniformity": Some alleles are dominant while others are recessive; an organism with at least one dominant allele will display the effect of the dominant allele.

L2. "Law of segregation": During gamete formation, the alleles for each gene segregate from each other so that each gamete carries only one allele for each gene.

L3. "Law of independent assortment": Genes of different traits can segregate independently during the formation of gametes.

Figure 15.51: **Evolution and Original of Life experimental evidence as in the beginning of the 121st century**

Remark

After Mendel's studies and discoveries more and more new discoveries about genetics were made. Mendel himself has said that the regularities he discovered apply only to the organisms and characteristics he consciously chose for his experiments. Mendel explained inheritance in terms of discrete factors - genes - that are passed along from generation to generation according to the rules of probability. Mendel's laws are valid for all sexually reproducing organisms, including garden peas and human beings. However, Mendel's laws stop short of explaining some patterns of genetic inheritance. For most sexually reproducing organisms, cases where Mendel's laws can strictly account for all patterns of inheritance are relatively rare. Often the inheritance patterns are more complex.

In cases of codominance the phenotypes produced by both alleles are clearly expressed. Mendel chose genetic traits in plants that are determined by only two alleles, such as "A" and "a". In nature, genes often exist in several different forms with multiple alleles. Furthermore, many traits are produced by the interaction of several genes. Traits controlled by two or more genes are said to be polygenic traits.

15.1.6 Growth rate with temperature

For many species (mammals, fish, micro-organisms), it is reasonable to consider as a first approximation, the relation of the population growth rate with the temperature of the environment is a second degree polynomial:

$$\mu=aT^2+bt+c \tag{15.1.179}$$

where the values a,b,c will depend of the considered species.

We know also that there is for most individuals a given optimum growth rate at a given temperature denoted T_{opt}, as well as minimum T_{min} and maximum T_{max} temperatures below and above which there is no more growth.

Therefore, the parameters a,b,c must satisfy the following relations:

$$\frac{\mathrm{d}\mu(T_{\text{opt}})}{\mathrm{d}T}=0 \tag{15.1.180}$$

$$\mu(T_{\text{min}})=\mu(T_{\text{max}})=0 \tag{15.1.181}$$

This implies for the three temperatures $T_{\text{opt}},T_{\text{min}},T_{\text{max}}$ to respect the relations proved in the context of the study of polynomials of the second degree in the section Calculus (see page 1382):

$$\begin{aligned}T_{\text{opt}}&=-\frac{b}{2a}\\T_{\text{min}}&=\frac{-b-\sqrt{b^2-4ac}}{2a}=-\frac{b}{2a}-\frac{\sqrt{b^2-4ac}}{2a}=T_{\text{opt}}-\frac{\sqrt{b^2-4ac}}{2a}\\T_{\text{max}}&=\frac{-b+\sqrt{b^2-4ac}}{2a}=-\frac{b}{2a}+\frac{\sqrt{b^2-4ac}}{2a}=T_{\text{opt}}+\frac{\sqrt{b^2-4ac}}{2a}\end{aligned} \tag{15.1.182}$$

So if we know for a living entity T_{opt} and T_{min} it is easy to deduce theoretically an approximation of T_{max} in the context of the main assumption...

Remark

Again, for people interested in exploring the subject further, we highly recommend reading [118], which is a masterpiece in this field!

15.2. Game and Decision Theory

THE Decision and Game Theory goes far beyond the narrow confines of social games, even if they constituted the first object of study and gave it its name in most commercially available books. Furthermore, the two theories are very close to each other from which the fact that they are very often non-differentiated in the literature.

Definitions (#15.2.634):

D1. "Game theory" is the study of decision making models in uncertain future with unknown probabilities.

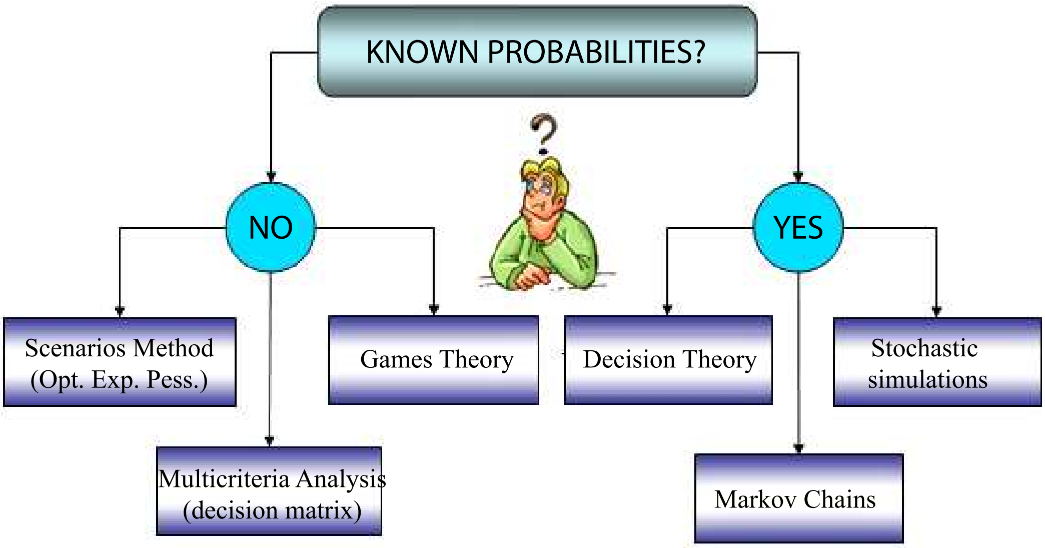
D2. "Decision theory" (sometimes also named "decision analysis") is the study of decision-making models in an uncertain probabilistic (objectively or subjectively) future.

D3. "Data drive decision making" is the practice of basing decisions on the analysis of data ("Machine Learning" or "Data Mining"), rather than purely on intuition (see section Numerical Methods page 6768).

D4. "Evidence based management" is the practice of taking decisions based on best available scientific evidence in peer-reviewed research papers (see [41] for more details).

Each of the methods of analysis of these two theories is mainly made in tabular (table) form or as a vertical or horizontal tree.

Here is a fairly familiar pattern for project manager who sums up the whole situation (data driven decision is not included as treated in the Theoretical Computing section during the study of decision trees):



KNOWN PROBABILITIES?
NO
YES
Scenarios Method (Opt. Exp. Pess.)
Games Theory
Decision Theory
Stochastic simulations
Multicriteria Analysis (decision matrix)
Markov Chains

Figure 15.52: **Elementary classification of decision techniques**

To summarize, "game theory" is the study of interdependent choice and action. It includes the study of "strategic decision making", the analysis of how the choices and decisions of a rational agent depend on (or should be influenced by) the choices of other agents, as well as the study of "group dynamics", the analysis of how the distribution of strategies in a population evolves in various contexts and how these distributions impact the outcomes of individual interactions. It should be distinguished from "decision theory", the study of individual choice in contexts where the agent is choosing independently of other agents, and from social choice theory, the study of collective decision making.

These tools aim to try to formalize to decide which configuration or decision is better than another[5]. We will look for this purpose to find the optimum of certain parameters that quantify the quality of a strategic situation. We must also determine which conditions lead to a configuration that is considered optimal.

Game theory and the decision is now quite common and used in academic circles, not only in economy (particularly corporate finance), but also by a whole class of other science in which the study on conflictual situations is relevant: sociology, biology, evolution, computer (video games), marketing, etc.

Remark

In the world of corporations, and especially in Europe, decisions techniques are unknown to almost all of the leaders whose choices are often more qualitative and instinctive than scientific and thus less accurate... That's why "Evidence based Management" has been developed. Most management decisions are not based on the best available evidence. Indeed some practitioners often prefer to base decisions solely on their judgement based on personal experience. However, personal judgement alone is not a very reliable source of evidence because it is highly susceptible to systematic errors.

We will try, as always in this textbook, to minimize as possible the number of definitions and concepts in order not to drown the rigour of mathematical analysis in the chaos of useless vocabulary and not necessary for such analysis (and in the field of game theory it is otherwise a bit like in graph theory... a real nightmare of definitions!).

Definition (naive #635): A "game" is a situation where the players are driven to make strategic choices among a number of possible actions, within the framework defined in advance by the "rules of the game", the result of these choices constituting an "outcome of the game", which is associated with a "gain" (or payment), positive or negative, for each player.

Remark

A player may be a person, a group of people, a society, a region, a political party, a country or even mother Nature ...

Assumptions (we will find them again in the Econometry section):

A1. The market is governed by competition and cooperation

---

[5] For example, a survey of 950 US HR practitioners showed large discrepancies between what practitioners think is effective and what the current scientific research shows [474]. This study has been repeated in other countries with similar findings.

A2. The behaviour of economic agents are rational (...)

A3. It is possible to formalize competitive behaviour

A4. All competitive phenomena have a utilitarian dimension

We differentiate and define mainly six types of games which we will formalize further below.

Definitions (#15.2.636):

D1. The "cooperative or non-cooperative games": a game is said to be cooperative when players can freely communicate and make agreements (e.g. in the form of a contract). They thus form a coalition and seek the general interest followed by a partition of earnings between all players. In a non-cooperative game, players (who do not communicate or can not communicate with one another) act according to the principle of economic rationality: each seeks to make the best decisions for themselves (i.e. seeks to maximize selfishly its individual earnings). This type of game involves probabilities.

A first possible approach (without using math at first) of this game spirit is accessible to young children (without they know it!). Indeed, let us consider the following example:

✍**Example:**

Imagine two children, both gourmands in the presence of a homogeneous cake, perfectly divisible (and very good ...). If mom does two parts, there will inevitably disputes, each one finding the part of the other bigger. The only way (expected order) to avoid any argument is for the mother to impose the following rule: one of the children makes the parts, and the other one chooses first the part. The one who cuts can therefore not reason anymore taking into account only his own preferences, which would push him to cut a big part. He knows that the other will choose it. If then he cut a larger part than the other, it could find the latter in the neighbour's plate. He will therefore try to cut as evenly as possible in his point of view. Thus, whatever the choice of the other, he will think that the game is strategically equilibrated. It is this anticipation of the choice of the other decision which makes the originality of the theory of decision and also of cooperation!

D2. The "simultaneous or sequential move games": Simultaneous games are the one in which the move of two players (the strategy adopted by two players) is simultaneous. In simultaneous move, players do not have knowledge about the move of other players. On the contrary, sequential games are the one in which players are aware about the moves of players who have already adopted a strategy. However, in sequential games, the players do not have a deep knowledge about the strategies of other players. For example, a player has knowledge that the other player would not use a single strategy, but he/she is not sure about the number of strategies the other player may use.

D3. The "zero-sum or non-zero game": a game is said to be "zero sum" when the sum of the earnings of players is constant (or by the subtle choice of a utility function may be constant...) or in other words: what one wins is necessarily lost by another (chess, poker and some say that the stock market is a zero sum game but in reality it is false when you think about it globally ...). The social games are often zero-sum games but the real situations are often better described by the non-cooperative games with non-zero sum because some issues are profitable for all, or harmful for all (political, business situations...). For example slavery is a non-zero sum game.

Remarks

R1. Some theorists criticize zero-sum games, at least in the area of economic situation, on the basis that economic exchange is in principle mutually beneficial and that the zero-sum games would be totally unrealistic.

R2. Zero sum games are sometimes named "antagonistic games".

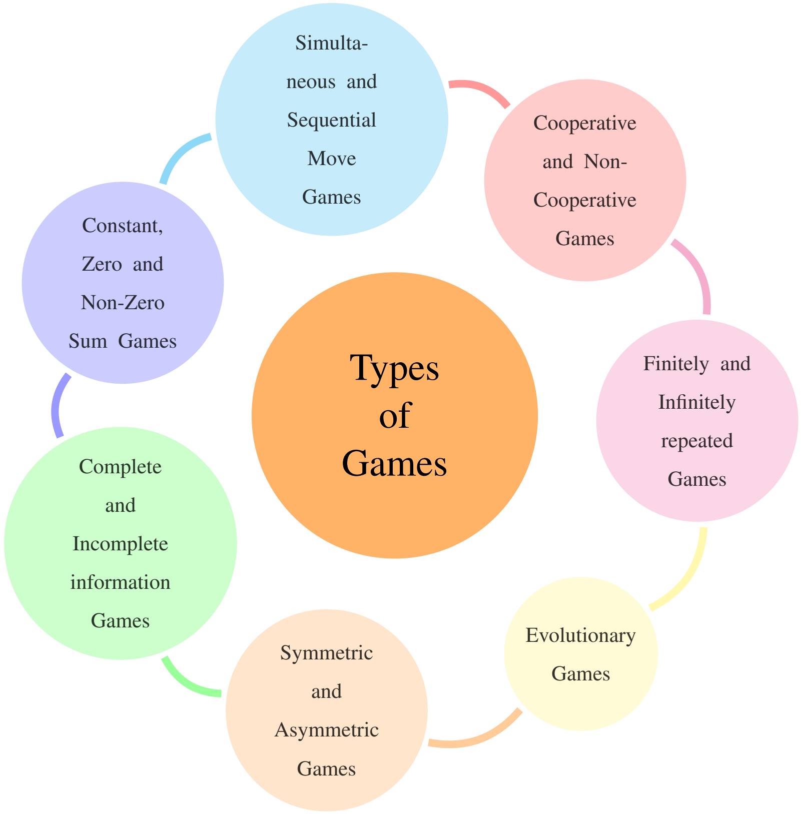
R3. Since the invention of the atomic bomb, the balance of terror is based on the doctrine of offensive deterrence. Opposed by the reciprocal ability to inflict massive damage, the respective nuclear arsenals self-cancelling in a zero-sum game, by a principle of mutually assured destruction.

D4. The "with and without balance games": a cooperative non zero sum game is said with "Nash equilibrium" if there are a couple of strategies (in the case of a two-player game) such that no player has the interest to unilaterally change his strategy to ensure the maximum minimum (the "maximin") earnings.

D5. The "competitive or non-competitive games": a non-competitive game is the opposite of a competitive game such as by definition, when any pair of strategies (in the case of a two-player game) is such that it makes win or lose all players simultaneously a given gain (i.e. when I lose something, you lose something, when I win something you also win something).

D6. The "symmetric and asymmetric games": in symmetric games. strategies adopted by all players are same. Symmetry can exist in short-term games only because in long-term games the number of options with a player increases. The decisions in a symmetric game depend on the strategies used, not on the players of the game. Even in case of interchanging players, the decisions remain the same in symmetric games. Example of symmetric games is prisoner's dilemma. On the other hand, asymmetric games are the one in which strategies adopted by players are different. In asymmetric games, the strategy that provides benefit to one player may not be equally beneficial for the other player.

Most of these types of games are interlaced and therefore it is quite hard to created an orgchart of the existing ones. A quite good illustration that summarize the six of them and the fact that they are interconnect is given by the following smart art:



Simultaneous and Sequential Move Games
Cooperative and Non-Cooperative Games
Constant, Zero and Non-Zero Sum Games
Types of Games
Finitely and Infinitely repeated Games
Complete and Incomplete information Games
Evolutionary Games
Symmetric and Asymmetric Games

Figure 15.53: **Common types of games in Game Theory**

Scientists (and afterwards politicians, based on scientists recommendations) have to take sometimes decisions that are no popular! Indeed, a non-negligible percentage of humans are sadly totally irrationals (see for example the toilet paper shortage from year 12020 - according to holocene calendar - during the COVID-19 pandemic). That's why sometimes scientists have to recommend the retirement of some freely accessible medications because in a crisis situation a fraction of the population may create an irrational shortage of a product and even worst... use that same product in a way that may do more harm than good!

quote 15.2:7380.#79

> *Sooner or later the moment arrives when a decision must be made which is neither certain, neither suitable, nor popular, but it must be taken, because it is right.*
>
> Martin Luther King

quote 15.2:7380.#80

> *A good compromise is when both parties are dissatisfied.*
>
> Larry David

15.2.1 Behavioural decision bias (cognitive bias)

Before starting with technical and mathematics techniques it is important for the manager, top manager, CEO/CFO and any other CXO (or even the student in Economy) to understand why it is more important to rely in mathematical results rather than to trust on human intuition and to try not forget what follows as most of time I see huge error of evaluation in Fortune 500 companies!

First, for information, the study of human intuition in economy is named "behavioural economics". And in this study field "cognitive biases" are tendencies by humans to think in certain ways that can lead to systematic deviations from a standard of rationality or good judgement, and are often studied in psychology and behavioural economics.

In the early 11970s (holocene calendar), Amos Tversky and Daniel Kahneman introduced the term "cognitive bias" to describe people's systematic but purportedly flawed patterns of responses to judgement and decision problems (managers, students, economists, and so on...). Indeed, they have showed that people routinely employ heuristics - rules of thumb, or mental shortcuts - to simplify and, worse, oversimplify decisions under uncertainty. Moreover, they have shown time and again that our choices are frequently skewed by an array of cognitive biases.

Most work before the 11970 (holocene calendar) were done in behavioural finance and focused on asset pricing and the behaviour of investors. But increasingly, attention is being paid to decision-making in the corporate realm. Because of their training and experience, managers might be presumed to be less likely to use mental shortcuts, and less vulnerable to cognitive biases. True or not, consultants in decision analysis have made a good living by showing managers how they fall into decision traps, and professors have delighted in showing their executive MBA students just how flawed their judgement can be.

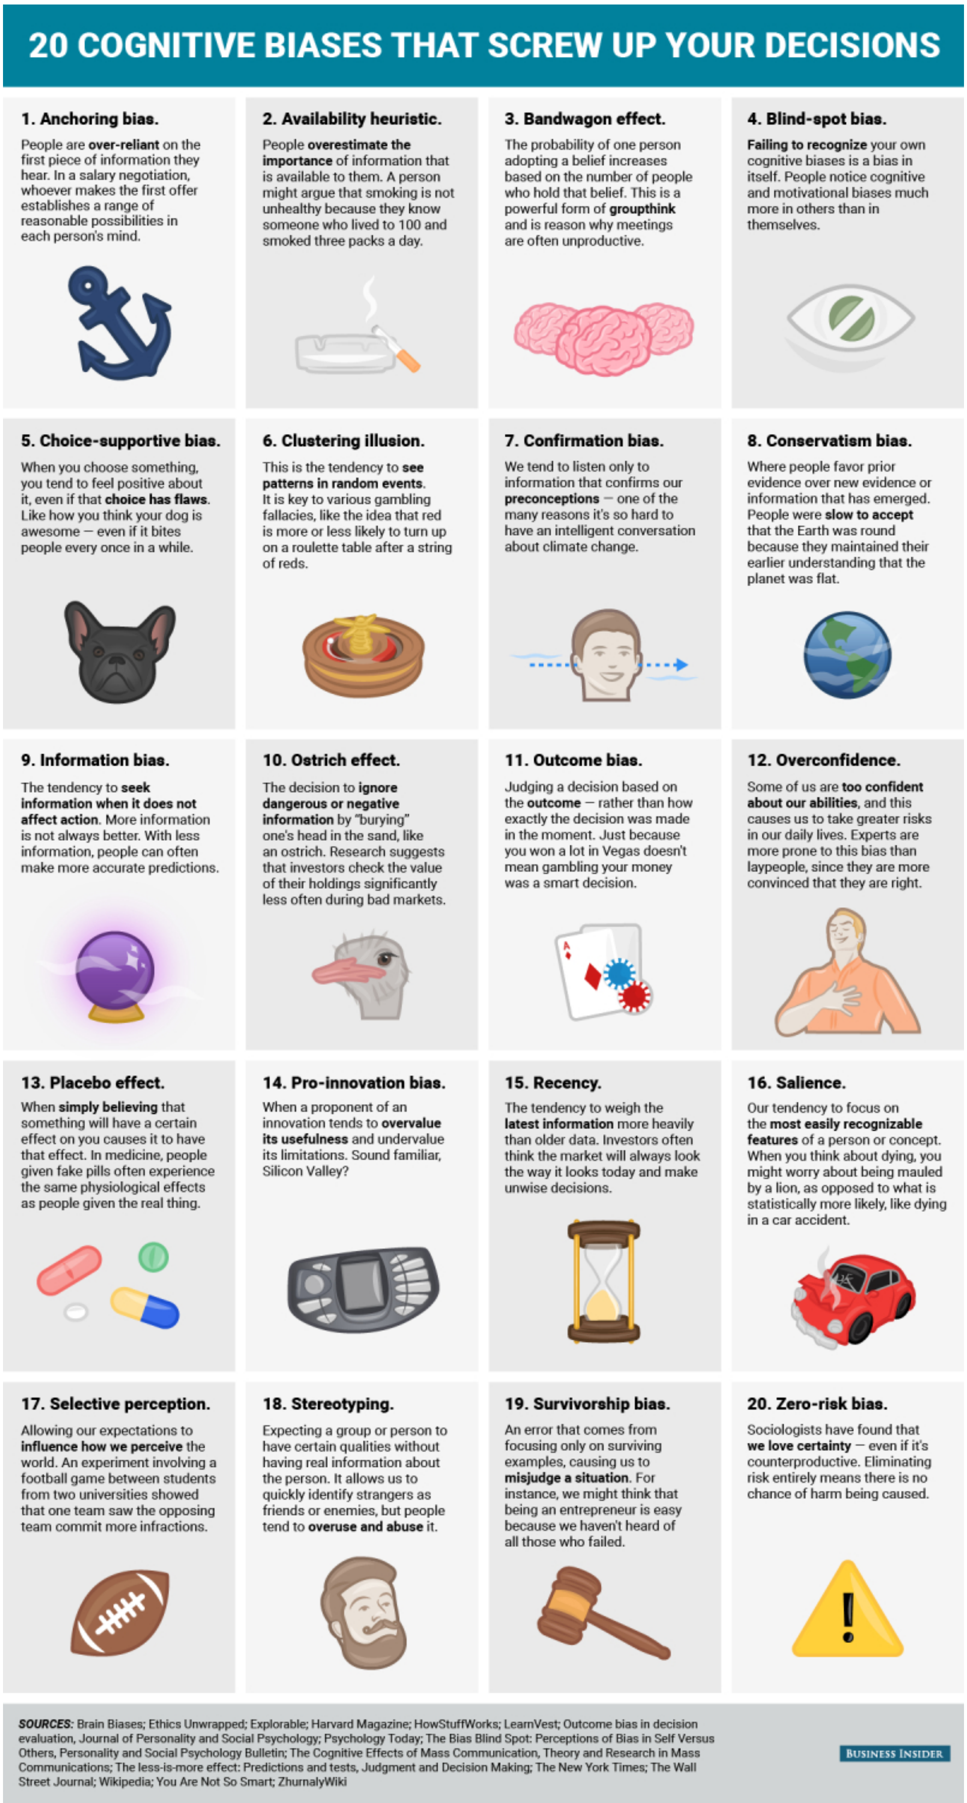
On the way it is also important to distinguish between "cognitive biases" and "logical fallacies". A logical fallacy is an error in logical argumentation (e.g. ad hominem attacks, slippery slopes, circular arguments, appeal to force, etc.). A cognitive bias, on the other hand, is a genuine deficiency or limitation in our thinking — a flaw in judgement that arises from errors of memory, social attribution, and miscalculations (such as statistical errors or a false sense of probability[6]).

Although the reality of these biases is confirmed by replicable research, there are often controversies about how to classify these biases or how to explain them. Some are effects of information-processing rules (i.e., mental shortcuts), named "heuristics", that the brain uses to produce decisions or judgements. Such effects are named "cognitive biases". Biases have a variety of forms and appear as cognitive ("cold") bias, such as mental noise, or motivational ("hot") bias, such as when beliefs are distorted by wishful thinking. Both effects can be present at the same time.

Over time, the behaviourists have compiled a long list of biases and heuristics. No one can say with certainty which of these inflict the most harm, but financial managers would do well to watch out for five: anchoring and adjustment, framing, optimism, overconfidence, and self-serving bias. In the figure below the reader can see a quite good summary illustration (the original author is sadly unknown) of the most common well known cognitive biases:

---

[6] These latter being often the most difficult point during debates when people don't understand that when they use arguments, they have the **burden of proof**, and even more difficult when they don't understand the concept of "proof"!!!!



20 COGNITIVE BIASES THAT SCREW UP YOUR DECISIONS

1. Anchoring bias.
People are **over-reliant** on the first piece of information they hear. In a salary negotiation, whoever makes the first offer establishes a range of reasonable possibilities in each person's mind.

2. Availability heuristic.
People **overestimate the importance** of information that is available to them. A person might argue that smoking is not unhealthy because they know someone who lived to 100 and smoked three packs a day.

3. Bandwagon effect.
The probability of one person adopting a belief increases based on the number of people who hold that belief. This is a powerful form of **groupthink** and is reason why meetings are often unproductive.

4. Blind-spot bias.
Failing to recognize your own cognitive biases is a bias in itself. People notice cognitive and motivational biases much more in others than in themselves.

5. Choice-supportive bias.
When you choose something, you tend to feel positive about it, even if that **choice has flaws**. Like how you think your dog is awesome — even if it bites people every once in a while.

6. Clustering illusion.
This is the tendency to **see patterns in random events**. It is key to various gambling fallacies, like the idea that red is more or less likely to turn up on a roulette table after a string of reds.

7. Confirmation bias.
We tend to listen only to information that confirms our **preconceptions** — one of the many reasons it's so hard to have an intelligent conversation about climate change.

8. Conservatism bias.
Where people favor prior evidence over new evidence or information that has emerged. People were **slow to accept** that the Earth was round because they maintained their earlier understanding that the planet was flat.

9. Information bias.
The tendency to **seek information when it does not affect action**. More information is not always better. With less information, people can often make more accurate predictions.

10. Ostrich effect.
The decision to **ignore dangerous or negative information** by "burying" one's head in the sand, like an ostrich. Research suggests that investors check the value of their holdings significantly less often during bad markets.

11. Outcome bias.
Judging a decision based on **the outcome** — rather than how exactly the decision was made in the moment. Just because you won a lot in Vegas doesn't mean gambling your money was a smart decision.

12. Overconfidence.
Some of us are **too confident about our abilities**, and this causes us to take greater risks in our daily lives. Experts are more prone to this bias than laypeople, since they are more convinced that they are right.

13. Placebo effect.
When **simply believing** that something will have a certain effect on you causes it to have that effect. In medicine, people given fake pills often experience the same physiological effects as people given the real thing.

14. Pro-innovation bias.
When a proponent of an innovation tends to **overvalue its usefulness** and undervalue its limitations. Sound familiar, Silicon Valley?

15. Recency.
The tendency to weigh the **latest information** more heavily than older data. Investors often think the market will always look the way it looks today and make unwise decisions.

16. Salience.
Our tendency to focus on the **most easily recognizable features** of a person or concept. When you think about dying, you might worry about being mauled by a lion, as opposed to what is statistically more likely, like dying in a car accident.

17. Selective perception.
Allowing our expectations to **influence how we perceive** the world. An experiment involving a football game between students from two universities showed that one team saw the opposing team commit more infractions.

18. Stereotyping.
Expecting a group or person to have certain qualities without having real information about the person. It allows us to quickly identify strangers as friends or enemies, but people tend to **overuse and abuse** it.

19. Survivorship bias.
An error that comes from focusing only on surviving examples, causing us to **misjudge a situation**. For instance, we might think that being an entrepreneur is easy because we haven't heard of all those who failed.

20. Zero-risk bias.
Sociologists have found that **we love certainty** — even if it's counterproductive. Eliminating risk entirely means there is no chance of harm being caused.

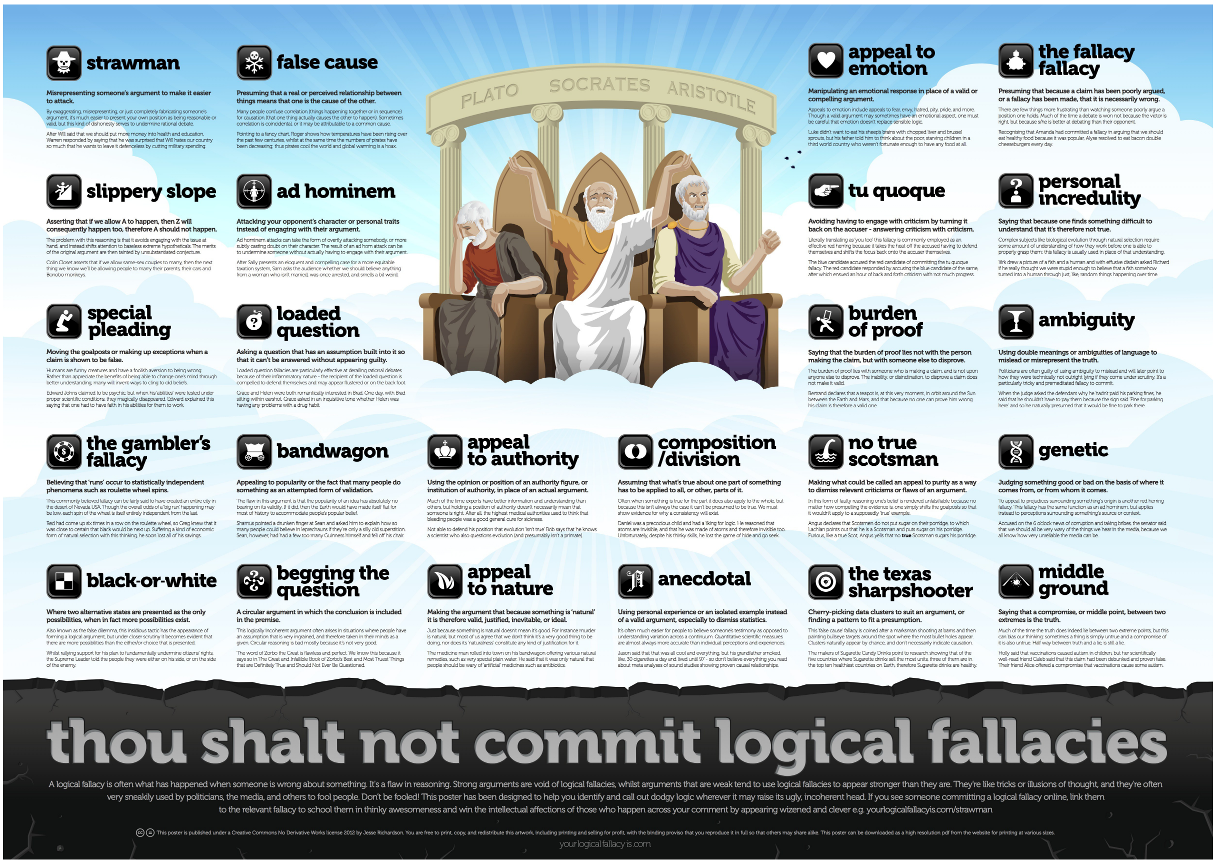
BUSINESS INSIDER

Also here is another useful and nice complementary poster that will be appreciated by any scientist or any person that has for purpose to reason following some good practices:



strawman

Misrepresenting someone's argument to make it easier to attack.

By exaggerating, misrepresenting, or just completely fabricating someone's argument, it's much easier to present your own position as being reasonable or valid, but this kind of dishonesty serves to undermine rational debate.

After Will said that we should put more money into health and education, Warren responded by saying that he was surprised that Will hates our country so much that he wants to leave it defenceless by cutting military spending.

false cause

Presuming that a real or perceived relationship between things means that one is the cause of the other.

Many people confuse correlation (things happening together or in sequence) for causation (that one thing actually causes the other to happen). Sometimes correlation is coincidental, or it may be attributable to a common cause.

Pointing to a fancy chart, Roger shows how temperatures have been rising over the past few centuries, whilst at the same time the numbers of pirates have been decreasing; thus pirates cool the world and global warming is a hoax.

appeal to emotion

Manipulating an emotional response in place of a valid or compelling argument.

Appeals to emotion include appeals to fear, envy, hatred, pity, pride, and more. Though a valid argument may sometimes have an emotional aspect, one must be careful that emotion doesn't replace sensible logic.

Luke didn't want to eat his sheep's brains with chopped liver and brussel sprouts, but his father told him to think about the poor, starving children in a third world country who weren't fortunate enough to have any food at all.

the fallacy fallacy

Presuming that because a claim has been poorly argued, or a fallacy has been made, that it is necessarily wrong.

There are few things more frustrating than watching someone poorly argue a position one holds. Much of the time a debate is won not because the victor is right, but because s/he is better at debating than their opponent.

Recognising that Amanda had committed a fallacy in arguing that we should eat healthy food because it was popular, Alyse resolved to eat bacon double cheeseburgers every day.

slippery slope

Asserting that if we allow A to happen, then Z will consequently happen too, therefore A should not happen.

The problem with this reasoning is that it avoids engaging with the issue at hand, and instead shifts attention to baseless extreme hypotheticals. The merits of the original argument are then tainted by unsubstantiated conjecture.

Colin Closet asserts that if we allow same-sex couples to marry, then the next thing we know we'll be allowing people to marry their parents, their cars and Bonobo monkeys.

ad hominem

Attacking your opponent's character or personal traits instead of engaging with their argument.

Ad hominem attacks can take the form of overtly attacking somebody, or more subtly casting doubt on their character. The result of an ad hom attack can be to undermine someone without actually having to engage with their argument.

After Sally presents an eloquent and compelling case for a more equitable taxation system, Sam asks the audience whether we should believe anything from a woman who isn't married, was once arrested, and smells a bit weird.

tu quoque

Avoiding having to engage with criticism by turning it back on the accuser - answering criticism with criticism.

Literally translating as 'you too' this fallacy is commonly employed as an effective red herring because it takes the heat off the accused having to defend themselves and shifts the focus back onto the accuser themselves.

The blue candidate accused the red candidate of committing the tu quoque fallacy. The red candidate responded by accusing the blue candidate of the same, after which ensued an hour of back and forth criticism with not much progress.

personal incredulity

Saying that because one finds something difficult to understand that it's therefore not true.

Complex subjects like biological evolution through natural selection require some amount of understanding of how they work before one is able to properly grasp them; this fallacy is usually used in place of that understanding.

Kirk drew a picture of a fish and a human and with effusive disdain asked Richard if he really thought we were stupid enough to believe that a fish somehow turned into a human through just, like, random things happening over time.

special pleading

Moving the goalposts or making up exceptions when a claim is shown to be false.

Humans are funny creatures and have a foolish aversion to being wrong. Rather than appreciate the benefits of being able to change one's mind through better understanding, many will invent ways to cling to old beliefs.

Edward Johns claimed to be psychic, but when his 'abilities' were tested under proper scientific conditions, they magically disappeared. Edward explained this saying that one had to have faith in his abilities for them to work.

loaded question

Asking a question that has an assumption built into it so that it can't be answered without appearing guilty.

Loaded question fallacies are particularly effective at derailing rational debates because of their inflammatory nature - the recipient of the loaded question is compelled to defend themselves and may appear flustered or on the back foot.

Grace and Helen were both romantically interested in Brad. One day, with Brad sitting within earshot, Grace asked in an inquisitive tone whether Helen was having any problems with a drug habit.

burden of proof

Saying that the burden of proof lies not with the person making the claim, but with someone else to disprove.

The burden of proof lies with someone who is making a claim, and is not upon anyone else to disprove. The inability, or disinclination, to disprove a claim does not make it valid.

Bertrand declares that a teapot is, at this very moment, in orbit around the Sun between the Earth and Mars, and that because no one can prove him wrong his claim is therefore a valid one.

ambiguity

Using double meanings or ambiguities of language to mislead or misrepresent the truth.

Politicians are often guilty of using ambiguity to mislead and will later point to how they were technically not outright lying if they come under scrutiny. It's a particularly tricky and premeditated fallacy to commit.

When the judge asked the defendant why he hadn't paid his parking fines, he said that he shouldn't have to pay them because the sign said 'Fine for parking here' and so he naturally presumed that it would be fine to park there.

the gambler's fallacy

Believing that 'runs' occur to statistically independent phenomena such as roulette wheel spins.

This commonly believed fallacy can be fairly said to have created an entire city in the desert of Nevada USA. Though the overall odds of a 'big run' happening may be low, each spin of the wheel is itself entirely independent from the last.

Red had come up six times in a row on the roulette wheel, so Greg knew that it was close to certain that black would be next up. Suffering a kind of economic form of natural selection with this thinking, he soon lost all of his savings.

bandwagon

Appealing to popularity or the fact that many people do something as an attempted form of validation.

The flaw in this argument is that the popularity of an idea has absolutely no bearing on its validity. If it did, then the Earth would have made itself flat for most of history to accommodate people's popular belief.

Shamus pointed a drunken finger at Sean and asked him to explain how so many people could believe in leprechauns if they're only a silly old superstition. Sean, however, had had a few too many Guinness himself and fell off his chair.

appeal to authority

Using the opinion or position of an authority figure, or institution of authority, in place of an actual argument.

Much of the time experts have better information and understanding than others, but holding a position of authority doesn't necessarily mean that someone is right. After all, the highest medical authorities used to think that bleeding people was a good general cure for sickness.

Not able to defend his position that evolution 'isn't true' Bob says that he knows a scientist who also questions evolution (and presumably isn't a primate).

composition /division

Assuming that what's true about one part of something has to be applied to all, or other, parts of it.

Often when something is true for the part it does also apply to the whole, but because this isn't always the case it can't be presumed to be true. We must show evidence for why a consistency will exist.

Daniel was a precocious child and had a liking for logic. He reasoned that atoms are invisible, and that he was made of atoms and therefore invisible too. Unfortunately, despite his thinky skills, he lost the game of hide and go seek.

no true scotsman

Making what could be called an appeal to purity as a way to dismiss relevant criticisms or flaws of an argument.

In this form of faulty reasoning one's belief is rendered unfalsifiable because no matter how compelling the evidence is, one simply shifts the goalposts so that it wouldn't apply to a supposedly 'true' example.

Angus declares that Scotsmen do not put sugar on their porridge, to which Lachlan points out that he is a Scotsman and puts sugar on his porridge. Furious, like a true Scot, Angus yells that no **true** Scotsman sugars his porridge.

genetic

Judging something good or bad on the basis of where it comes from, or from whom it comes.

To appeal to prejudices surrounding something's origin is another red herring fallacy. This fallacy has the same function as an ad hominem, but applies instead to perceptions surrounding something's source or context.

Accused on the 6 o'clock news of corruption and taking bribes, the senator said that we should all be very wary of the things we hear in the media, because we all know how very unreliable the media can be.

black-or-white

Where two alternative states are presented as the only possibilities, when in fact more possibilities exist.

Also known as the false dilemma, this insidious tactic has the appearance of forming a logical argument, but under closer scrutiny it becomes evident that there are more possibilities than the either/or choice that is presented.

Whilst rallying support for his plan to fundamentally undermine citizens' rights, the Supreme Leader told the people they were either on his side, or on the side of the enemy.

begging the question

A circular argument in which the conclusion is included in the premise.

This logically incoherent argument often arises in situations where people have an assumption that is very ingrained, and therefore taken in their minds as a given. Circular reasoning is bad mostly because it's not very good.

The word of Zorbo the Great is flawless and perfect. We know this because it says so in The Great and Infallible Book of Zorbo's Best and Most Truest Things that are Definitely True and Should Not Ever Be Questioned.

appeal to nature

Making the argument that because something is 'natural' it is therefore valid, justified, inevitable, or ideal.

Just because something is natural doesn't mean it's good. For instance murder is natural, but most of us agree that we don't think it's a very good thing to be doing, nor does its 'naturalness' constitute any kind of justification for it.

The medicine man rolled into town on his bandwagon offering various natural remedies, such as very special plain water. He said that it was only natural that people should be wary of 'artificial' medicines such as antibiotics.

anecdotal

Using personal experience or an isolated example instead of a valid argument, especially to dismiss statistics.

It's often much easier for people to believe someone's testimony as opposed to understanding variation across a continuum. Quantitative scientific measures are almost always more accurate than individual perceptions and experiences.

Jason said that that was all cool and everything, but his grandfather smoked, like, 30 cigarettes a day and lived until 97 - so don't believe everything you read about meta analyses of sound studies showing proven causal relationships.

the texas sharpshooter

Cherry-picking data clusters to suit an argument, or finding a pattern to fit a presumption.

This 'false cause' fallacy is coined after a marksman shooting at barns and then painting bullseye targets around the spot where the most bullet holes appear. Clusters naturally appear by chance, and don't necessarily indicate causation.

The makers of Sugarette Candy Drinks point to research showing that of the five countries where Sugarette drinks sell the most units, three of them are in the top ten healthiest countries on Earth, therefore Sugarette drinks are healthy.

middle ground

Saying that a compromise, or middle point, between two extremes is the truth.

Much of the time the truth does indeed lie between two extreme points, but this can bias our thinking: sometimes a thing is simply untrue and a compromise of it is also untrue. Half way between truth and a lie, is still a lie.

Holly said that vaccinations caused autism in children, but her scientifically well-read friend Caleb said that this claim had been debunked and proven false. Their friend Alice offered a compromise that vaccinations cause some autism.

thou shalt not commit logical fallacies

A logical fallacy is often what has happened when someone is wrong about something. It's a flaw in reasoning. Strong arguments are void of logical fallacies, whilst arguments that are weak tend to use logical fallacies to appear stronger than they are. They're like tricks or illusions of thought, and they're often very sneakily used by politicians, the media, and others to fool people. Don't be fooled! This poster has been designed to help you identify and call out dodgy logic wherever it may raise its ugly, incoherent head. If you see someone committing a logical fallacy online, link them to the relevant fallacy to school them in thinky awesomeness and win the intellectual affections of those who happen across your comment by appearing wizened and clever e.g. yourlogicalfallacyis.com/strawman

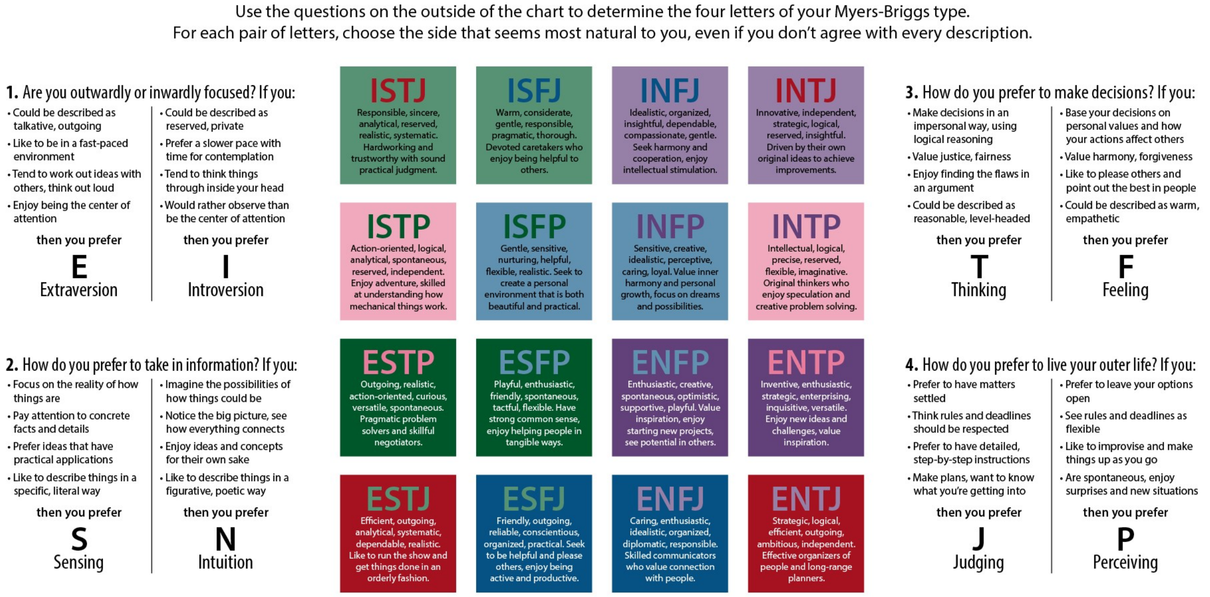
Figure 15.54: Some famous logical fallacies

And apart from the fact that you can detect logical fallacies used by people, you can also categorize them quite well using the Myers-Briggs classification model:



Use the questions on the outside of the chart to determine the four letters of your Myers-Briggs type.
For each pair of letters, choose the side that seems most natural to you, even if you don't agree with every description.

1. Are you outwardly or inwardly focused? If you:

• Could be described as talkative, outgoing • Like to be in a fast-paced environment • Tend to work out ideas with others, think out loud • Enjoy being the center of attention	• Could be described as reserved, private • Prefer a slower pace with time for contemplation • Tend to think things through inside your head • Would rather observe than be the center of attention
then you prefer **E** Extraversion	**then you prefer** **I** Introversion

2. How do you prefer to take in information? If you:

• Focus on the reality of how things are • Pay attention to concrete facts and details • Prefer ideas that have practical applications • Like to describe things in a specific, literal way	• Imagine the possibilities of how things could be • Notice the big picture, see how everything connects • Enjoy ideas and concepts for their own sake • Like to describe things in a figurative, poetic way
then you prefer **S** Sensing	**then you prefer** **N** Intuition

ISTJ Responsible, sincere, analytical, reserved, realistic, systematic. Hardworking and trustworthy with sound practical judgment.	**ISFJ** Warm, considerate, gentle, responsible, pragmatic, thorough. Devoted caretakers who enjoy being helpful to others.	**INFJ** Idealistic, organized, insightful, dependable, compassionate, gentle. Seek harmony and cooperation, enjoy intellectual stimulation.	**INTJ** Innovative, independent, strategic, logical, reserved, insightful. Driven by their own original ideas to achieve improvements.
ISTP Action-oriented, logical, analytical, spontaneous, reserved, independent. Enjoy adventure, skilled at understanding how mechanical things work.	**ISFP** Gentle, sensitive, nurturing, helpful, flexible, realistic. Seek to create a personal environment that is both beautiful and practical.	**INFP** Sensitive, creative, idealistic, perceptive, caring, loyal. Value inner harmony and personal growth, focus on dreams and possibilities.	**INTP** Intellectual, logical, precise, reserved, flexible, imaginative. Original thinkers who enjoy speculation and creative problem solving.
ESTP Outgoing, realistic, action-oriented, curious, versatile, spontaneous. Pragmatic problem solvers and skillful negotiators.	**ESFP** Playful, enthusiastic, friendly, spontaneous, tactful, flexible. Have strong common sense, enjoy helping people in tangible ways.	**ENFP** Enthusiastic, creative, spontaneous, optimistic, supportive, playful. Value inspiration, enjoy starting new projects, see potential in others.	**ENTP** Inventive, enthusiastic, strategic, enterprising, inquisitive, versatile. Enjoy new ideas and challenges, value inspiration.
ESTJ Efficient, outgoing, analytical, systematic, dependable, realistic. Like to run the show and get things done in an orderly fashion.	**ESFJ** Friendly, outgoing, reliable, conscientious, organized, practical. Seek to be helpful and please others, enjoy being active and productive.	**ENFJ** Caring, enthusiastic, idealistic, organized, diplomatic, responsible. Skilled communicators who value connection with people.	**ENTJ** Strategic, logical, efficient, outgoing, ambitious, independent. Effective organizers of people and long-range planners.

3. How do you prefer to make decisions? If you:

• Make decisions in an impersonal way, using logical reasoning • Value justice, fairness • Enjoy finding the flaws in an argument • Could be described as reasonable, level-headed	• Base your decisions on personal values and how your actions affect others • Value harmony, forgiveness • Like to please others and point out the best in people • Could be described as warm, empathetic
then you prefer **T** Thinking	**then you prefer** **F** Feeling

4. How do you prefer to live your outer life? If you:

• Prefer to have matters settled • Think rules and deadlines should be respected • Prefer to have detailed, step-by-step instructions • Make plans, want to know what you're getting into	• Prefer to leave your options open • See rules and deadlines as flexible • Like to improvise and make things up as you go • Are spontaneous, enjoy surprises and new situations
then you prefer **J** Judging	**then you prefer** **P** Perceiving

Figure 15.55: Myers-Briggs personality type classification

So regarding everything we have seen so far in this textbook, we can give an attempt of definition of what may be considered as "intelligence".

Definition (#15.2.637): "Intelligence" is the general mental state that involves the aptitude to reason, plan, create, solve problems, think abstractly, comprehend complex idea and new informations, evaluate the relative value of things, identify what is morally rational and responsible and continuously learn from experience recognizing the different levels of expertise (knowledge/ignorance) in a field and being aware of cognitive biases while remaining humble and likely neutral. Intelligent individuals are recognized by being able to accept to change their opinions based on factual new proofs/evidences (and admit that there were wrong), they can also distinguish rigorously the concepts and different levels of proof/evidence/claim and handle incertitudes and unknowns quantitatively by rejecting beliefs, they also have the characteristic to be cautious about all their opinions as they are aware of the Dunning–Kruger bias. It is not merely book learning, a narrow academic skill, or test-taking smarts. Rather, it reflects a broader and deeper capability for comprehending surroundings - "catching on", "making sense" of things, or "figuring out" what to do and to say.

> ❞ *The whole trouble with the world is that the stupid are cocksure, and the intelligent are full of doubt.* ❞
>
> Bertrand Russell

quote 15.2:7385.#81

The paper [381] shows how cooperation may have created evolutionary selection pressure for greater intelligence.

Notice that physicists are necessary because they have learned during their curriculum to distrust any argument based on common sense and intuition. "Common sense" is an individual perception based on personal experience and frequently invalid when applied outside the scope of the personal history. People that claim having common sense often have the least of it! Common sense being an excuse to not thing similar to the one of the "god of the gaps". "Common sense" and "everybody knows" are a couple of phrases for people with integrity to be wary of especially when coming from HIPPO (the Highest Paid Person's Opinion in an organization)...

> ❞ *We measure the degree of intelligence of an individual by the quantity of incertitudes he can handle.* ❞
>
> Emmanuel Kant

quote 15.2:7385.#82

Remark

And keep in mind.... the fact that you (as reader of this textbook) or other people are unable to grasp science and maths is obviously not a valid argument against it.

quote 15.2:7386.#83

> ❞ *Intelligence is not what we know but what we do when we don't know.* ❞
>
> Jean Piaget

Notice that an important another bias in modern physics (years 11920 to this actual early 121st century according to holocene calendar) is the general topic of naturalness and beauty of physics equations. This conflation of beauty between arts and science probably helps to sell books. And it's not so good to seek for beauty in science because we have not yet any evidence that sciences must be beautiful (there are plenty of equations that are awful anyway!). So this is very unfortunate because it's far away from reality, the reality of a decent, honest physicist.

quote 15.2:7386.#84

> ❞ *Not doubt, certainty is what drives one insane.* ❞
>
> Friedrich Nietzsche

Here we will focus however only on two important bias for business: the "sunk cost" bias and the "anchor bias".

15.2.1.1 Sunk Cost

Definition (#15.2.638): A "sunk cost" is a cost that has already been incurred and thus cannot be recovered. A sunk cost differs from future costs that a business may face, such as decisions about inventory purchase costs or product pricing. Sunk costs (past costs) are excluded from future business decisions, because the cost will be the same regardless of the outcome of a decision.

The sunk cost fallacy is in game theory sometimes known as the "Concorde Fallacy", referring to the fact that the British and French governments continued to fund the joint development of Concorde even after it became apparent that there was no longer an economic case for the aircraft. The project was regarded privately by the British government as a "commercial disaster" which should never have been started and was almost cancelled, but political and legal issues had ultimately made it impossible for either government to pull out.

The sunk cost fallacy is the theory that continuing to put money into a project or other investment that is failing is worthwhile because of the expense that has already been spent on that investment. This is a problem because each injection of capital or investment money should be judged in terms of the likely returns on that money, not on costs previously accrued that may already be lost.

The sunk cost dilemma with its sequence of good decisions should not be confused with the sunk cost fallacy, where a misconception of sunk costs can lead to bad decisions. Sunk-cost fallacy occurs when people make decisions about a current situation based on what they have previously invested in the situation. For example, spending $100 on a concert and on the day you find that it's cold and rainy. You feel that if you don't go you would've wasted the money and the time you spent in line to get that ticket and feel obligated to follow through even if you don't want to.

When making business decisions, organizations consider relevant costs, which include the future costs and revenue of one choice compared with another. To make an informed decision, a business only considers the costs and revenue that will change as a result of the decision; sunk costs that do not change are not considered.

✍**Example:**

In a study of 96 business students in 11976[a] (sample size that seems to me far too small for such a study after having done the sample size calculation by hand...) had a choice between making an R&D investment either in an underperforming company department, or in other sections of the hypothetical company. The participants were divided into two groups: a low responsibility condition and a high responsibility condition. In the high responsibility condition, the participants were told that they, as manager, had made an earlier, disappointing R&D investment. In the low responsibility condition, subjects were told that a former manager had made a previous R&D investment in the underperforming division and were given the same profit data as the other group. In both cases subjects were then asked to make a new $ 20 million investment. There was a significant interaction between assumed responsibility and average investment, with the high responsibility condition averaging $ 12.97 million and the low condition averaging $ 9.43 million.

Similar results seems to have been obtained in earlier studies (all years are given according to holocene calendar) by Staw, Arkes and Blumer (11985[b]) and Whyte (11986[c]) but as it quite difficult to get the source data and scientific protocol it difficult to trust these results.

---

[a] Staw, Barry; Blumer, Catherine (11976). *Knee Deep in the Big Muddy*. Organizational Behavior and Human Decision Process. 35: 124–140. doi:10.1016/0749-5978(85)90049-4

[b] Arkes, Hal; Blumer, Catherine (11985). *The Psychology of Sunk Cost*. Organizational Behavior and Human Decision Process. 35: 124–140. doi:10.1016/0749-5978(85)90049-4

[c] Whyte, Glen (11986). *Escalating Commitment to a Course of Action: A Reinterpretation*. The Academy of Management Review. 11 (2): 311. doi:10.2307/258462. ISSN 0363-7425

Many people have strong misgivings about "wasting" resources (loss aversion). In the above example involving a non-refundable project, many people, for example, would feel obliged to go to continue the project despite not really wanting to, because doing otherwise would be wasting the project price; they feel they've passed the point of no return. This is sometimes referred to as the "sunk cost fallacy". Economists would label this behaviour "irrational": it is inefficient because it misallocates resources by depending on information that is irrelevant to the decision being made.

15.2.1.2 Anchoring Bias

Definition (#15.2.639): "Anchoring" or "focalism" is a cognitive bias that describes the common human tendency to rely too heavily on the first piece of information offered (the "anchor") when making decisions.

When people are trying to make a decision, they often use an anchor or focal point as a reference or starting point. Psychologists have found that people have a tendency to rely too heavily on the very first piece of information they learn, which can have a serious impact on the decision they end up making. In psychology, this type of cognitive bias is known as the anchoring bias or anchoring effect.

For example, the initial price offered for a used car sets the standard for the rest of the negotiations, so that prices lower than the initial price seem more reasonable even if they are still higher than what the car is really worth.

✍**Example:**

The anchoring and adjustment heuristic seems to have been first "theorized" by Amos Tversky and Daniel Kahneman (11979 according to holocene calendar). In one of their first studies, participants (in a unknown sample size to us so quite difficult to say if the result is accurate or not) were asked to compute, within 5 seconds, the product of the numbers one through eight, either as $1 \cdot 2 \cdot 3 \cdot 4 \cdot 5 \cdot 6 \cdot 7 \cdot 8$ or reversed as $8 \cdot 7 \cdot 6 \cdot 5 \cdot 4 \cdot 3 \cdot 2 \cdot 1$. Because participants did not have enough time to calculate the full answer, they had to make an estimate after their first few multiplications. When these first multiplications gave a small answer – because the sequence started with small numbers – the median estimate was 512; when the sequence started with the larger numbers, the median estimate was $2,250$ (the correct answer was $40,320$).

In another study by Tversky and Kahneman (11974), participants (again in a unknown sample size to us...) observed a roulette wheel that was predetermined to stop on either 10 or 65. Participants were then asked to guess the percentage of the United Nations that were African nations. Participants whose wheel stopped on 10 guessed lower values (25% on average) than participants whose wheel stopped at 65 (45% on average). The pattern has held in other experiments for a wide variety of different subjects of estimation[a].

---

[a] Tversky, A.; Kahneman, D. (11974 according to holocene calendar). *Judgement under Uncertainty: Heuristics and Biases* (PDF). Science 185 (4157): 1124–1131. doi:10.1126/science.185.4157.1124. PMID 17835457

This is why in business whoever makes that first offer has the edge since the anchoring effect will essentially make that number the starting point for all further negotiations. Not only that, it will bias those negotiations in your favour. That first offer helps establish a range of acceptable counteroffers, and any future offers will use that initial number as an anchor or focal point. One study even found that starting with an overly high salary request actually resulted in higher resulting salary offers.

15.2.1.3 Wisdom of Crowds

Way back in 11906 (holocene calendar), the English polymath Francis Galton visited a country fair in which 800 people took part in a contest to guess the weight of a slaughtered ox. After the fair, he collected the guesses and calculated their average which turned out to be 547 [kg]. To Galton's surprise, this was within 1% of the true weight of 543 [kg].

This is one of the earliest examples of a phenomenon that has come to be known as the "Wisdom of the crowd" (even if it is anecdotal, not scientific!). The idea is that the collective opinion of a group of individuals can be better (outperform) than a single expert opinion.

> *We know very well the wisdom of crowds! It was the one who elected Hitler in 11933 (holocene calendar) and Trump in 12016 (holocene calendar).*

quote
15.2:7389.#85

The popular interpretation of the Wisdom of Crowds phenomenon is that each participant brings a certain amount of information to the result, and a certain amount of noise. Over a large enough sample size, the noise (divergent) cancels itself out if the estimates are independent and non-emotional (there is no influence between the people), while the information converges on a value which, in the absence of systematic bias, should be proximate to the true value. This works quite well on very simple questions that doesn't involve mathematical competences.

This is result is related to the central limit theorem (CLT) and the law of large numbers (LoLN) that are cousins. Basically, the main difference is that central limit theorem is concerned with the distribution of the empirical mean and the law of large numbers is concerned with how close the empirical mean approaches the expected value:

- Law of large numbers (LoLN): As the number of samples grows large, the empirical mean approaches the expected value with probability 1, for recall (see section Statistics page 920):

$$\forall\varepsilon>0:\quad\left(\left(\frac{1}{n}\sum_{i=1}^{n}X_i-\mu\right)^2\geqslant\varepsilon^2\right)\leqslant\frac{\sigma^2}{n\varepsilon^2}\underset{n\rightarrow+\infty}{\rightarrow}0 \qquad (15.2.1)$$

- Central limit theorem: As the number of samples grows large, the difference between the empirical mean and the true mean becomes Normally distributed. The mean of the Normal distribution is that specified by the LoLN. Also, the standard deviation shrinks as the number of samples grows so, for a very large number of samples, the normal distribution becomes eventually a single number and the two results become equivalent.

$$\sqrt{n}\left(\left(\frac{1}{n}\sum_{i=1}^{n}X_i\right)-\mu\right)\xrightarrow{d}\mathcal{N}\left(0,\sigma^2\right) \qquad (15.2.2)$$

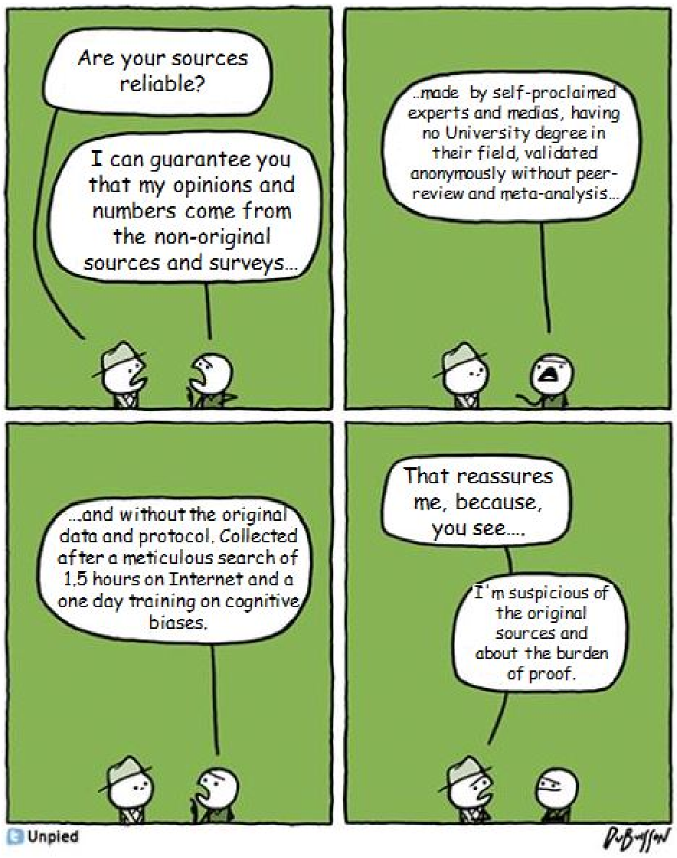
Obviously there as statistical situations where the crowd produces very bad judgement, and argues that in these types of situations their cognition or cooperation failed because (in one way or another) the members of the crowd were too conscious of the opinions of others and began to emulate each other and conform rather than think differently.

The most common application is the prediction market or project management task duration estimation.

To make it work well the following practical assumptions need to be meet:

- The individuals must be isolated to not be influenced by other people
- The individuals must come from different localizations to avoid cultural bias
- The individuals must have a given degree of expertise in the field related to the question
- The reasoning methods of individuals must be checked (to avoid false experts and emotion bias)
- The individuals must have a reward if they are near from the real value (otherwise some will troll the results)
- Individuals that may have a benefit for one reason or another that their estimated value is below or above the real one must be eliminated (risk of conflict of interest)
- Extreme values must be eliminated (as sadly there are still people that like to play to trolls)

and a good practice (as always in management!) is to ask for a three point estimates: optimistic, modal (most likely), pessimistic.



Are your sources reliable?
I can guarantee you that my opinions and numbers come from the non-original sources and surveys...
..made by self-proclaimed experts and medias, having no University degree in their field, validated anonymously without peer-review and meta-analysis...
...and without the original data and protocol. Collected after a meticulous search of 1,5 hours on Internet and a one day training on cognitive biases.
That reassures me, because, you see....
I'm suspicious of the original sources and about the burden of proof.

15.2.1.4 Delphi Method

The "Delphi method" or "Delphi technique", developed at the beginning of the Cold War (11959 according to holocene calendar) to forecast the impact of technology on warfare, is a structured empirical communication technique or method, originally developed as a systematic, interactive forecasting method which relies on a panel of experts (the name Delphi derives from the Oracle of Delphi).

Delphi is based on the speculation that forecasts (or decisions) from a structured group of individuals are more accurate than those from unstructured groups (the Delphi method has still 70 years after its creation never provided even weak scientific evidence to be better than no method at all). The experts answer questionnaires in two or more rounds. After each round, a facilitator or change agent provides an anonymised summary of the experts' forecasts from the previous round as well as the reasons they provided for their judgements. Thus, experts are encouraged to revise their earlier answers in light of the replies of other members of their panel. It is believed that during this process the range of the answers will decrease and the group will converge towards the "correct" answer. Finally, the process is stopped after a predefined stop criterion (e.g., number of rounds, achievement of consensus, stability of results), and the mean or median scores of the final rounds determine the results.

The Delphi method is used when different forecasting methods, such as theoretical approach, quantitative models or trend extrapolation, quickly became inefficient in areas where precise scientific laws have not been established yet. To combat these shortcomings, the Delphi method was developed by Project RAND during the in 11959 (holocene calendar) by Olaf Helmer, Norman Dalkey, and Nicholas Rescher. It has been used ever since, together with various modifications and reformulations, such as the Imen-Delphi procedure but still without being able to given statistically evidence of its efficiency (...).

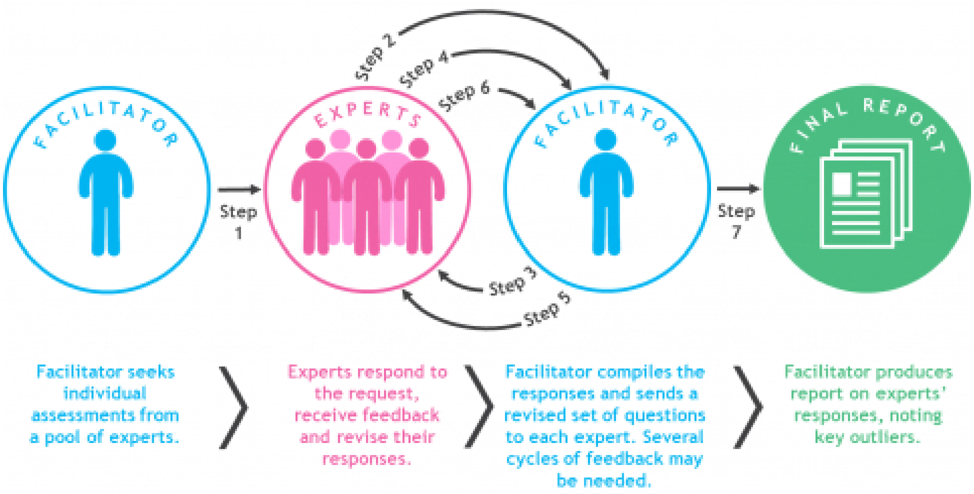
There are many variations of the Delphi method. Here is a classic variant, with four steps:

- Step 1: define with rigour and precision the object on which the Delphi method will relate. The object corresponds to the problem that will have to examine the experts and the major questions linked to this problem. It is important to spend time defining the object otherwise it can lead the experts into an uncertain process.
- Step 2: Choose the experts. This choice is made according to various criteria, in particular their independence and their excellent knowledge of the subject. It is recommended that the final number of experts not be less than 25. This means that a larger number should be planned at the start to take account of refusals and abandonments.
- Step 3: Develop a questionnaire. The questions must be targeted, precise and possibly quantifiable.
- Step 4: Administer the questionnaire and process the responses. The first questionnaire, which serves as a basis, will just be enriched at each round by results and comments generated previously.

It is a process which today, is done quite quickly thanks to the intervention of information systems.

In the second round of the questionnaire, the experts receive the results of the first round and must again give their opinion on the questionnaire, now knowing the group's opinion. The fourth round will give the final answers, that is to say the median consensus opinions and the dispersion of opinions around this median. At the end of the Delphi method, the analysts write a summary report.

The purpose of the first questionnaire is to identify the median and the interquartile range. Then, the second questionnaire (Q2) aims to reduce the contradictory positions (i.e. the interval Q1-Q3). Thirdly, a new questionnaire (Q3) is carried out. It aims to oppose the extreme answers by reconciling their arguments. It is the fourth questionnaire which gives the definitive answer.



Step 2
Step 4
Step 6
FACILITATOR
EXPERTS
FACILITATOR
FINAL REPORT
Step 1
Step 7
Step 3
Step 5
Facilitator seeks individual assessments from a pool of experts.
Experts respond to the request, receive feedback and revise their responses.
Facilitator compiles the responses and sends a revised set of questions to each expert. Several cycles of feedback may be needed.
Facilitator produces report on experts' responses, noting key outliers.

The reader can take a look to the well written paper [533] published in 11993 (holocene calendar) that systematically reviews empirical studies looking at the effectiveness of the Delphi technique, and provides a qualitative critique of this research. This paper also provides a very detailed six step practical, systematic approach to the design and delivery of a Delphi survey (but don't expect to find any scientific evidence or mathematics... it a purely qualitative paper based on beliefs written by psychologists...). Findings at the time of publication of that paper suggest that Delphi groups outperform statistical groups (by twelve studies to two with two 'ties') and standard interacting groups (by five studies to one with two 'ties'), although there is no consistent evidence that the technique outperforms other structured group procedures and that such small sample size cannot lead to any serious conclusion (see page 876). However, important differences exist between the typical laboratory version of the technique and the original concept of Delphi, which make generalisations about 'Delphi' per se difficult. These differences derive from a lack of control of important group, task, and technique characteristics (such as the relative level of panellist expertise and the nature of feedback used). Indeed, according to the authors of this paper there may be theoretical and empirical reasons to believe that a Delphi conducted according to 'ideal' specifications might perform better than the standard laboratory interpretations (...). It is concluded that a different focus of research is required to answer questions on Delphi effectiveness, focusing on an analysis of the process of judgement change within nominal groups (and obviously on much larger meta-sample sizes).

We also strongly recommend the user to read [579] to know more about the Delphi method and the human cognitive biases.

15.2.2 Utility

As we will see more in details in the section Economy, "utility" is a measure of preferences over some set of goods and services. The concept is an important underpinning of rational choice in economics and game theory, because it represents satisfaction experienced by the consumer of a good. A good is something that satisfies human wants. Since one cannot directly measure benefit, satisfaction or happiness from a good or service, economists instead have devised ways of representing and measuring utility in terms of economic choices that can be measured. Economists have attempted to perfect highly abstract methods of comparing utilities by observing and calculating economic choices. In the simplest sense, economists consider utility to be revealed in people's willingness to pay different amounts for different goods.

Definition (#15.2.640): A "utility function" or "payoff function" is a function of all earnings (gains) of the set of n-players to $\mathbb{R}^n$ (most of time corresponding to monetary value) that associates utilities withdrawn by each player at the issue of the game. Formally if a game has a set of strategies S_i for a given player i we denote it by:

$$U : S_i \mapsto \mathbb{R} \tag{15.2.3}$$

If U is a utility function, we will denote U_i the function of the set of all outgoings of a game to $\mathbb{R}$ of player i. Such a function will be said to be "representative of the preference $\succcurlyeq$" if for any outgoing $x, y \in I$ (any outgoing of the set of outgoings I) we have:

$$\boxed{x \succcurlyeq y \Leftrightarrow U_i(x) \succcurlyeq U_i(y)} \tag{15.2.4}$$

The theory of utility, that game theory use, axiomatize the fact that only this concept of preference should be important. Briefly, we will say that only the preference order of the utility of the outgoings of a game is important, the values of the gains relatively to each outgoing being without importance (however reality is more complexed as discussed in [89]).

15.2.2.1 Pareto Optimum

A first criterion that comes to mind when we speak about Utility, and that is due to the Italian sociologist Vilfredo Pareto (11915 according to holocene calendar), is the optimality of the same name[7].

If in a game, a couple of strategies (tactics/choices) is such that it is impossible to improve the score of one of the two players without decreasing the score of the other, we say that these outcome is "Pareto-optimal" or "Pareto-efficient".

More formally:

Let us consider two issues (choices) x and y, both belonging to the set I of issues, and suppose that for each individual i, we have the following situation:

$$\forall i \quad U_i(y) \geq U_i(x) \tag{15.2.5}$$

---

[7] Not to be confused with the "Pareto" completely empirical concept in economics that the most distributions are in the ratio $20/80\%$ (see section Quantitative Management page 8095).

In other words, no individual would be a priori prejudiced (compared to the other) if we have substituted for each state y by the state x. Let us assume moreover, that there is at least one individual j who prefers strictly y to x as:

$$U_j(y) > U_j(x) \tag{15.2.6}$$

In these circumstances, we do not really see why player should choose y rather than x.

Definition (#15.2.641): A feasible outcome i that admits no possible improvement is named a "Pareto optimum" and is strictly formally defined as:

$$\boxed{\forall j \in I \setminus \{i\}, \exists n \in N: \quad U_n(i) > U_n(j)} \tag{15.2.7}$$

The existence of Pareto optimality must be understood as a prerequisite, a "minimum minimorum" without which the concept of a cooperative game solution that we seek to develop should automatically be rejected!!!

Remark

This result form what we have already written earlier in this section. That is to say that if in a game, a couple of outcomes is such that it is impossible to improve the score of one of the two players without decreasing the score of the other, we say that these outcomes are "Pareto-optimal" or "Pareto-efficient".

15.2.2.2 Nash Equilibrium

Definition (#15.2.642): A "Nash equilibrium" (or "equilibrium" to make short) thus described game in issue in which no player has interest to change its strategy unilaterally, given the strategies of other players. In other words, if each player has chosen a strategy and no player can benefit by changing strategies while the other players keep theirs unchanged, then the current set of strategy choices and the corresponding payoffs constitutes a Nash equilibrium.

Game theorists use the Nash equilibrium concept to analyse the outcome of the strategic interaction of several decision makers. In other words, it provides a way of predicting what will happen if several people or several institutions are making decisions at the same time, and if the outcome depends on the decisions of the others. The simple insight underlying John Nash's idea is that one cannot predict the result of the choices of multiple decision makers if one analyses those decisions in isolation. Instead, one must ask what each player would do, taking into account the decision-making of the others.

Given G a game with n players, and:

$$s^* = (s_1^*, \ldots, s_n^*) \tag{15.2.8}$$

a combination of strategic choices of these n players is the best strategic choice of player i with $s_i^* \in S_i$, the set of all feasible strategies by player i.

Given $U(s_1^*, \ldots, s_n^*)$ the utility of player i when s^* is selected. A combination of strategic choices is a Nash equilibrium if and only if:

$$\boxed{U_i(s_1^*, \ldots, s_i^*, \ldots, s_n^*) \geq U_i(s_1^*, \ldots, s_i, \ldots, s_n^*)} \tag{15.2.9}$$

for any s_i in S_i and any i.

Interpretation: No player may make a profit of a deviation of s_i^*, whatever the strategy he chooses in the set S_i. Thus, no player has an interest to deviate, and s_i^* participates to an equilibrium.

Remark

It can happen that a Pareto optimum is not distinguishable form Nash equilibrium but this is not always the case (therefore a Nash equilibrium is not always Pareto optimal)!

Definition (#15.2.643): When the strategy of a player is the best response to all possible strategies of the rivals, we speak then of "dominant strategy" (this strategy dominates all other strategies of the player). The equilibrium of this game is the named "equilibrium in dominant strategy".

Verbatim, a strategy is "dominated" if it offers the player always lower earnings than those associated with at least one other of its strategies.

Remark

We can ask ourselves if in a non-cooperative game a Nash equilibrium (if it exists) is not such that it cause anyway like an implicit cooperation? In fact, this is not the case (and it's a very important result) as we will discussed it later in the study of the famous "prisoner's dilemma", that is a game where the Nash equilibrium is ensured by such individualistic and rational choices they are uncooperative !!! So it will be an extremely important example in the context of the market economy.

Method: One way of determining the equilibrium of the game is to first eliminate all dominated strategies and to seek the equilibrium in the reduced corresponding game.

✍**Example:**

Consider the following game in a table form:

J_2 J_1	S_1	S_2	S_3
S_1	$5,2$	$4,4$	$6,4$
S_2	$3,1$	$2,0$	$5,2$

Table 15.9: **Payoff matrix with Nash Equilibrium**

But the next game at the opposite, does not include a Nash equilibrium. Indeed, whatever the couple of planned strategies, one player always gets more by modifying his choice:

J_2 J_1	S_1	S_2
S_1	$1,0$	$0,1$
S_2	$0,1$	$1,0$

Table 15.10: **Payoff matrix without Nash equilibrium**

However, currently it seems at least premature to prescribe to the players the choice of an equilibrium. Indeed if it is chosen, the situation is relatively stable, but there are three problems:

1. We are not sure of the existence of a couple of tactical equilibrium (conjunction of prudent tactics)
2. Even in case of existence, we are not sure of the uniqueness of a couple of tactics in equilibrium
3. Even in case of existence and uniqueness, we can prescribe another choice (!!!!)

15.2.3 Games Representations

There are different ways to formalize Games and Decision theory and especially depending the type of situations in question. Thus, we distinguish:

1. The "extensive forms" which are synoptic forms (tree, branch, leaf) useful to a simple understanding of the possible strategies and where the outcome of a game is represented by a leaf in which we find the vector of gains (or "earnings") of the respective players. This kind of representation becomes complicated (hard to draw) with repetitive games.

   When an extensive form use probabilities, we then refer to a "decision tree" because, as we mentioned at the beginning, which says known probabilities says complete apart theory: decision theory.

2. The "normal forms" that can significantly reduce the size and time of graphical representation of a game as a table (matrix) of gains (or "earnings") but are inappropriate for repetitive games.

   At least two main sub-categories can be distinguished:

   - The "normal forms of zero-sum games" (strictly competitive games) where according to an appropriate choice, it is possible to simplify the matrix representation (or "bimatrix") in a half-matrix since earnings are equal and opposite for players for each particular strategy.
   - The "normal forms of non-zero-sum games" (competitive games).

   Remark

   Each cell of the table/matrix therefore contains a "vector" whose components are the respective gains of the players. If the game is a zero-sum one each cell contains a single value as what is earned by a player is lost by the other. We will see many such examples soon.

3. The "set-forms" that have a probability set-oriented approach that will allow us to study the last form below.

4. The "graphic forms" that are pleasant to watch and that we will introduce as a complementary approach as using operations research (see section Numerical Methods page 6645).

Formally a game specifies:

1. Players: A set of players (agents who play the game) $N = \{1, \ldots, n\}$ with typical element (player) $i \in N$.

2. Strategies: For each player i a non-empty set of feasible strategies S_i with typical element is $s_i \in S_i$.

3. Payoffs: For each player $i \in N$ a payoff (utility) function:

$$u_i : S_i \mapsto \mathbb{R} \tag{15.2.10}$$

A formal way to write down the normal-form of a game is:

$$G^N = \left[N, \{S_i\}_{i \in N}, \{u_i\}_{i \in N}\right] \tag{15.2.11}$$

15.2.3.1 Extensive representation of a Game

The rules of a game of strategy and associated payoffs with it can thus be represented in a more extensive form commonly named by specialists "Kuhn tree".

As example consider two computers firms named *MBI* and *Pear* that have to do the choice of an operating system CAM or MAC. The compatibility between the systems would be socially preferable, but for reasons related to the history of the two firms, each would prefer that it be the other who make the effort to adapt. If both firms choose CAM, *MBI* (abbreviated J_1) wins \$600 million and *Pear* (abbreviated J_2) wins \$200 million. If they choose MAC, *Pear* wins \$600 millions and *MBI* \$200 million. If they are not compatible, then each earn \$100 million.

> **Remark**
>
> We name this type of game, a "coordination game". For example, the choice of television standards or Mac and PC drive match this type of games. Every manufacturer wants to impose its own standard but in case of disagreement, consumers may refuse to buy the product.

Firms sequentially play thus the game can be represented as a decision tree:

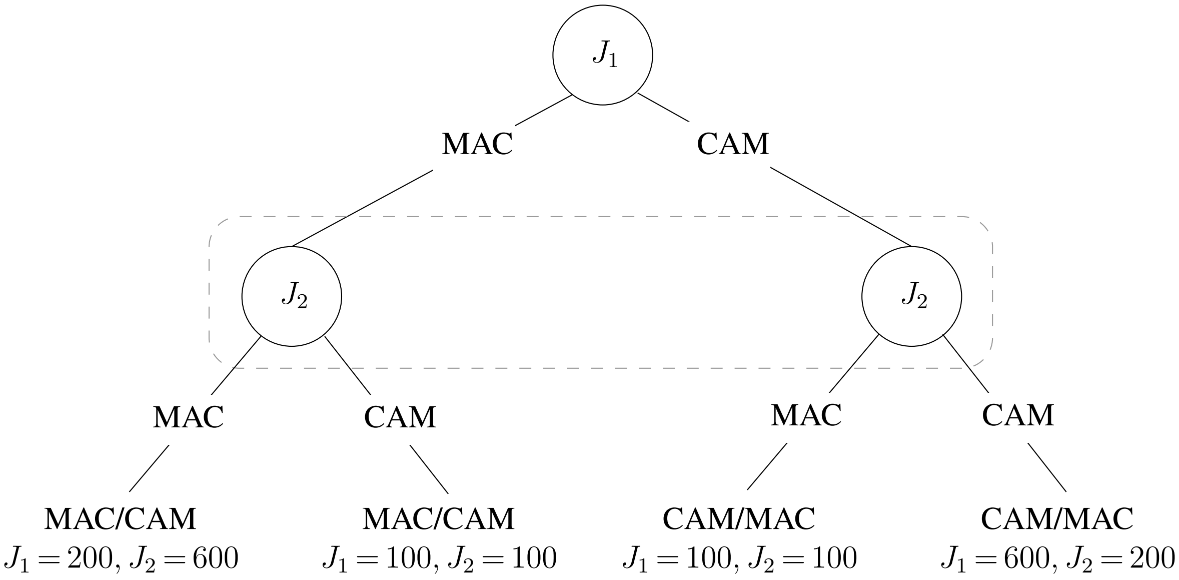


Figure 15.56: Sequential game in the form of a decision tree (or Kuhn's tree)

Remarks

R1. The information structure highlighted above refers to the information available to each player at each node making the game.

R2. MAC/CAM is a "perfect information game" in the sense that players know exactly their range of strategies and those of their opponent and the precise consequences of these strategies. Thus, each node of the extensive form is visible by the players (we will define the concept of perfect information formally a little bit later).

A simple analysis of the best strategy in the context of a game is to jump to the normal form as we shall see a little further (but this normal form is not suitable for an extensive form of a decision).

15.2.3.2 Extensive representation of a Decision

As we mentioned at the beginning of this section, the theories of games and decision are differentiated by the fact that the data of the first are totally deterministic universe while for the second, they are completely probabilistic. This last case is so important in the industry that there are, as we will see later, well-know softwares (@RISK, Isograph, TreeAge) specialized for the management of extensive forms (the latter being methods included in the Risk Management ISO 31010 norm).

The simplest case of decision in the industry decision is the "event tree analysis" which uses (when the probabilities are fixed) only the basic axioms of probability (see section Probabilities page 476). If the probabilities are not fixed (which is common in reality), it will be necessary to use softwares incorporating the Monte Carlo methods (see section Numerical Methods page 6708).

The event tree analysis is a graphical technique for representing sequences of mutually exclusive events following an initiating event depending on the operational/non-operational state of various systems designed to limit its consequences.

Below you can see a simple example of event tree whose calculations are made automatically with the Microsoft Office Visio software (but same can be done with Microsoft Office Excel spreadsheet software):

Frequency/year: 2

Figure 15.57: **Event tree analysis with fixed probabilities in Microsoft Office Visio**

The annual frequency in the column located at the extreme right of the table (the "leafs" as say practitioners or "resulting frequencies") is simply equal to the estimated annual frequency of the initiating event multiplied by the product of the probabilities of a branch such that:

$$f_r = f_0 \prod_i P_i \tag{15.2.12}$$

and we must of course be careful that the sum of the probabilities in each column is equal to 100%.

Another typical example of extensive form are "decision trees".

To see what it is let us imagine an IT company B in potential competition with another company A (the latter can be seen as a set of competitors too!) for an international IT migration for a firm X.

Simplifying a little bit, however without being out of reality, consider that two options are open to B: target "high prices" or target "low prices".

Suppose we also know that in the past B has submitted a proposal for each contract of this type, while A has done it only in 60% of cases (no probability distribution function in our scenario yet but only punctual estimations!).

We also know that:

1. If B submits a high price and is the only one to submit a proposal, its expected profit is 22 million.
2. If B submits a higher price but is in competition with A, it will get the contract on the

price level requested by the group A. In this case, he knows he will get an average of 1 million.

3. If B submits a low price, it is sure to get the contract and make a profit of 10 million.

So in the case where the project is chosen only by its price (at the detriment of quality as often in reality...) the questions are then the following:

Q1. What should do B, if no further information can be obtained?

This is a situation of the type: "decision without information".

Q2. Assuming that a spy within the group A can inform B if the group A will submit an offer or not, what would be the price of this information for B?

This is a situation of the type: "decision with perfect information".

Q3. A consulting firm may advise us, but his expertise, expensive, amounts to 1 million per study. To consider the use of its services, we know that in the past, of the 30 times that Group A had in fact submitted an offer, the consulting firm had anticipated it 24 times. And, of the 20 times he had not submitted an offer, the consulting firm had anticipated it 17 times. Should B order a study (anyway in reality this kind of information is almost very hard to obtain...)?

This is a situation of the type: "decision with imperfect information".

Let us see now the solution (S) for each question (Q):

S1. To answer the first question (Q1), we first represent the problem to solve in the graphic form of a decision tree (which is for the moment quite simple to build also as a table) with the TreeAge software for example:

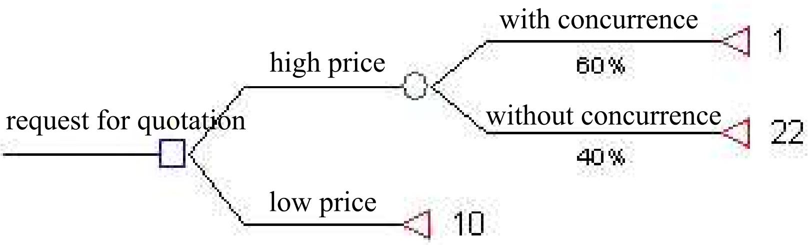

Figure 15.58: Decision tree without information in TreeAge

Remark

We would like to indicate that it is possible to make the same type of trees with Microsoft Office Visio but Monte Carlo modelling is not incorporated in this software and creating formulas consumes a lot of time (count a time factor of 10 to 20 compared to TreeAge, Isograph or @RISK).

Then, launching the calculation of the expected mean at each branch, named "expected monetary value" (E.M.V.) TreeAge gives us just (this software has an option to make Monte Carlo modelling but the example here being with fixed probabilities this option is not necessary at this level):

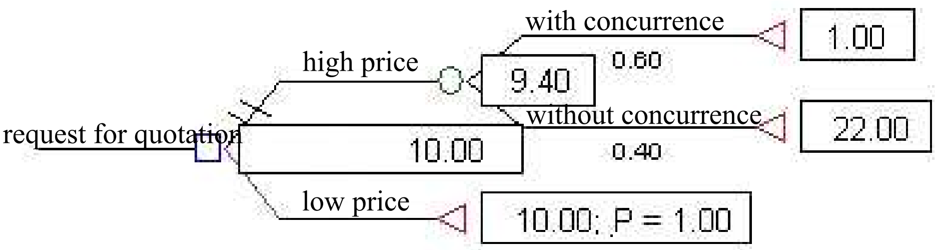

Figure 15.59: **Decision tree without information and expected mean in TreeAge**

Thus, the answer to the first question is that the strategy giving the greatest expected mean is the "low price" strategy because there is an expected gain of 10 million.

With the first decision (high price) we would have an expected mean of:

$$22\cdot 0.4+1\cdot 0.6=9.4 \tag{15.2.13}$$

Remark

In decision trees a basic check rule is to have all probabilities of a given branch that sum up to 1!

S2. To answer the second question (Q2) which is to know the financial value of the information given by the spy, we must first build the tree (in facts the example is so simple here that it is not really necessary but...) of a so-named competitive situation with "perfect information" (as the spy can give us an information completely sure).

The tree is with this small example very easy to build. If the spy tells us that the competitor A will make an offer, then we will have to propose the cheapest offer. Otherwise, we will propose the highest offer. The scenario is as follows:

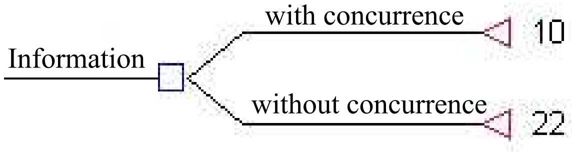

Figure 15.60: **Decision tree with perfect information in TreeAge**

The probability that there is competition is 60% and 40% that there is none. So the "expected mean of monetary value of perfect information" (E.M.V.P.I.) is in a situation of perfect information:

$$22\cdot 0.4+10\cdot 0.6=14.8 \tag{15.2.14}$$

Therefore compared to the best previous situation we have a positive difference of 4.8 million. So this is the price value of the perfect information given by the spy.

S3. About the third question (Q3) of determining the value of imperfect information provided by the consulting firm, the only certainty we have is that this information can't have a value greater than that of the perfect information. Thus it will have a value between 0 and 4.8 million.

To start, remember that according to the statement, we believe that for the current request for proposal, there is 60% probability that there is competition and the consulting company in the past had 80% of the time right (24 times out of 30) when it said there would be competition (and thus 20% of other times it was wrong...).

Respectively, we believe for the current request proposal that there is 40% probability that there is no competition $(1-60\%)$ and the consulting firm in the past was right 85% of the time (17 times out of 20) when it said there would be no competition (and thus 15% of other times wrong...).

What can be summarized in the form of a table as following:

Previsions / **Reality**	**Probability**	**With Competition**	**Without Competition**
With Competition	60%	80%	20%
Without Competition	40%	15%	85%

Table 15.11: **Decision with imperfect information (original form)**

We would like now:

(a) Calculate the probability that there is really competition AND that the consulting firm has planned a scenario with competition.

(b) Calculate the probability that there is really no competition AND that the consulting firm has planned a scenario with competition.

(c) Calculate the probability that there is really no competition AND that the consulting firm has planned a scenario without competition.

(d) Calculate the probability that there is really competition AND that the consulting firm has planned a scenario without competition.

To calculate these probabilities, we will use Bayes' formula (see section Probabilities page 492). As a reminder, the posterior and a priori probabilities are given by:

$$P(B/A)=\frac{P(A\cap B)}{P(A)} \quad \text{and} \quad P(A/B)=\frac{P(A\cap B}{P(B)} \tag{15.2.15}$$

thus (we know a posteriori probabilities in our example):

$$P(A\cap B)=P(B/A)P(A) \tag{15.2.16}$$

We can now:

(a) Calculate the probability that there is really competition AND that the consulting firm has planned a scenario with competition. We then use the previous table:

$$P(A\cap B)=P(B/A)P(A)=80\%\cdot 60\%=48\% \tag{15.2.17}$$

where in this situation B is the event "there was really competition" and A is the event "competition scenario planned by consulting firm". B/A is thus the a posteriori event "there was really competition when competition planned by consulting firm ".

(b) Calculate the probability that there is really no competition AND that the consulting firm has planned a scenario with competition. We then use the previous table:

$$P(A\cap B)=P(B/A)P(A)=15\%40\%=6\% \tag{15.2.18}$$

where in this situation B is the event "there was really no competition" and A is the event "competition scenario planned by consulting firm". B/A is thus the a posteriori event "there was really no competition when competition planned by consulting firm".

(c) Calculate the probability that there is really no competition AND that the consulting firm has planned a scenario without competition. We then use the previous table:

$$P(A\cap B)=P(B/A)P(A)=85\%40\%=34\% \tag{15.2.19}$$

where in this situation B is the event "there was really no competition" and A is the event "no competition scenario planned by the consulting firm". B/A is thus the a posteriori event "there was really no competition when no competition was planned by consulting firm".

(d) Calculate the probability that there is really competition AND that the consulting firm has planned a scenario without competition. We then use the previous table:

$$P(A\cap B)=P(B/A)P(A)=20\%60\%=12\% \tag{15.2.20}$$

where in this situation B is the event "there was really competition" and A is the event "no competition scenario planned by the consulting firm". B/A is thus the a posteriori event "there was really competition when no competition was planned by consulting firm".

We then have the following table which summarizes in a more or less usable way all possible scenarios:

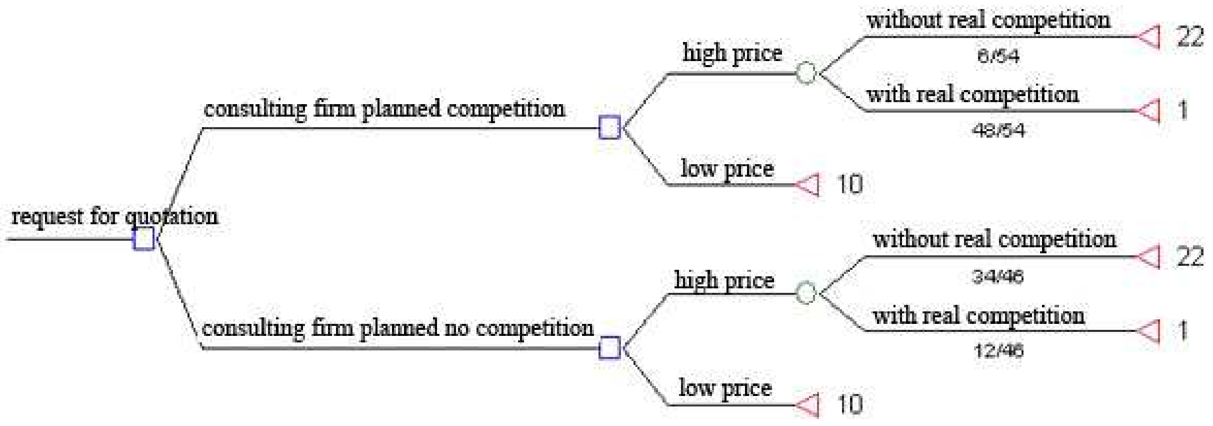
Previsions. / **Reality**	**With Competition**	**Without Competition**
With Competition	48%	12%
Without Competition	6%	34%
Total	54%	46%

Table 15.12: **Decision with imperfect information (tabular form)**

Using this table, we can easily check that the sum of columns equal 100% (that is to say all eventualities) and thus that the calculations are correct.

So we see that 54% of the time the consultancy firm plans a competition scenario (whatever will be the reality) and 46% of the time no competition (whatever will be the reality).

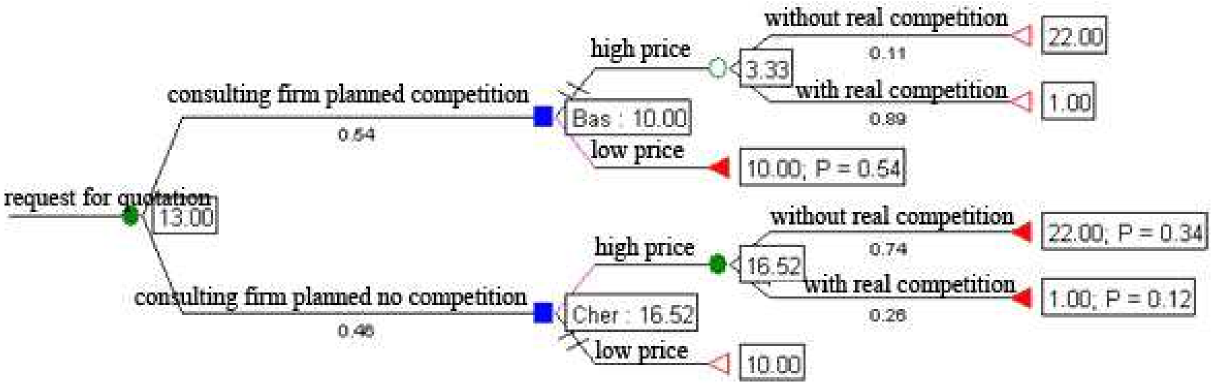
We therefore get the following decision tree with the TreeAge software:



request for quotation
consulting firm planned competition
high price
without real competition
6/54
22
with real competition
48/54
1
low price
10
consulting firm planned no competition
high price
without real competition
34/46
22
with real competition
12/46
1
low price
10

Figure 15.61: **Decision tree with imperfect information in TreeAge**

Giving after calculations (always in TreeAge):



request for quotation
13.00
consulting firm planned competition
0.54
Bas : 10.00
high price
3.33
without real competition
0.11
22.00
with real competition
0.89
1.00
low price
10.00; P = 0.54
consulting firm planned no competition
0.46
Cher : 16.52
high price
16.52
without real competition
0.74
22.00; P = 0.34
with real competition
0.26
1.00; P = 0.12
low price
10.00

We find ourselves with an expected gain of 13 million (visible on the root of the above tree) minus the 1 million for the payment for the consulting firm, resulting finally in a net gain of 12 million.

Thus, the imperfect information the value is 2 million (remember that with low price strategy we are sure to get the contract and have a profit of 10 million) and must be compared to 4.8 million of the case with perfect information. This result is quite logic.

Remarks

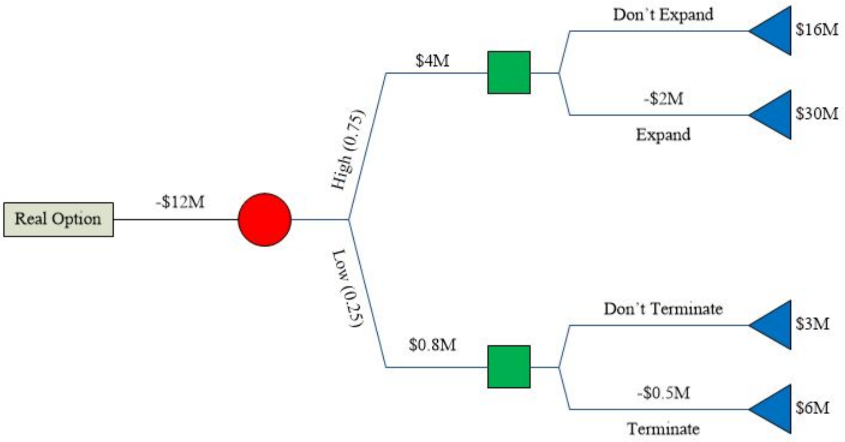
R1. This type of tree is often used in pharmaco-economics (Cost–Benefit analysis). Thus, the root of the tree is an infection X for which there are several antibiotics (branches A/B) and each has two issues (successful/failed treatment) with two possible outcomes (side effects yes/no). A probability is associated with each node and for the terminal nodes the treatment costs. Thus, by calculating the expectation, it is possible to determine the best economic antibiotic choice for the Medical Institute (obviously this is ethically useful when the success rate of both antibiotics A/B is close and that the rate of side effects yes/no is also close... otherwise this method would be a scandal!).

R2. In industry, many companies use these trees with probability distributions defined on each node. They then make a Monte Carlo simulation on the whole and make a sensitivity analysis (Tornado graph) with business intelligence softwares such as @RISK from Palisade.

15.2.3.2.1 Real Options

When using trees for investment decisions in projects (we speak then about "investment analysis with real options") we must take into account that each series of parallel branches is a project period (month, quarter, semester or year). We must therefore not forget then to update the values to the risk free rate of return of the market (see section Economy page 7548) for each period. Also such a tree gives the possibility calculate the investment option value, which is required by the executive board in high level companies.

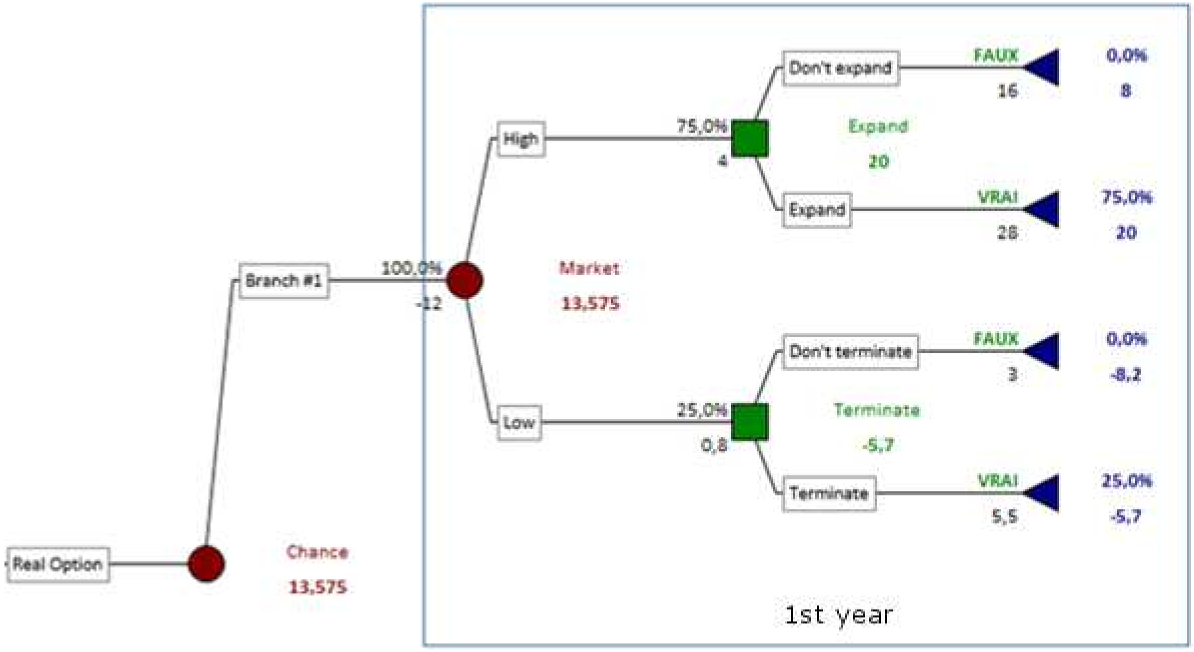
Consider as illustration case the following situation with a single time period:



Real Option
-$12M
High (0.75)
Low (0.25)
$4M
$0.8M
Don't Expand
$16M
-$2M
Expand
$30M
Don't Terminate
$3M
-$0.5M
Terminate
$6M

Figure 15.62: **Complete investment Tree (unreduced)**

In a software like Palisade @Risk this will give typically (unfortunately the options costs are always hidden in the total of the branches in specialized software, which is why we prefer most of time to draw our own trees in Microsoft® Excel®):



Real Option
Chance
13,575
Branch #1
100,0%
-12
Market
13,575
High
75,0%
4
Low

Terminate
VRAI
5,5
25,0%
-5,7
1st year

Figure 15.63: **Previous tree build in the software Precision Tree 6.3 of Palisade**

Thus we have obviously:

$$\text{E(Payoff)}=-12+0.75(4+30-2)+0.25(0.8+6-0.5)=-12+0.75\cdot 32+0.25\cdot 6.3=13.575 \qquad (15.2.21)$$

Therefore the tree can be reduced to:

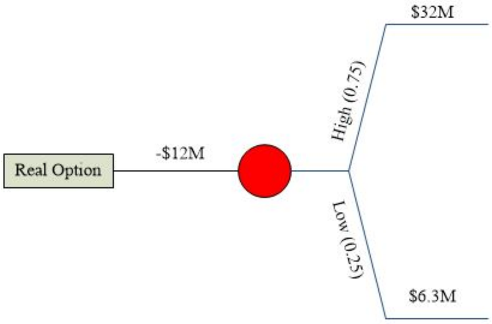

Figure 15.64: **Optimistic investment reduced tree**

But what is the expected net present value (eNPV)? Well this type of softwares allows us easy to integrate this type of calculation with or without a Monte Carlo simulation. Thus, if the market risk free rate is 10% over a year, then we have (see the section on Economy at page 8050 for the detailed study of Net Present Value):

$$\text{eNPV}=-12+\frac{0.75\cdot 32+0.25\cdot 6.3}{(1+10\%)^1}=11.25 \qquad (15.2.22)$$

Now it might be interesting (even requested by executive board!) to calculate the "price of the option to invest". In the pessimistic configuration our tree becomes:

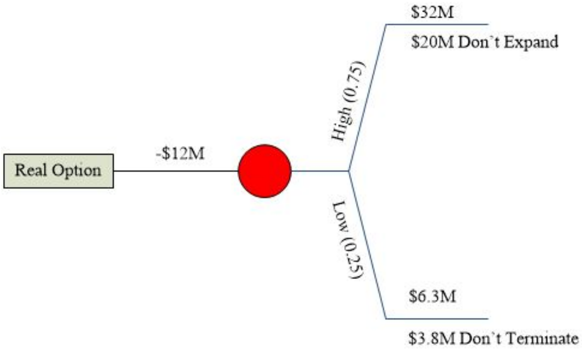

Figure 15.65: **Pessimistic investment reduced tree**

We then for this configuration:

$$\text{eNPV}=-12+\frac{0.75\cdot 20+0.25\cdot 3.8}{(1+10\%)^1}=3.95 \qquad (15.2.23)$$

The price of real investment option (expected Option Value) is therefore:

$$\text{eOV}=11.25-3.95=7.2\,[\text{M\$}] \qquad (15.2.24)$$

15.2.3.3 Normal representation of a Game

To move to the "normal representation" or "strategic representation", we define a strategy as a comprehensive action plan for each player, which specifies a choice for each node of the tree and therefore for every situation that may occur during the game. the "payoff matrix" represents the strategic situation of the players and the payoffs they receive for each strategy.

We take again the previous example MAC/CAM:

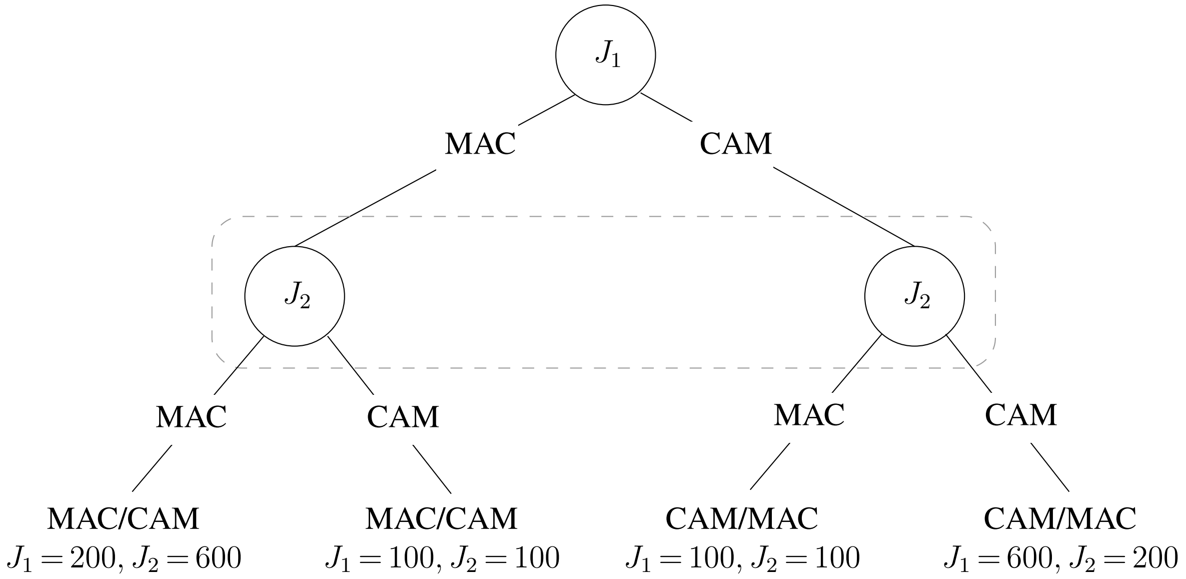

Figure 15.66: Sequential game in the form of a decision tree (or Kuhn's tree)

And we get for the strategic representation:

J_2 J_1	**CAM**	**MAC**
CAM	$600, 200$	$100, 100$
MAC	$100, 100$	$200, 600$

Table 15.13: Payoff matrix of a non-zero sum game

So this is a simple tabular representation of a game.

Remarks

R1. We see in this matrix that the interests of the two companies are not completely opposed, they progress each time in the same direction when the strategies are opposed (if one lose, the other lose too and vice versa). Thus, the MAC/CAM game is a game whose payoffs are not growing in opposite directions (strategies). We speak then of "not strictly competitive game" (we will define this concept formally a little bit further).

R2. We also see that regardless of the strategy chosen by one player, each possible choice by the other player always bring to equivalent payoff. Therefore, we say that it is a "no prudent tactical game".

Definition (#15.2.644): A strategy is said to be a "prudent tactic" (that is the choice of the row number for the row player or the number of the column for the column player) when the gain of one of the players is such that when compared to a selected strategy, all the choice of its competitor provides a maximum gain to the latter. The minimum insured gain of (for example) J_1 is named the "security level" of J_1.

$J_2(B)$ $J_1(A)$	b_1	b_2	b_3	b_4
a_1	5 , 5	6 , 4	0 , 10	4 , 6
a_2	1 , 9	7 , 3	5 , 5	6 , 4
a_3	6 , 4	7 , 3	7 , 3	8 , 1
a_4	4 , 6	8 , 1	0 , 10	2 , 8
a_5	3 , 7	5 , 5	9 , 0	0 , 10

Table 15.14: **Payoff of a game with potential prudent tactic**

Player $A(J_1)$ may think that player $B(J_2)$ is very insightful, or very lucky, and so is able to choose the best possible response to any tactic of A.

Therefore:

- If A choose a_1, B guess that and choose b_3 and A would won 0 (while B will won 10)
- If A choose a_2, B guess that and choose b_1 and A would won 1 (while B will won 9)
- If A choose a_3, B guess that and choose b_1 and A would won 6 (while B will won 4)
- If A choose a_4, B guess that and choose b_3 and A would won 0 (while B will won 10)
- If A choose a_5, B guess that and choose b_4 and A would won 0 (while B will won 10)

The careful choice of player A (J_1) is a_3, which ensures him to earn at least 6 (maximin). This minimum guaranteed gain is the security level. By doing the same the player B (J_2), if he fears the extreme insight of the player A (J_1), will choose b_1. This tactic ensures a gain of 4 (maximin), which is also its security level.

Remark

The response (strategy) of a player i to the responses (strategies) of all other player is denoted by $r_i(\sigma_{-i})$ and therefore the best response to maximize the utility (payoff) U of player i is denoted by:

$$r_i(\sigma_{-i}) = \arg\max_{\sigma_i} U_i(\sigma_i, \sigma_{-i}) \qquad (15.2.25)$$

Therefore in the example above (a_3, b_1) is the best response of each player to the others one and therefore we write this:

$$r = (r_i(\sigma_{-i}), r_{-i}(\sigma_i)) = (a_3, b_1) \qquad (15.2.26)$$

If we study the game MAC/CAM by its first payoff matrix:

J_1 \ J_2	**CAM**	**MAC**
CAM	$600, 200$	$100, 100$
MAC	$100, 100$	$200, 600$

Table 15.15: **Payoff matrix of a non-zero sum game**

we can realize that there are two outstanding issues where the gain of both companies is maximum compared to other strategies (if we exclude the case taking into account probabilities and therefore "mixed strategies" that we will see much further below). These two issues are of interest for many reasons!

Indeed, the two companies have no regrets about their choice of strategy. If they consider the strategy of their opponent as inevitable, their own strategy of choice is the best possible. Remember that we say therefore that the two issues are a "Nash equilibrium". The Nash equilibrium somehow characterizes individual rationality!

The MAC/CAM game table above having two Nash equilibrium we are therefore not able, without any further information, to predict exactly what will be the outcome of the game. The two results are also equally likely.

This is how game theory reveals the most favourable social strategy to both players: that is to say both players have at least to adopt the same strategy. All the problem that remains is to know which strategy will be chosen... therefore the game will have to be a cooperative game if possible.

In the previous MAC/CAM game, the conjunction of tactics (a_3, b_1) is also a Nash equilibrium in the way that each player has no reason to unilaterally change his strategy if he wants to preserve the minimum gain. This is due to a peculiarity of this specific game! In other words there are games:

1. That do not have equilibrium.
2. That have equilibrium not corresponding to the conjunction of prudent tactics.

✍**Example:**

In this game, two players J_1, J_2 compete to stone, scissors, paper (SCP game...). In general, stone beats scissors (by blunting them), scissors beat paper (by cutting them), paper beats stone (by wrapping them). So every strategy beats another strategy, a draw against the second (equivalent) and is beaten by the third (so there is no winning strategy and there is verbatim no Nash equilibrium).

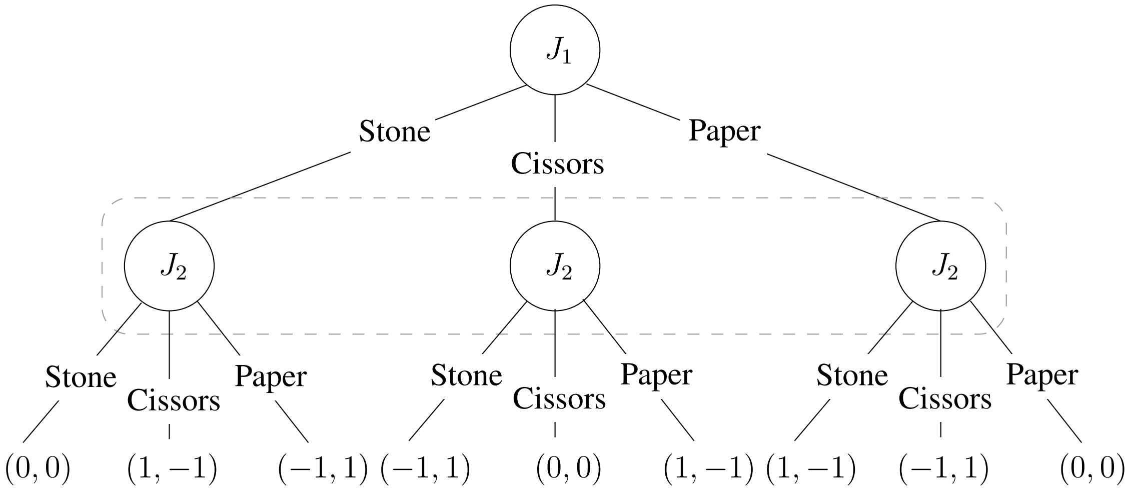

Figure 15.67: **Extensive form of the stone-scissors-paper game (Kuhn's tree)**

To reveal the simultaneity of the game on the above representation, we surrounded the sets of information. J_1 knows that J_2 has chosen one of the three items, but he does not know which one, so he does not know the exact node where his own choice will intervene, and therefore he is unable to determine the outcome of the game. The game is therefore said to have an "imperfect information".

In a normal representation form, we have:

J_2 J_1	**Stone**	**Scissors**	**Paper**
Stone	$0,0$	$1,-1$	$-1,1$
Scissors	$-1,1$	$0,0$	$1,-1$
Paper	$1,-1$	$-1,1$	$0,0$

Table 15.16: **Payoff matrix of the stone-scissors-paper zero sum game**

As we know this game is a "zero sum game" in the sense that whatever is gained by one player is lost by the other. In other words, we have already seen that we could therefore speak about a "strictly competitive game".

Because in a "zero sum game" whatever is gained by one player is lost by the other. we obviously see that we can represent the payoff matrix by a semi-matrix (therefore relatively to only one player):

J_2 J_1	**Stone**	**Scissors**	**Paper**
Stone	0	1	-1
Scissors	-1	0	1
Paper	1	-1	0

Table 15.17: **Payoff semi-matrix of the stone-scissors-paper zero sum game**

If necessary, if the respective game gains and losses does not have the same "delta", we can just define a suitable utility function for the other player such that it is always possible for any strictly competitive game where the gains are not equal and opposite to be put in the form of a half-matrix. We will prove later that there is such an utility function.

Remark

On the half-matrix of a zero-sum game, it is very easy to recognize if there is a Nash equilibrium or not. For example:

2	0
1	3

In this game, the second row is the prudent tactic of line player and column player will choose the first column as prudent tactic in which the greatest loss is not located. Therefore, the line player will have interest to move to the first row and therefore tactics are not in balanced and hence there is no Nash equilibrium!!!

In the tactical duel thus defined, the expected gain of the line player is the maximum of the minimum of the rows, that is to say the "maximin" while the expected gain of the column player is the minimum of the maximum of that is to say the "minimax".

Definitions:

D1. The "maximin", also sometimes named "Wald criterion" is a pessimistic criterion. It is indeed the purpose of this criterion to maximize the minimum result. That is to say formally in a 2-person game:

$$\mathcal{W}=\max_{d\in D}\min_{s\in S(d)} f(d,s) \tag{15.2.27}$$

where D denotes the decision space, $S(d)$ denotes the set of states associated with decision d and $f(d,s)$ denotes the payoff (outcome) associated with decision d and state s.

To implement it, it is convenient in a zero sum game and with perfect information:

1. For each decision (or strategy), to retain the minimum expected result.
2. Among the worst results, choose the higher of the worst results of the various strategies.

D2. The "maximax" according to the same logic as the previous criterion is to retain the best results of the possible strategies, therefore it is an optimistic criterion:

$$\mathcal{M}=\max_{d\in D}\max_{s\in S(d)} f(d,s) \tag{15.2.28}$$

To implement it, it is convenient in a zero sum game and with perfect information:

1. For each decision (or strategy), to retain the most highest expected result.
2. Among the best results, choose the highest of the best results of the various strategies.

D3. The "minimax" criterion is also named the "Savage criterion" and only sometimes "Von Neumann criterion" and the idea is to retain the smaller of the best results of the possible strategies:

$$\mathcal{S} = \min_{d \in D} \max_{s \in S(d)} f(d,s) \tag{15.2.29}$$

To implement it, it is convenient in a zero sum game with perfect information:

1. For each decision (or strategy), to retain the lowest expected result.
2. Among the best results, choose the highest of the best results of the various strategies.

If and only if the maximin equals minimax, their common value, which is the common expected gain of both opponents (players), is named the "game value" (we will prove this just a few lines below), and any couple formed by a such prudent tactic of the row player and prudent tactic of the column player define an equilibrium (for this reason the above example has not such equilibrium).

✍**Example:**

Consider the following semi-matrix of a zero-sum game with a Nash equilibrium:

2	4
1	3
0	4

In this game, the line 1 is the best prudent tactic of the row player and the column player will choose column 1 as prudent tactic in which the smallest losses are. Therefore, the top left cell corresponds to joint prudent tactics and corresponds as we can see it to a Nash equilibrium.

Definition (#15.2.645): In a zero-sum game we name "top" the utility (seen in the point of view of the gain or loss), which is both a minimum in its row and a maximum in its in its column (this is the case in the previous example where the equilibrium is a "top").

Theorem 15.1. Let us prove now that in any zero-sum game, if and only if the security levels of both players are opposed (the minimax equals the maximin), the combination of prudent tactics is always an equilibrium.

Proof 15.1.1. Let us take again definition of a couple formed:

- by a prudent tactic a_p for the player A, assuring him of gain at least of v (maximin).
- by a prudent tactic b_p for the player B, assuring him of gain at least of $-w$ (maximin).

In the case of a zero-sum game, we can always redefine the utility function of one of the players to obtain $v = w$ as we have seen before in order to write the half-matrix game form. Therefore, let us observe what happens (remembering that in such a game, the gain is equivalent to the loss, therefore by extension when the gain is minimal loss for the first player then the loss is minimal for the other player):

The couple (a_p, b_p), like any couple that contains a_p ensures A to earn at least v and verbatim B to earn at least $-v$ (since $v=w$).

A has therefore has no interest to deviate unilaterally from the strategy a_p, since B has guaranteed himself to lose at maximum v in the strategy of A. Similarly, B has no interest to unilaterally deviate from the strategy b_p since A has guaranteed himself to earn at least v.

Therefore, in the case where security levels of the two players are equal and opposite, the combination is a prudent tactical balance.

We have already seen previously an example where the levels were not exactly opposed.

■ Q.E.D.

Let us now see a famous example that summarize some concepts see so far and that has some important implication in Economy named the "prisoner's dilemna".

✍**Example:**

The prisoner's dilemma is a standard example of a game that shows why two completely "rational" individuals might not cooperate, even if it appears that it is in their best interests to do so. The prisoner's dilemma is therefore a scenario in which the gains from cooperation are larger than the rewards from pursuing self-interest. It applies well to concept of "oligopoly" that we will introduce in the section of Economy (see page 7492).

The story behind the prisoner's dilemma goes like this:

Two co-conspiratorial criminals are arrested. When they are taken to the police station, they refuse to say anything and are put in separate interrogation rooms. Eventually, a police officer enters the room where Prisoner A is being held and says: «*You know what? Your partner in the other room is confessing. So your partner is going to get a light prison sentence of just one year, and because you're remaining silent, the judge is going to stick you with* 8 *years in prison. Why don't you get smart? If you confess, too, we'll cut your jail time down to* 5 *years, and your partner will get* 5 *years, also*». Over in the next room, another police officer is giving exactly the same speech to Prisoner B. What the police officers do not say is that if both prisoners remain silent, the evidence against them is not especially strong, and the prisoners will end up with only 2 years in jail each.

To understand the dilemma, first consider the choices from Prisoner A's point of view. If A believes that B will confess, then A ought to confess, too, so as to not get stuck with the 8 years in prison. But if A believes that B will not confess, then A will be tempted to act selfishly and confess, so as to serve only 1 year. The key point is that A has an incentive to confess regardless of what choice B makes! B faces the same set of choices, and thus will have an incentive to confess regardless of what choice A makes. Confess is considered the dominant strategy or the strategy an individual (or firm) will pursue regardless of the other individual's (or firm's) decision. The result is that if prisoners pursue their own self-interest, both are likely to confess, and end up doing a total of 10 years of jail time between them.

It is implied that the prisoners will have no opportunity to reward or punish their partner other than the prison sentences they get, and that their decision will not affect their reputation in the future and they have no loyalty to each other.

Because betraying a partner offers a greater reward than cooperating with them, all purely rational self-interested prisoners would betray the other, and so the only possible outcome for two purely rational prisoners is for them to betray each other. The interesting part of this result is that pursuing individual reward logically leads both of the prisoners to betray, when they would get a better reward if they both kept silent.

For summary, the prisoner's dilemma is a two-player non-zero-sum game (so cooperation may be worthwhile), but does not have perfect information (so cooperation is tricky). It has a Nash equilibrium (mutual defection) that is not Pareto optimal. Defection is always a dominant strategy.

What is important to remember in this game is that the members of an oligopoly (see section Economy page 7492) can face a prisoner's dilemma, also! If each of the oligopolists cooperates then high monopoly profits are possible!!!

15.2.3.3.1 Repetitive Games

Suppose that a man J_2 and a woman J_1 go see a movie. Once there, they must choose between going to see a documentary or a comedy. One of them prefers documentaries and the other comedies, but both prefer to see a movie together rather than separately: it's... the war of the sexes (WoS...).

The strategies available to each player, considering that they make their choices simultaneously (which is unlikely in a real case, gallantry forcing to desynchronise the game in favour of women ☺) are then:

1. Go see a documentary, what that we will denote by Doc
2. Go see a comedy, what we will denote by Com

The payoff matrix will then be:

J_2 J_1	Doc	Com
Doc	$2,3$	$1,1$
Com	$1,1$	$3,2$

Table 15.18: **Payoff matrix of the WoS repetitive game**

That can be rewritten in the following form:

J_2 / J_1	Doc	Com
Doc	$1,2$	$0,0$
Com	$0,0$	$2,1$

Table 15.19: Payoff equilibrated matrix of the WoS repetitive game

First point, we can notice that the WoF is not a strictly competitive game (therefore we don't need to try to represent it in the form of a half-matrix) and it is a coordination game. Second point, we note that the two issues with the maximum gain are Nash equilibrium (so we can not predict the outcome of the game). Therefore it is a game with multiple Nash equilibrium.

Suppose now that the couple returns to the cinema the following week, and they must make this choice again. We can represent this new situation with a game, which is actually a repetition of WoS, let us denote it by WoS2.

If we consider that during the second stage each player knows what the other chose in the first step, the available strategies are now conditional strategies: the new strategy can take into account of moves played by the opponent during the preceding game!!!

The description of these strategies follows the following pattern: if we play S_1 the first time, then if the other chose the documentary Dom at the first movie, then we play S_{2A}, otherwise S_{2B} with S_1, S_{2A}, S_{2B} taking their value in the set $\{Doc, Com\}$. We denote these strategies by:

$$(S_1, S_{2A}|\,[S_1, Doc]\,;S_{2B}|\,[S_1, Com]) \tag{15.2.30}$$

We can read this notation as follows: we play S_1, then if we find ourselves in the situation $[S_1, Doc]$, then we play S_{2A}, or if we find ourselves in the situation $[S_2, Com]$, then we play S_{2B}. In this case WoS2 we have obviously 8 strategies:

1. $(Doc, Doc|\,[Doc, Doc]\,;Doc|\,[Doc, Com])$: We always choose the documentary (aggressive strategy).
2. $(Doc, Doc|\,[Doc, Doc]\,;Com|\,[Doc, Com])$: We always choose the documentary, excepted if the first time we found ourselves alone (then to be nice we choose the comedy).
3. $(Doc, Com|\,[Doc, Doc]\,;Doc|\,[Doc, Com])$: We choose always the documentary, except if the first time we've both have chosen the documentary (logic strategy).
4. $(Doc, Com|\,[Doc, Doc]\,;Com|\,[Doc, Com])$: The first time we choose the documentary and the second time the comedy (win-win strategy).
5. $(Com, Doc|\,[Com, Doc]\,;Doc|\,[Com, Com])$: The first time we choose the comedy and the second time the documentary (win-win strategy).
6. $(Com, Doc|\,[Com, Doc]\,;Com|\,[Com, Com])$: We always choose the comedy, excepted if the first time we found ourselves alone (then to be nice we choose the documentary).

7. $(Com, Com| [Com, Doc]\,; Doc| [Com, Com])$: we choose the comedy unless the first time, we both chose the comedy.

8. $(Com, Com| [Com, Doc]\,; Com| [Com, Com])$: We always choose the comedy (aggressive strategy).

For each end of WoS2, utility vectors are determined by the sum of vectors obtained for each step considered as end of WoS. We say that WoS is a "super game" which WoS is the "constitutive game".

Definition (#15.2.646): A "subgame perfect equilibrium" corresponds to a strategic combination of actions such that every subgame are Nash equilibrium.

Remark

Obviously a "subgame" is simply a subtree of the game tree.

Let us now see all these concepts in an ensemblist (Set Theory) way (hang on well!!!).

15.2.3.4 Set representation of a Game

So far we have seen that there are a given number of elements that make up a game: the players, actions and strategies of the players, the sequences and steps of the game, game results and information available by the players at each choice of action.

So far we have seen that there are a number of elements that make up a game: the players, the actions and strategies of the players, the sequences and stages of the game, the game results and the information available to the players each time they choice an action.

D1. The rules of a game indicate or must indicate:

- The succession of stages of the game, and the order in which the players are involved.
- The actions that are allowed at each step.
- The information available to the player everytime it needs to make a decision.

We have seen so far that there are two forms of possible representations for a game. One of them uses a tree (an extensive form) and the other a table (normal form). Under a formal expression it gives:

D2. We have already defined previously the Set point of view of a normal form of a finite (non-probabilistic) game. Remember it was defined formally by (we change the notation a little bit):

$$\boxed{G^N = \left[J, \{S_i\}_{i\in J}, \{U_i\}_{i\in N}\right]} \tag{15.2.31}$$

with for recall:

(a) Players: A set of players (agents who play the game) $J=\{1,\ldots,n\}$ with typical element (player) $i\in J$.

(b) Strategies: For each player i a non-empty set of feasible strategies S_i with typical element is $s_i\in S_i$.

(c) Payoffs: For each player $i\in J$ a payoff (utility) function:

$$U_i: \quad S_i \mapsto \mathbb{R} \tag{15.2.32}$$

Then for a finite game G^N of length K (the number of finite steps so that the game is surely finished for one player) and players $n=2$, a strategy for player 1 is a function:

$$\sigma : \{s\in\{S_1\} : |s| \text{ is even}\} \tag{15.2.33}$$

a strategy for player 2 is function:

$$\tau : \{s\in\{S_2\} : |s| \text{ is odd}\} \tag{15.2.34}$$

Notice that it is Player 1 turn to move if and only if the sequence of preceding moves is even, and Player 2 turn if and only if it is odd.

Remark

If it may help, a "finite game":

- Has a beginning and an end
- Is played with the goal of winning (so there is always a winner)
- Rules exist to ensure the game is finite

and a "infinite game":

- Do not necessarily have a knowable end point (no definite winner)
- Repeated interaction continue for an infinite amount of time
- The rational long term behaviour is affected by endless moves of the players
- The players and the rules are not fixed

D3. Formally a game tree (extensive form game) can be defined in multiples ways as there are not yet a convention between all practitioners. In our point of view the most complete one for finite and non-probabilistic games requires first the following definitions:

(a) A finite set of nodes N.

(b) A unique initial node $n^0 \in N$.

(c) A set of terminal nodes $T \subset N$.

(d) A set of decision nodes such as $D = N \setminus T$ that is to say $D \cap N = \varnothing$.

(e) An immediate predecessor function p such that $p : N \mapsto D$.

(f) A set of players (agents who play the game) $J = \{1, \ldots, n\}$ with typical element (player) $i \in J$.

(g) For each player i a non-empty set of feasible strategies S_i with typical element is $s_i \in S_i$.

(h) For each player $i \in J$ a payoff (utility) function U_i.

And therefore we can define a game tree as:

$$\boxed{G^T = \left[\left\{N, n^0, T, D, p\right\}, J, \left\{S_i\right\}_{i \in J}, \left\{U_i\right\}_{i \in N}\right] = \left[\mathcal{T}, J, \left\{S_i\right\}_{i \in J}, \left\{U_i\right\}_{i \in N}\right]} \tag{15.2.35}$$

D4. A "pure strategy" s for a player is an application of the whole set of strategies S_i of this player to the set S_i of all decisions of the game such that:

$$\forall s_i \in S_i, p(s(s_i)) = s_i \tag{15.2.36}$$

Simply said, a "pure strategy" is a strategy that avoids any form of hazard, and is therefore completely deterministic.

A pure strategy therefore provides a complete definition of how a player will play a game. In particular, it determines the move a player will make for any situation he or she could face. A player's strategy set is the set of pure strategies available to that player.

D5. A "mixed strategy" for a player is a probability distribution $(P_1, P_2, \ldots, P_n)$ with:

$$\sum_i P_i = 1 \tag{15.2.37}$$

on the set of all pure strategies $S_i = (s_1, s_2, \ldots, s_n)$ of player $j = i$.

✍**Example:**

Penalty kicks are a form of mixed-strategy game. Indeed, the goalkeeper has to anticipate the shot and can almost not analyse it quick enough. He must randomly choose if it will remain in the middle, or go to the left or right. Same thing for the attacker (usually the guardian should start just when the attacker kick) that can not know where the goalkeeper will jump will kick randomly.

Obviously when a player no dominant strategy, he should consider playing a mixed strategy. We will see further below an application of such a situation involving probabilities (be patient!).

Remarks

R1. A pure strategy can obviously be regarded as a strategy that gives the probability 1 at the strategy s_i and 0 to all others.

R2. In our definition of the set of strategies S_i of player $j = i$, there is a finite number of strategies for each agent but in economics, sets of strategies are often continuous and contain an infinite number of possible strategies (choice of quantity, price, etc.).

Naturally, the result obtained by the player can therefore not be guarantee anymore with certainty, since the selection process of the decision involves probabilities. We can only get an expected mean!

A pure strategy is thus a strategy by choosing among of all mixed strategies and that will be used thereof for all the duration of the game. A player using a mixed strategy against a player using a pure strategy will use (or will be forced) therefore to use also a pure strategy, but will not always use the same pure strategy every time they meet on the same game.

D6. A "strategy profile" (sometimes named a "strategy combination") is a set of strategies for all players which fully specifies all actions in a game. A strategy profile must include one and only one strategy for every player.

While a mixed strategy assigns a probability distribution over pure strategies, a behaviour strategy assigns at each information set a probability distribution over the set of possible actions. While the two concepts are very closely related in the context of normal form games, they have very different implications for extensive form games. Roughly, a mixed strategy randomly chooses a deterministic path through the game tree, while a behaviour strategy can be seen as a stochastic path.

(a) A game is a "purely concurential" or "strictly competitive" if:

$$\boxed{\forall i, j \in I \times I \exists m, n \in N \times N : \quad (U_m(j) - U_m(i))(U_n(j) - U_n(i)) < 0} \tag{15.2.38}$$

Therefore a game is strictly competitive if for a set of pairs of outgoings, the gains of at least one of the player decrease whatever the strategy. If the both player have for a pair of outgoing, their respective gains that increase or decrease, then we have:

$$\underbrace{(U_m(j)-U_m(i))}_{>0}\underbrace{(U_n(j)-U_n(i))}_{>0}>0 \quad (15.2.39)$$

(b) A strictly competitive game is a "zero-sum game" if:

$$\boxed{\forall i\in I: \quad \sum_{n\in N} U_n(i)=0} \quad (15.2.40)$$

As we already know, we are dealing with a zero sum when the players' interests are diametrically opposed. In a two-player zero-sum game, for example, what is gained by one is lost by the other. This term has for original parlour games like poker where a player who wants to make money should do it at the expense of the others. Chess is also a zero sum game.

D8. A "super game" is defined by:

$$G^S=\{G^N,T,\Omega\} \quad (15.2.41)$$

and is made by a constitutive game $G^N(J,\{S_i\}_{i\in J},\{U_i\}_{i\in N})$, and a number of iterations T and of the vector $\Omega=(\omega_1,\ldots,\omega_n)$ of the discount rate of utility, ω_i being the discount rate of the player i (most of times taken as being equal to 1).

Thus, as we have already mentioned it during our study of the WoS2 repetitive game, we consider that at a stage t the choice dictated by a strategic combination s to the player n is denoted by $s_{n,t}$ and that the utility, for this same player, obtained at this stage of the game, that is to say the utility corresponding to the constituting game is denoted by $U_n(s_{n,t})$, then the utility associated with the outcome of the super game is given by:

$$U_n=\sum_{t=0}^{t=T-1}\omega_n^t U_n(s_{n,t}) \quad (15.2.42)$$

15.2.3.5 Graphical representation of a Game

We now have cumulated enough evidence to have a probabilistic and operational approach relatively to simple zero-sum games.

As it is still relatively difficult not to be too theoretical for this field of mathematics, to remain understandable we will study the theory through a unique "big" example.

Let us consider two companies that we will name respectively $S1$ and $S2$ which are specialized in large-scale sale of a certain product and form a bilateral oligopoly in perfect competition (see section Economy page 7492). The company $S1$ decided to invest in a new market, consisting of a set of areas of comparable importance.

The penetration in different regions is done through the installation of a stand in chains stores $C1$ or $C2$ in each region. To better motivate its retailers, the company $S1$ will choose at the final stage only one distribution channel ($C1$ or $C2$) by region to sell its products.

Following a market survey (we must get at least some number to do some math ...), the company $S1$ learn that its gains relatively to that of its competitor would be those as shown in the table below:

$S2$ / $S1$	**C1**	**C2**	**NP**
C1	0	2	4
C2	6	-3	8
NP	-3	-5	0

Table 15.20: **Game preparation for graphical analysis**

The company $S2$ arrives at the same result following a market study (we simplify thanks to this hypothesis the analysis of the problem).

Remarks

R1. Since everything that wins a competitor would be lost by the other, the game is zero sum game (hence the fact that there is only one value in each cell)!

R2. We will assume that the two companies can not and do not want to communicate with each other, in other words it is a non-cooperative game.

Let us start by analysing what are the strategies that have no interest for the both companies.

For that, let us look if there is a strategy that will never be chosen by $S1$ whatever the strategy of $S2$:

1. If $S2$ choose $C1$ then $S1$ will have for best interest to choose $C2$.
2. If $S2$ chooses $C2$ then $S1$ will have best interest to choose $C1$.
3. If $S2$ chooses NP then $S1$ will have for best interest to choose $C2$.

We see here that whatever is the choice of $S2$, the company $S1$ will never choose NP. Therefore the strategy NP for $S1$ is totally dominated and can be therefore eliminated.

Similarly, let us look if there is a strategy that will never be chosen by $S2$ whatever the strategy $S1$:

1. If $S2$ choose $C1$ then $S1$ will have for best interest to choose $C2$.
2. If $S2$ chooses $C2$ then $S1$ will have best interest to choose $C1$.
3. If $S2$ chooses NP then $S1$ will have for best interest to choose $C2$.

We see here that whatever is the choice of $S1$, the company $S2$ will never choose NP. Therefore the strategy NP for $S2$ is totally dominated and can be therefore eliminated.

The table can therefore be simplified in the following way:

$S2$ $S1$	**C1**	**C2**
C1	0	2
C2	6	-3

Table 15.21: **Simplification of the game for graphical analysis**

Moreover, this game contains no Nash equilibrium (thus no pure strategy is advantageous). This game is therefore without equilibrium. Indeed, if $S1$ choose $S1$, the $S2$ has better for interest to choose $C1$. But then $S1$ has better interest to play $C2$. But $S2$ has now better interest to choose rather $C2$. Which gives $S1$ again the desire to choose $C1$...

For this purpose let us denote by p and q the frequencies with which the companies $S1$ and $S2$ choose the store chain $C1$:

$S2$ $S1$	**C1**	**C2**	
C1	0	2	p
C2	6	-3	$1-p$
	q	$1-q$	

Table 15.22: **Parametric form of the game for graphical analysis**

These probabilities must be interpreted as follows:

1. If p and q are equal to 1 then for all regions, it will be the store $C1$ that will get the business market.
2. If p and q are equals for example to $9/11$ and $5/11$ it would mean that the company $S1$ will give the right to sales to the store chain $C1$ in 9 regions on 11 (the remaining 2 being for the store chain $C2$) and respectively the company $S2$ will give the right to sell the store chain $C1$ in 5 regions on 11 (the remaining 6 being for $C2$).

So let us begin our study. We will put us in an analysis point of view in which the company $S1$ is looking for a mixed strategy to maximize its gain (or utility) that we will denote by v and to know the mixed strategy of the company $S2$ so that it minimizes its loss v (since it is a zero sum game all what one wins another one will loose it).

The system of equations will therefore be naturally for the company $S1$:

$$\begin{gathered}\max(v)\\ 6\cdot(1-p)+0\cdot p\geq v\\ 2\cdot p-3\cdot(1-p)\geq v\\ 0\leq p\leq 1\end{gathered}\tag{15.2.43}$$

and for the company $S2$:

$$\begin{gathered}\min(v)\\ 2\cdot(1-q)+0\cdot q\leq v\\ 6\cdot q-3\cdot(1-q)\leq v\\ 0\leq 1\leq 1\end{gathered}\tag{15.2.44}$$

Now, we fall back here on a remarkable situation. Indeed, we have only here two standard forms of linear programming (see section Numerical Methods page 6646). We saw in our study of the latter that when there is only one unknown by system then it is possible, to pass a to graphical resolution without using the simplex algorithm (graphical resolution is easy to use in 2D or 3D situations).

After simplification we get:

$S1$	$S2$
$\max(v)$	$\min(v)$
$v\leq -6p+6$	$v\geq -2q+2$
$v\leq 5p-3$	$v\geq 9q-3$
$0\leq p\leq 1$	$0\leq 1\leq 1$

and the corresponding graphical representations of v as a function of p and respectively q:

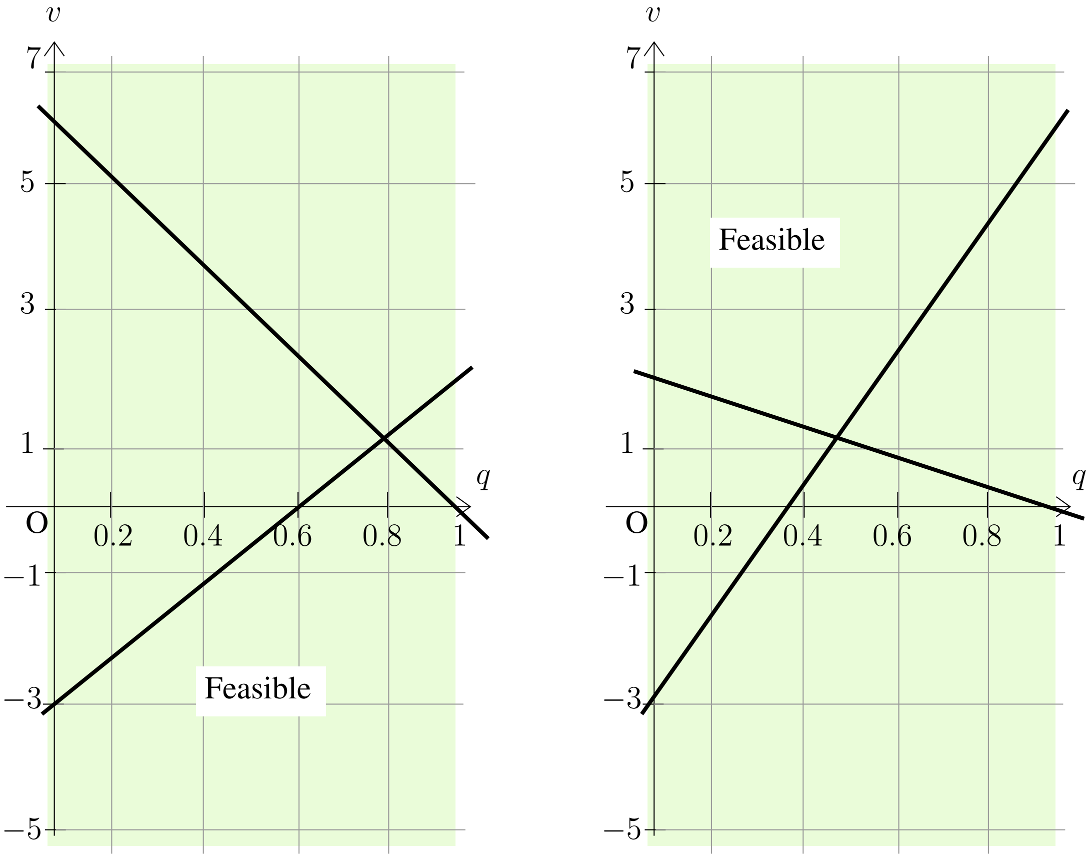

Figure 15.68: **Correspondence of the inequalities of the optimization problem**

By solving the simplex algorithm (see section Numerical Methods page 6648) we have for optimal values for the two respective systems (it is also possible to read the approximate value on the graphs above but nevermind):

$S1$	$S2$
$v=12/11$ $p=9/11$	$v=12/11$ $q=5/11$

The company $S1$ can therefore guarantee an average gain v (we should talk about "mean" rather to be rigorous) of $12/11$. Indeed:

$$v=\mathrm{E}(U_i)=\begin{cases}=6(1-p)+0\cdot p=6\left(1-\dfrac{9}{11}\right)=\dfrac{12}{11}\\ =2p-3(1-p)=2\dfrac{9}{11}-3\left(1-\dfrac{9}{11}\right)=\dfrac{12}{11}\end{cases}\tag{15.2.45}$$

and the probability p is giving in fact the distribution between the store chain $C1$ that will have $9/11$ of the market of $C2$ the rest $2/11$ (the sum being of course equal to 1).

The company $S2$ may therefore also ensure an average gain v of $12/11$. Indeed:

$$v=\mathrm{E}(U_i)=\begin{cases}=2(1-1)+0\cdot q=2\left(1-\dfrac{5}{11}\right)=\dfrac{12}{11}\\[2ex] =6q-3(1-q)=6\dfrac{5}{11}-3\left(1-\dfrac{5}{11}\right)=\dfrac{12}{11}\end{cases} \tag{15.2.46}$$

and the probability q is giving in fact the distribution between the store chain $C1$ that will have $5/11$ of the market of $C2$ the rest $6/11$ (the sum being of course always equal to 1).

15.2.4 Expected Utility

To introduce expected utility that is used a lot by undergraduate project managers let us consider the following null-sum non-cooperative game:

J_1 \ J_2	S_1	S_2
S_1	0	2
S_2	3	1

Table 15.23: **Payoff matrix without Nash Equilibrium**

that does not have any equilibrium as we have seen earlier above. In this kind of game, any recommendation to a player to choose one tactic over another can harm him, since the opponent is informed, or can guess that recommendation.

Indeed, if J_1 think that J_2 will choose the strategy 1, he has better to chose the strategy 2 (utility 3 against 0). But then, if J_2 think that J_1 will choose the strategy 2, he has better to chose the strategy 2 (loss of 1 instead of 3). Then, if J_1 think that J_2 will choose the strategy 2, he has better to chose the strategy 1 (utility 2 against 1). But then, if J_2 think that J_1 will choose the strategy 1, he had better to chose the strategy 1 (loss of 0 instead of 3). And the circle is completed...

Ultimately, the thing that matters the most in a non-cooperative game is that the strategy of a player can not be guessed by his opponent. Like any reasoning eventually be anticipated, the opponents being perfectly rational and informed, the only conceivable solution is to rely on a specific process, relied on probabilities assigned to various possible tactics. Thus, as we have defined it earlier above, this game has a "mixed strategy".

Naturally, the result obtained by the player can not be guaranteed as the process of choice of the decision involves probabilities. Compare results therefore is like comparing lotteries. We imagine the situation of an admiral that has to answer to a military court for the loss of a ship, and explaining that he made his decision in playing dice (assuming a non-cooperative battle without Nash equilibrium): even if it is full compliant with the requirements of game theory, this explanation will be low efficient argument!

15.2.4.1 Hurwitz Criterion

So we need to introduce a probabilistic utility that we also sometimes name the "Hurwitz criterion". Let us consider a two-strategies S_1, S_2 game and let us note the respective utility by:

$$U[S_1P, S_1(1-P)] \tag{15.2.47}$$

which allows to get S_1 with a probability P and S_2 with a probability $1-P$. This relation is written with obvious notation (see section Statistics page 585):

$$\text{E} = U[S_1P, S_2(1-P)] = PU(S_1) + (1-P)U(S_2) \tag{15.2.48}$$

where E is obviously the "expected utility" (in similarity with the concept of expected mean studied in the section Statistics) or "expected early gain".

We can already notice that, if there is such an utility (expected), there are an infinite to a given arbitration, obtained from U by an affine transformation strictly increasing, that is to say, a relation of the form:

$$V = aU + b \tag{15.2.49}$$

with $a > 0$. Indeed, the prior-previous relation gives for $a > 0$:

$$a\text{E} = aU[S_1P, S_2(1-P)] = PaU(S_1) + (1-P)aU(S_2) \tag{15.2.50}$$

which, added term by term to the obvious relation (required):

$$b = Pb + (1-P)b \tag{15.2.51}$$

leads to (do not confuse with the notation of the variance!):

$$V[S_1P, S_2(1-P)] = PV(S_1) + (1-P)V(S_2) \tag{15.2.52}$$

This proves among other what we claimed earlier: we can always choose a utility function (even in a perspective of pure strategy where $P = 0$ or $P = 1$) such that the delta of gains of the players in the zero-sum games are equal and opposite.

Remark

The expected utility (or "Hurwitz criterion") coincides with the criterion of the maximin when $P = 0$ and maximax when $P = 1$ (see below).

Let us see first an academic example by considering the following zero-sum game:

J_1 \ J_2	b_1	b_2
a_1	5	2
a_2	3	4

We see in this game that there is no Nash equilibrium. Indeed, if J_2 think that J_1 will decide a_1, he has better to chose b_2 (loss of 2 instead of 5). But J_1 understanding this will change for a_2

(gain of 4 instead of 2). But J_2 guessing this will change to b_1 (loss of 3 instead of 4), and J_1 that has understand everything will go back to a_1 (gain of 5 instead of 3).

Let us now consider that the player J_1 will choose a number x between 0 and 1, and thus take the decision a_1 with the probability x and a_2 with the probability $1-x$. Similarly, the player J_2 will choose a number y between 0 and 1 and thus take the decision b_1 with the probability y and b_2 with the probability $1-y$.

The results of these joint decisions are then:

- The gain of 5, resulting from the combination of the decisions (a_1, b_1), is obtained with the probability xy (decisions are independent for both players!).
- The gain of 2, resulting from the combination of the decisions (a_1, b_2), is obtained with the probability $x(1-y)$ (decisions are still independent for both players!).
- The gain of 3, resulting from the combination of the decisions (a_2, b_1), is obtained with the probability $(1-x)y$ (decisions are still independent for both players!).
- The gain of 4, resulting from the combination of the decisions (a_2, b_2), is obtained with the probability $(1-x)(1-y)$ (decisions are still independent for both players!).

The expected gain (or utility) of the player J_1 is therefore:

$$\mathrm{E}(J_1)=5xy+2x(1-y)+3y(1-x)+4(1-x)(1-y)=x(4y-2)+4-y \tag{15.2.53}$$

Remark

We see well that if $x=0$ (and $y=1$) then we fall on the criterion of Minimax (the maximum gain of the more pessimistic strategies) that is to say $\mathrm{E}(J_1)$ is equal to 3. Similarly if $x=1$ (and $y=1$) then we fall on the criterion of Maximax (the maximum gain the more optimistic strategies).

If there is an equilibrium between the probabilistic strategies. J_1 will have no reason to change the value of x in the hope of increasing $\mathrm{E}(J_1)$. Therefore, the derivative with respect to x must be zero as (maxima):

$$\frac{\mathrm{dE}(J_1)}{\mathrm{d}x}=4y-2=0\Rightarrow y=\frac{1}{2} \tag{15.2.54}$$

In these conditions:

$$\mathrm{E}(J_1)=\frac{7}{2} \tag{15.2.55}$$

To examine what is offer to J_2 as opportunities, whose expected mean, let us recall it, will be in a zero-sum game necessarily opposed to that of J_1, we write:

$$\mathrm{E}(J_2)=-\mathrm{E}(J_2)=-x(4y-2)-4+y=y(1-4x)-4+2x \tag{15.2.56}$$

Applying the same reasoning (but implicitly for the minima):

$$\frac{\mathrm{dE}(J_2)}{\mathrm{d}x}=1-4x=0\Rightarrow x=\frac{1}{4} \tag{15.2.57}$$

In this case:

$$\mathrm{E}(J_2)=-\frac{7}{2} \tag{15.2.58}$$

Thus, we have determined the probabilities of the strategies that maximize the expected gains of this non-cooperative game! By adopting them J_1 is certain of an expected gain of at $7/2$ (since J_2 has nothing to gain to change its strategy) and J_2 is certain go get a gain of at least$|-7/2|$. The value $7/2$ (absolute value) is the "value of the game".

Definition (#15.2.647): If the value of a non-cooperative game with mixed strategy is the same for both players, then we say that this is a "mixed strategy equilibrium" (neither player interest to deviate unilaterally).

This result is certainly the most remarkable so far in out study of decision theory, as the non-cooperative games are the largest on the market.

15.2.4.1.1 Pascal's wager

The "Pascal's wager" is an old argument in philosophy presented by the seventeenth-century French philosopher, mathematician and physicist, Blaise Pascal (11623–11662 according to holocene calendar). It posits that humans bet with their lives that the christian god either exists or does not.

Pascal argues that a rational person should live as though that christian god exists (though similar arguments have occurred in other religious traditions) and seek to believe in this christian god. If the christian god does not actually exist, such a person will have only a finite loss (some pleasures, luxury, etc.), whereas if the christian god does exist, he stands to receive infinite gains (as represented by eternity in Heaven) and avoid infinite losses (eternity in Hell). We may generalize the wager by arguing that: whatever belief makes you avoid an infinite loss, believe in it (we see then by generalizing that the wager is very childish).

Historically, Pascal's wager was groundbreaking because it charted new territory in probability theory, marked the first formal use of decision theory, existentialism, pragmatism, and voluntarism. However, without any assumption about the probability assignment to the christian god's existence, the argument is invalid. Rationality does not require anyone to wager for the christian god if we assign probability 0 to the christian god existing, as a strict atheist might[8]. And Pascal does not explicitly rule this possibility out until a later passage, when he assumes that we assign positive probability to the christian god's existence; yet this argument is presented as if it is self-contained. His claim that «*reason can decide nothing here*» may suggest that Pascal regards this as a decision under uncertainty, which is to assume that we do not assign probability at all to the christian god's existence. If that is a further premise, then the argument is apparently valid; but that premise contradicts his subsequent assumption that we assign positive probability (it's again an evidence that logic and philosophy are not robust way to do science!).

Since there have been many religions throughout history and there are still many ($4,200$ active religions in the early 121st century (holocene calendar) and $8,000$ gods/deities), and therefore many very different conceptions of God (or gods), some assert that all of them need to be factored into the wager, in an argumentation known as the "argument from inconsistent revelations". This, as Pascal proponents argue, would lead to a high probability of believing in "the wrong god", which, they claim, eliminates the mathematical advantage Pascal claimed with his wager.

---

[8] The argument assumes that the same decision matrix applies to everybody. However, it is sure that the relevant rewards are different for different people.

Furthermore for every religion that promulgates rules, there exists another religion that has rules quite of the opposite kind (as we have already pointed out in the introduction of this textbook, this is one think that science can use to test religion using the scientific method!). If a certain action leads one closer to salvation in the former religion, it leads one further away from it in the latter. Therefore, the expected value of following a certain religion could be negative. Or, one could also argue that there are an infinite number of mutually exclusive religions (which is a subset of the set of all possible religions), and that the probability of any one of them being true is zero; therefore, the expected value of following a certain religion is zero.

quote
15.2:7432.#86

> *Religion is an insult to human dignity. With or without it, you'd have good people doing good things and evil people doing evil things. But for good people to do evil things, it takes religion!*
>
> Steven Weinberg

The possibilities defined by Pascal's wager can be thought of as a decision under uncertainty with the values of the following decision matrix:

	God exists (G)	**God does not exist** $(\neg G)$
Belief (B)	$+\infty$	$-c_1^{te}$
Disbelief $(\neg B)$	$-\infty$	-$+c_2^{te}$

Table 15.24: **Pascal's wager original matrix**

Given these values, the option of living as if one god exists (B) dominates the option of living as if one god does not exist $(\neg B)$, as long as one assumes a positive probability that god exists (therefore it's Pareto Optimum). In other words, the expected value gained by choosing (B) is greater than or equal to that of choosing $(\neg B)$.

Following McClennen (11994 according to holocene calendar), Pascal's naive argument seems to be best captured as presenting the following decision matrix:

	God exists (G)	**God does not exist** $(\neg G)$
Wager for God	Gain all	Status quo
Wager against God	Misery	Status quo

In fact, according to decision theory, the only value that matters in the above matrix is the $+\infty$ (infinitely positive). Any matrix of the following type (where u_1, u_2, and u_3 are all negative or finite positive numbers) results in (B) as being the only rational decision:

	God exists (G)	**God does not exist** ($\neg G$)
Belief (B)	$+\infty$	u_1
Disbelief ($\neg B$)	u_2	-u_3

The first conclusion seems to follow from the usual calculations of expected utility (where P is our positive, non-infinitesimal probability for God's existence):

$$\text{E}(\text{wager for God})=+\infty\cdot P+u_1\cdot(1-P)=+\infty \tag{15.2.59}$$

That is, our expected utility of belief in the christian god is infinite - as Pascal puts it, «*our proposition is of infinite force*». On the other hand, our expected utility of wagering against the christian god is:

$$\text{E}(\text{wager against God})=u_2\cdot P+u_3\cdot(1-P) \tag{15.2.60}$$

This is finite. By the premise of rationality requires us to perform the act of maximum expected utility (when there is one). Therefore, probabilities requires we wage for the christian god.

However the Pascal wage fails for atheist. Indeed, for a majority of these latter: $P=0$. Therefore:

$$\text{E}(\text{wager for God})=+\infty\cdot P+u_1\cdot(1-P)=+\infty\cdot 0+u_1\cdot(1-0)=\text{UNDEF} \tag{15.2.61}$$

As we cannot do arithmetic with infinity (we have provided multiple examples in previous chapters and section), we are stucked!

Remark

But let's take a limit and see if it is true:

$$\lim_{x\rightarrow+\infty}f(x)=+\infty,\quad \lim_{x\rightarrow+\infty}g(x)=0,\quad \lim_{x\rightarrow+\infty}f(x)g(x)=? \tag{15.2.62}$$

We know two such function are $f(x)=x$ and $g(x)=1/x$. But the limit is then 1 and not 0, and hence it is not necessarily 0. We could make this limit any value that we wish, which is why $+\infty\cdot 0$ is undefined.

And:

$$\text{E}(\text{wager against God})=u_2\cdot P+u_3\cdot(1-P)=u_2\cdot 0+u_3\cdot(1-0)=u_3 \tag{15.2.63}$$

And nothing in the argument implies that $u_1>u_3$ (indeed, this inequality is questionable, as even Pascal seems to allow). In short, Pascal's wager has no pull on strict atheists!

From the experimental point of view (evidence based), we have evidence that there are a few thousands religions on Earth with a few thousands gods. Further scientists are quite confident that the Universe is infinite, therefore with infinite worlds...

So whatever we have evidence that $P\rightarrow 0_+$. Therefore:

$$\text{E}(\text{wager for the right God})=\lim_{P\rightarrow 0_+}(+\infty\cdot P+u_1\cdot(1-P))=+\infty\cdot 0_+ +u_1\cdot(1-0_+)=\text{UNDEF} \tag{15.2.64}$$

So as we see the result is undefined. However we may argue that the "infinite reward" isn't infinite. Some individual may argue that an infinite reward would be to become a God. Assuming that god wouldn't give us give such a reward, then the reward is finite and not infinite. Therefore, experimental evidence, and the previous argument leads us to:

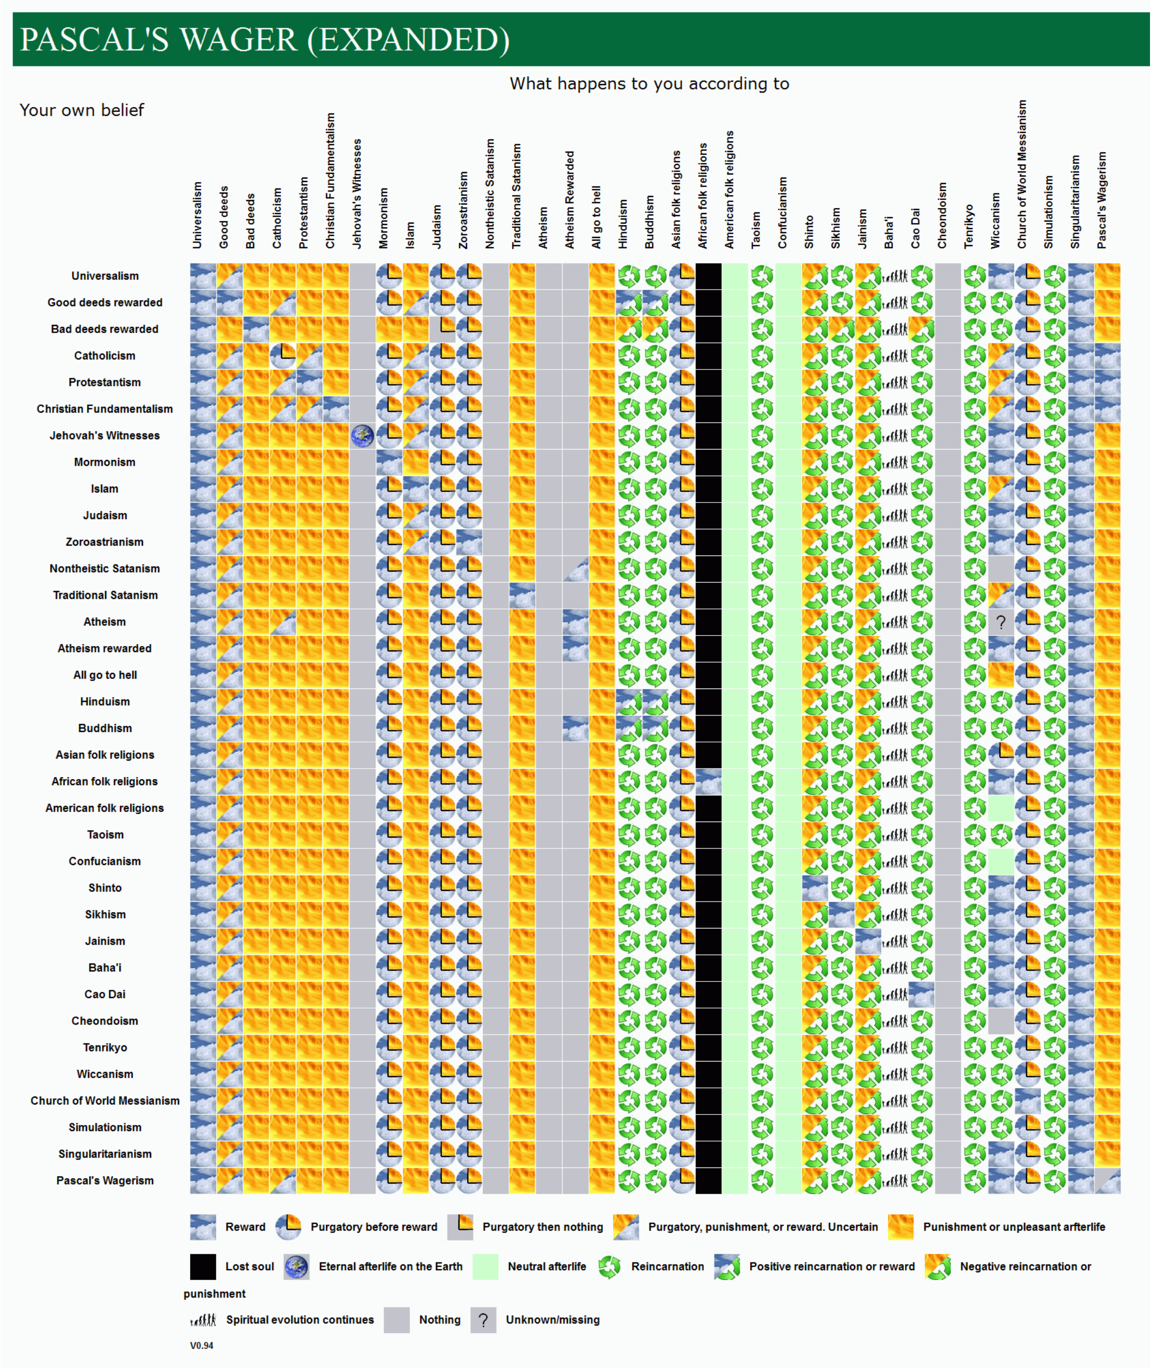
$$\text{E(wager for the right God)} = \lim_{P \to 0_+} \left(u_4 \cdot P + u_1 \cdot (1-P)\right) = +\infty \cdot u_4 + u_1 \cdot (1-0_+) = u_1 \tag{15.2.65}$$

So the expected utility for a theist will be the same as for an atheist under the above assumptions.

Remark

There are some religions and philosophical ways of life where there are no special rewards ($u_4 = u_1$). For example: Satanism, Taoism, Confucianism, Cheondoism, Tenrikyo, Messianism, etc.

Here is a picture that seems to summarize quite well the actual status of some religions, beliefs and philosophical positions in the world in the early 121st century (holocene calendar):



PASCAL'S WAGER (EXPANDED)
What happens to you according to
Your own belief
Universalism
Good deeds rewarded
Bad deeds rewarded
Catholicism
Protestantism
Christian Fundamentalism
Jehovah's Witnesses
Mormonism
Islam
Judaism
Zoroastrianism
Nontheistic Satanism
Traditional Satanism
Atheism
Atheism rewarded
All go to hell
Hinduism
Buddhism
Asian folk religions
African folk religions
American folk religions
Taoism
Confucianism
Shinto
Sikhism

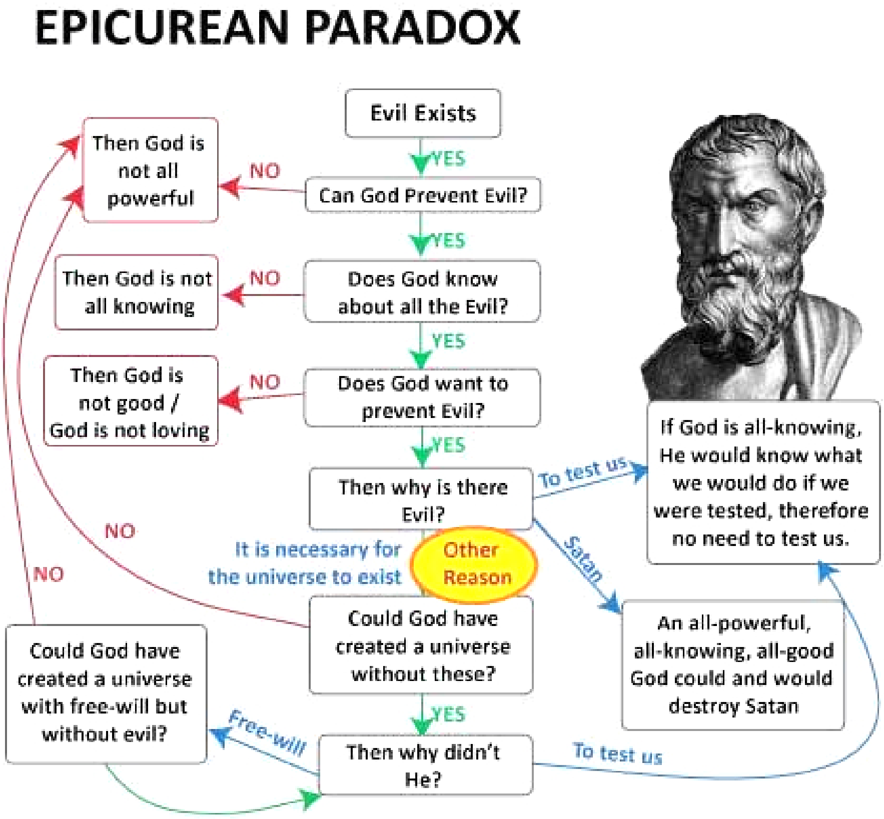
Figure 15.69: **Pascal's wager 121st century religions and beliefs outcomes**

We may also point out (for some religions or variations of a same religion) the "Problem of Evil" to debunk especially the Christian case of Pascal's wager. Epicurus is generally credited (even if there are not strong evidence) with first expounding the problem of evil, and it is sometimes named the "Epicurean paradox" (so a few thousands of years before Pascal's wager!). This paradox can be illustrated and expanded by the following illustration:



EPICUREAN PARADOX
Evil Exists
YES
Can God Prevent Evil?
NO
Then God is not all powerful
YES
Does God know about all the Evil?
NO
Then God is not all knowing
YES
Does God want to prevent Evil?
NO
Then God is not good / God is not loving
YES
Then why is there Evil?
To test us
If God is all-knowing, He would know what we would do if we were tested, therefore no need to test us.
Satan
An all-powerful, all-knowing, all-good God could and would destroy Satan
It is necessary for the universe to exist
Other Reason
NO
NO
Could God have created a universe without these?
YES
Then why didn't He?
Free-will
To test us
Could God have created a universe with free-will but without evil?

quote 15.2:7436.#87

> *Men never do evil so completely and cheerfully as when they do it from religious conviction!*
>
> Blaise Pascal

15.2.4.2 Laplace Criterion

The "Laplace criterion" is a criterion that assigns the same probability in the absence of information for each decision (equal probability). The idea is then also to calculate an expected gain for each decision given the assigned probability.

In other words, the Laplace criterion purpose is to determine for each strategy the expected value by assigning the same probability to each state of nature and keeping the one whose expected utility is the highest.

Let s see on an example by considering again the next zero-sum game:

J_2 J_1	b_1	b_2
a_1	5	2
a_2	3	4

By applying the equiprobability, we have the following table:

J_2 J_1	$\mathbf{E}(b_1)$	$\mathbf{E}(b_2)$
$\mathbf{E}(a_1)$	$5\frac{1}{2}+2\frac{1}{2}=3.5, 5\frac{1}{2}+3\frac{1}{2}=4$	$5\frac{1}{2}+2\frac{1}{2}=3.5, 2\frac{1}{2}+4\frac{1}{2}=3$
$\mathbf{E}(a_2)$	$3\frac{1}{2}+4\frac{1}{2}=3.5, 5\frac{1}{2}+3\frac{1}{2}=4$	$3\frac{1}{2}+4\frac{1}{2}=3.5, 2\frac{1}{2}+4\frac{1}{2}=3$

Table 15.25: **Detailed application of Laplace criterion**

The game then becomes:

J_2 J_1	$\mathbf{E}(b_1)$	$\mathbf{E}(b_2)$
$\mathbf{E}(a_1)$	$3.5, 4$	$3.5, 3$
$\mathbf{E}(a_2)$	$3.5, 4$	$3.5, 3$

Table 15.26: **Laplace criterion simplified table**

In this example, where the expected utilities is always equal for the player J_1 whatever his strategy, the player J_2 will choose the strategy where his loss is the lowest either b_2. So here we have a Nash equilibrium (without Pareto optimality).

15.2.4.3 Kelly criterion

So we have found an investment we really like. That's great, but what do we do next? In other words, after deciding what to invest in, what's the next question you should ask? If we're thinking of asking exactly how much money you should invest, then we're exactly right! Luckily, the mathematics of betting has an incredibly useful idea that we can use: the "Kelly Criterion". That latter maximises growth when the wealth compounds multiplicatively. It makes no assumption about the shape of utility! In other words, it's prescriptive, not descriptive. The Kelly criterion says that if you want to maximise growth, you should adopt log utility.

The Kelly Criterion was developed by John L. Kelly Jr. in 11956 (holocene calendar), who was a scientist at Bell Labs who developed this method through research into game theory and information theory combined with trials in Las Vegas betting and investments in the stock market.

When we're putting money in some effort to receive more money back, i.e. a bet, we will need to find out how much of your money you should wager. We wouldn't bet all our money unless we are 100% sure that you will win a bet and you would not bet any of your money unless we are 100% sure we will lose the bet. Intuitively, we would only bet some of ou money — and what *some of your money* amounts to depends on how likely we think the winning outcome is.

If we think the winning outcome is more likely to occur, we will bet more of our money, and if we think a losing outcome is more likely, we will bet less of our money. Think of the lottery — we never bet all our money on one lottery ticket because the chance of winning is infinitesimal. Using this intuition of betting more or less depending on the likelihood of a profitable outcome, we can begin understanding the exact amount to bet.

The math behind the Kelly Criterion is based on simple probability and manipulation. What is important to understand is the compounding nature of bets it assumes. What that means is that each bet and its profits feed into the next bet. If you bet 100.- and get 110.- back, that 110.- is used entirely in the next bet you place. This compounding principle is essentially the same one that compound interest uses.

The following hypothesis are required to successfully implement the Kelly criterion. They are:

H1. The expected rate of return must be greater than 0.

H2. It must be possible to reinvest the cash flows coming from investment.

H3. The existence of an independent relationship between the final cash flows must be held.

H4. The cash flows of investment must satisfy the conditions of a Bernoulli process[9].

H5. The investing activities must be carried out infinitely.

H6. It must be possible to dissemiate an investment capital in an infinitesimal size.

H7. The winning probability of p must be kept constant to investors.

Because the Kelly Criterion leads to higher wealth than any other strategy in the long run (i.e., the theoretical maximum return as the number of bets goes to infinity), it is a scientific gambling method.

The practical use of the formula has been demonstrated for gambling and the same idea was used to explain diversification in investment management. In the 12000s (holocene calendar), Kelly-style analysis became a part of mainstream investment theory and the claim has been made that well-known successful investors including Warren Buffett and Bill Gross use Kelly methods.

---

[9] This can be tested with the well-known nonparametric Pearson's χ^2 goodness of fit test!

15.2.4.3.1 Discrete time Kelly criterion

Theorem 15.2. The Kelly bet size, i.e. optimal theoretical size for a bet, is found by maximizing the expected value of the logarithm of wealth (i.e. the point of the Kelly Criterion is to maximize the expected geometric growth rate - not the expected arithmetic return and not the expected terminal wealth!!!!), which is equivalent to maximizing the expected geometric growth rate is equal to:

$$f^*=p-\frac{q}{b}=p+\frac{p-1}{b}=\frac{p(b+1)-1}{b} \tag{15.2.66}$$

where:

- f^* is the fraction of the current bankroll to wager
- p is the probability of a win
- q is the probability of a loss ($q=1-p$)
- b is the proportion of the bet gained with a win[10].

That is a special case of the following more general case:

$$f^*=\frac{p}{a}-\frac{q}{b} \tag{15.2.67}$$

where a is the fraction that is lost in a negative outcome.

Proof 15.2.1. Heuristic proofs of the Kelly criterion are straightforward (for a rigorous and general proof, see Kelly's original paper!). The Kelly criterion maximizes the expected value of the logarithm of wealth (the expectation value of a function is given by the sum, over all possible outcomes, of the probability of each particular outcome multiplied by the value of the function in the event of that outcome). We start with 1 unit of wealth and bet a fraction f of that wealth on an outcome that occurs with probability p and offers odds of b.

The probability of winning is p, and in that case the resulting wealth is equal to:

$$1+f\cdot b \tag{15.2.68}$$

Every time we win, our money grows by this amount. Since we have a p percent chance of winning on the long run, it makes sense to mathematically model the overall percentage growth from winning bets as follows (the detailed explanation if this is given in a remark box just below):

$$(1+f\cdot b)^p \tag{15.2.69}$$

So because our investment is compounded so we get exponential growth (or decay as we will see just below)!

---

[10] For example, if betting 10.- on a 2-to-1 odds bet, (upon win you are returned 30, winning you 20), then $b=\$20/\$10=2.0$

The probability of losing is $q=1-p$, and in that case the resulting wealth is equal to:

$$1-f\cdot a \tag{15.2.70}$$

Every time we loss, our money falls by this amount. Since we have a q percent chance of losing on the long run, it makes sense to mathematically model the overall percentage growth from winning bets as follows:

$$(1-f\cdot a)^q \tag{15.2.71}$$

Therefore, the geometric growth rate is given by:

$$r=(1+f\cdot b)^p\cdot(1-f\cdot a)^q \tag{15.2.72}$$

and the logarithmic geometric growth rate is then given by:

$$\log(r)=p\log(1+f\cdot b)+q\log(1-f\cdot a) \tag{15.2.73}$$

To quote from Kelly's original paper "*The reason (for the log rule) has nothing to do with the value which (the gambler) attached to his money, but merely with the fact that it is the logarithm which is additive in repeated bets*".

Remark

Our current wealth at any stage $t=T$ will be given by the number of winning N and the number of looses M (where $N+M=T$). Now let try to calculate the equivalent Compound Growth rate τ for the process at stage T:

$$\begin{aligned} r=(1+\tau)^T &= (1+f\cdot b)^N\cdot(1-f\cdot a)^M \\ &= \left((1+f\cdot b)^{\frac{N}{T}}\cdot(1-f\cdot a)^{\frac{M}{T}}\right)^T \\ &= \left((1+f\cdot b)^{\frac{N}{N+M}}\cdot(1-f\cdot a)^{\frac{M}{N+M}}\right)^T \\ &\overset{\text{behave as when }T\to\infty}{\approx} \left((1+f\cdot b)^p\cdot(1-f\cdot a)^q\right)^T \end{aligned} \tag{15.2.74}$$

Taking the derivative to find the optimum point:

$$\left.\frac{\mathrm{d}\log(r)}{\mathrm{d}f}\right|_{f=f^*}=\frac{p\cdot b}{1+f^*\cdot b}+\frac{-qa}{1-f^*\cdot a}=0 \tag{15.2.75}$$

Rearranging this equation to solve for the value of f^* gives the "discrete Kelly criterion":

$$\boxed{f^*=\frac{p}{a}-\frac{q}{b}} \tag{15.2.76}$$

Notice that this expression reduces to the simple "gambling formula" when $a=1=100\%$, when a loss results in full loss of the wager:

$$\boxed{f^*=p-\frac{q}{b}} \tag{15.2.77}$$

The latter is often written as:

$$f^*=p-\frac{q}{b}=\frac{p\cdot b-q}{b}=\frac{\text{edge}}{\text{odds}} \tag{15.2.78}$$

■ Q.E.D.

✍**Examples:**

E1. If a gamble has a 60% chance of winning ($p=0.6$, $q=1-p=0.4$), and the gambler receives 1-to-1 odds on a winning bet (i.e. $b=1$), then the gambler should bet 20% of the bankroll at each opportunity as:

$$f^*=0.6-\frac{0.4}{1}=0.2$$

in order to maximize the long-run growth rate of the bankroll.

E2. If the gambler has zero edge, i.e. if $b=q/p$ (typically the case of a coin flip game), then the criterion recommends for the gambler to bet nothing as:

$$f^*=p-\frac{q}{b}=p-\frac{q}{q/p}=0$$

However, the major difficulty in applying the criterion is that it assumes that the true probabilities p of events occurring is known to the bettor.

In reality, these are often unknown and the probabilities have to be estimated by the bettor. Unfortunately, any estimate is, by definition, likely to be wrong since it's just a guess. The criterion is sensitive to the estimated probabilities, and since the criterion maximizes the wealth doubling exponent, mistakes made in the estimated probabilities can easily ruin the bettor over time.

Now let us see an example on how to apply the above results in a naive way on a simple trading case.

✍**Example:**

We have the history of 75 trades. From these trades we have the following informations:

- Number of trades that gained money: 66
- Number of trades that lost money: 9
- Average gain per winning trade: 659.12.-
- Average loss per losing trade: $1,799.06$.-

We calculate the following needed for edge over odds:

- The win probability:

$$p=\frac{66}{75}=0.88$$

- The gain per unit bet:

$$b=\frac{659.12}{1799.06}=0.366$$

Hence:

$$f^*=p-\frac{q}{b}=p-\frac{1-p}{b}=0.88-\frac{0.88}{0.366}\cong 0.552$$

15.2.4.3.2 Continuous time Kelly criterion

The formula we have derived above is in fact the "discrete Kelly criterion". That's not so useful in trading, where the outcomes are continuous! So let us see how to derive it for the continuous case!

We have strategy with a return stream r_i, where r_i are independent identically distributed random variables with such properties:

$$\begin{aligned}-1\leq r_i &\leq +1\\ \mathrm{E}\left(r_i\right)&=\mu_r\\ \mathrm{V}\left(r_i\right)&=\sigma_r^2\end{aligned} \tag{15.2.79}$$

C_0 is the total initial capital, C_t is the total capital after t trades, f is the fraction of capital we invest in every trade:

$$\begin{aligned}&C_1=C_0\left(1+f\cdot r_1\right)\\ &C_2=C_1\left(1+f\cdot r_2\right)=C_0\left(1+f\cdot r_1\right)\left(1+f\cdot r_2\right)\\ &\ldots\\ &C_t=C_0\left(1+f\cdot r_1\right)\left(1+f\cdot r_2\right)\ldots\left(1+f\cdot r_t\right)=C_0\prod_{i=1}^{t}\left(1+f\cdot r_i\right)\end{aligned} \tag{15.2.80}$$

At period t we define the "gain" G as the ratio between the capital C_t and the initial capital C_0 :

$$G=\frac{C_t}{C_0}=\prod_{i=1}^{t}\left(1+f\cdot r_i\right) \tag{15.2.81}$$

Since C_t depends on the random variables r_i, it is itself a random variable.

So we want to find the fraction f^* that maximises the expected value of G, i.e.:

$$\begin{aligned}\mathrm{E}(G)&=\mathrm{E}\left(\prod_{i=1}^{t}\left(1+f\cdot r_i\right)\right)\\ f^*&=\mathrm{argmax}_f\mathrm{E}(G)\end{aligned} \tag{15.2.82}$$

This is equivalent to the easier task of maximizing $\mathrm{E}\left(\log(G)\right)$:

$$\log(G)=\log\left(\prod_{i=1}^{t}\left(1+f\cdot r_i\right)\right)=\sum_{i=1}^{t}\log\left(1+f\cdot r_i\right) \tag{15.2.83}$$

Therefore:

$$\mathrm{E}\left(\log(G)\right)=\mathrm{E}\left(\sum_{i=1}^{t}\log\left(1+f\cdot r_i\right)\right)=\sum_{i=1}^{t}\mathrm{E}\left(\log\left(1+f\cdot r_i\right)\right)=t\mathrm{E}[\log(1+f\cdot r)] \tag{15.2.84}$$

So:

$$f^{*}=\operatorname{argmax}_f \mathrm{E}\left(\log(G)\right)\equiv\operatorname{argmax}_f t\mathrm{E}[\log(1+f\cdot r)]=\operatorname{argmax}_f\mathrm{E}\left(\log(1+f\cdot r)\right) \tag{15.2.85}$$

So to find the optimum we seek the derivative such that:

$$\frac{\mathrm{d}}{\mathrm{d}f}\mathrm{E}\left(\log(1+f\cdot r)\right)=0 \tag{15.2.86}$$

For an easier differentiation, we use a well known second order Taylor series expansion (see section Sequences and Series page 1710):

$$\log(1+x)\cong x-\frac{x^2}{2}\Rightarrow\log(1+f\cdot r)\cong(fr)-\frac{(f\cdot r)^2}{2} \tag{15.2.87}$$

Therefore:

$$\begin{aligned}\mathrm{E}\left(\log(1+f\cdot r)\right)\cong\mathrm{E}\left((f\cdot r)-\frac{(f\cdot r)^2}{2}\right)&=\frac{\mathrm{d}}{\mathrm{d}f}\mathrm{E}\left(f\cdot r\right)-\frac{\mathrm{d}}{\mathrm{d}f}\mathrm{E}\left(\frac{f^2r^2}{2}\right)\\&=\mathrm{E}(r)\frac{\mathrm{d}}{\mathrm{d}f}f-\mathrm{E}\left(r^2\right)\frac{\mathrm{d}}{\mathrm{d}f}\frac{f^2}{2}=\mathrm{E}(r)-\mathrm{E}\left(r^2\right)f\end{aligned} \tag{15.2.88}$$

We equate to zero:

$$\frac{\mathrm{d}}{\mathrm{d}f}\mathrm{E}\left(\log(1+fr)\right)\cong\mathrm{E}(r)-\mathrm{E}\left(r^2\right)f=0 \tag{15.2.89}$$

Therefore:

$$\mathrm{E}(r)\cong\mathrm{E}\left(r^2\right)f \tag{15.2.90}$$

By rearranging:

$$f^{*}\cong\frac{\mathrm{E}(r)}{\mathrm{E}\left(r^2\right)} \tag{15.2.91}$$

But as $\mathrm{E}(r)=\mu_r$ and using Huygens relation (see section Statistics page 593) $\mathrm{E}\left(r^2\right)=\sigma_r^2+\mu_r^2$, we finally have:

$$f^{*}\cong\frac{\mu_r}{\sigma_r^2+{\mu_r}^2}\cong\frac{\mu_r}{\sigma_r^2}\qquad\text{if }\mu_r\ll\sigma_r \tag{15.2.92}$$

The average return stream μ_r is the superposition of the (average) rate of the risky bet (i.e. asset) and the average return of the non-risky bet (i.e. asset). We have to focus on the risky part! Therefore, denoting as always by r_f the return without risk and r_A the risky asset return such that $\mu_r=r_A+r_f$, we have then to replace μ_r by μ_r-r_f such that:

$$\boxed{f^{*}\cong\frac{\mu_r-r_f}{\sigma_r^2+(\mu_r-r_f)^2}\cong\frac{\mu_r-r_f}{\sigma_r^2}}\qquad\text{if }\mu_r\ll\sigma_r \tag{15.2.93}$$

We don't need to correct the variance and the denominator by including the variance of the free risk rate return as by definition that latter is supposed to be zero! For single assets (stock, index fund, etc.), and a risk-free rate r, the optimal fraction to invest through geometric Brownian motion $\mathrm{d}S_t/S_t = \mu \mathrm{d}t + \sigma \mathrm{d}W_t$ lead to exactly the same result as above!

That is sometimes rewritten using the Sharpe ratio (see page 7723) as following:

$$f^* \cong \frac{S_P}{\sigma_r} \tag{15.2.94}$$

Remark

There are other ways to get the same result but some well known other derivations have some strange counter-intuitive assumptions that we wanted to avoid here.

This is how $\mathrm{E}\left(\log(G)\right)$ and $\mathrm{E}(G)$ vary with f :

$$\begin{aligned}
\mathrm{E}\left(\log(G)\right) &= t\mathrm{E}\left(\log(1+f\cdot r)\right) \cong t\mathrm{E}\left((f\cdot r)-\frac{(f\cdot r)^2}{2}\right) = t\left(f\mathrm{E}(r)-\frac{f^2}{2}\mathrm{E}\left(r^2\right)\right)\\
&= t\left(f\cdot\mu_r - f^2\frac{(\sigma_r^2+\mu_r^2)}{2}\right) \cong t\left(f\cdot\mu_r-\frac{1}{2}f^2\sigma_r^2\right) \text{ if } \mu_r \ll \sigma_r \\
\mathrm{E}(G) &= \mathrm{E}\left(e^{\log(G)}\right) = e^{\mathrm{E}(\log(G))} \cong e^t\left(f\cdot\mu_r - f^2\frac{\sigma_r^2}{2}\right)
\end{aligned} \tag{15.2.95}$$

This is the max value of $\mathrm{E}[\log G]$ and $\mathrm{E}[G]$ when $f = f^*$:

$$\begin{aligned}
\max\mathrm{E}\left(\log(G)\right) &= t\left(\frac{\mu_r}{\sigma_r^2+\mu_r^2}\mu_r - \left(\frac{\mu_r}{\sigma_r^2+\mu_r^2}\right)^2\frac{(\sigma_r^2+\mu_r^2)}{2}\right) = t\left(\frac{\mu_r^2}{\sigma_r^2+\mu_r^2}-\frac{1}{2}\frac{\mu_r^2}{\sigma_r^2+\mu_r^2}\right)\\
&= \frac{t}{2}\frac{\mu_r^2}{\sigma_r^2+\mu_r^2} \cong \frac{t}{2}\frac{\mu_r^2}{\sigma_r^2} \text{ if } \mu_r \ll \sigma_r \\
\max\mathrm{E}(G) &= \max e^{\mathrm{E}(\log(G))} = e^{\max\mathrm{E}(\log(G))} \cong e^{\frac{t\mu_r^2}{2\sigma_r^2}}
\end{aligned} \tag{15.2.96}$$

Moreover, no money management system is perfect. This system will help you to diversify your portfolio efficiently, but there are many things that it can't do. It cannot pick winning stocks for you or predict sudden market crashes (although it can lighten the blow). There is always a certain amount of "luck" or randomness in the markets which can alter your returns.

15.2.5 Evolutionary Games

The strategies of biological evolution, as we have mentioned it earlier in this section, can be modelled using game theory. In this context, the biologist is bring to define remarkable relations defining a given development strategy (dominance, stagnation, suicide or other). Evolutionary Games originated in 11973 (holocene calendar) with John Maynard Smith and George R. Price's formalisation of contests, analysed as strategies, and the mathematical criteria that can be used to predict the results of competing strategies (hence 23 years after the publication by Nash of its famous paper just to put into context...).

Definition (#15.2.648): An "evolutionary steady strategy" (ESS) is a strategy adopted by the majority and preventing a population is invaded by a mutant that would use a different strategy.

This strategy is written in the form of a stable condition such that given two strategies S_1, S_2 of two players we have (explanations are given just after):

$$\boxed{U(S_1,S_1)>U(S_2,S_1)} \tag{15.2.97}$$

or (if it does not occur) by the simultaneity of the two strategies of non-selection and suicide:

$$\boxed{U(S_1,S_1)=U(S_2,S_1) \qquad \text{and} \qquad U(S_1,S_2)=U(S_2,S_2)} \tag{15.2.98}$$

1. The first relation means that in no case an individual has to change from strategy to defend against a mutant evolution with the same strategy than him, because any other strategy would be unfavourable.

2. The second relation means that whatever the strategy adopted against a mutant strategy, there will be stagnation.

3. The third relation means that against S_2 any strategy different of S_2 is preferable to counteract S_2 itself. In other words, apply a strategy S_2 different from S_1 is suicidal (the opposite is therefore not!).

To introduce such decision situation let use again a long companion example: the Hawk (bad) against Doves (good) game.

The H/D game has for purpose to model the relations between individuals competing for a rare resource (food, water, area, companion, contract, etc.) which degree of adaptation will be changed both by obtaining this resource and the violence they suffer or inflict to them to get it.

In their competitive interactions, biological organisms use two types of strategies (behaviours): the strategy of the hawk or that of the dove (as you can notice the "neutral" one is not present as it a suicide strategy).

The falcon intensify the conflict until he is injured or until the other run away. The dove withdrew after a first fight if the opponent chooses to escalate the violence of the conflict. When two hawks meet, one is injured and the other carries the resource. If a hawk and a dove fight, the hawk seized the safe resource to be injured and the dove gets no advantage or damage (at least on the short term and if there is not implicit trap). Finally, two doves share equally the resource.

We also put the following hypothesis (assumptions):

H1. Fight take place one by one

H2. The population can be considerate as infinite

H3. The encounters are random

H4. The battles are balanced (in the sense that neither age nor size nor experience influence the outcome of the battle)

H5. It is impossible to know before the start of a conflict which strategy will be adopted by one of the player

Based on these rules of interaction (where some are quite far from reality ...), it is possible to construct the tabular form of the game that allow us to calculate the advantages or disadvantages of the various strategies depending on the circumstances.

Therefore the tabular form of the game is (explanations of the variables are given after):

J_2 / J_1	H **(Hawk)**	D **(Dove)**
H **(Hawk)**	$\dfrac{V-C}{2},\dfrac{V-C}{2}$	$V,0$
D **(Dove)**	$0,V$	$\dfrac{V}{2},\dfrac{V}{2}$

Table 15.27: Hawk vs Dove evolutionary game matrix

As we can see the above game is a zero sum game, thus we can simplify the above table:

J_2 / J_1	H **(Hawk)**	D **(Dove)**
H **(Hawk)**	$\dfrac{V-C}{2}$	V
D **(Dove)**	0	$\dfrac{V}{2}$

Table 15.28: Simplified Hawk vs Dove evolutionary game matrix

We denote here by V the advantage that a player withdraws from obtaining the resource. V does not designate the resource itself, but the increased degree of adaptation that it provides to the player that gets it. C represents the cost paid, endangerment or injury, to acquire the resource.

First let us make explicit how this table should be read technically:

1. For the strategy (D,D) - everyone is nice to everyone - the total gain of the two individuals is:

$$\frac{V}{2}+\frac{V}{2}=V \tag{15.2.99}$$

   The population will therefore remain constant (it's the stagnation). In short, by their behaviour doves amicably share the resource value.

2. For the strategies (H,D), (D,H) the "doves" D always lose (they do not progress in their evolution). Their gain is zero while the "hawks" have eliminated a number V of doves (hence the gain).

3. For the (H,H) strategy the "hawks" support a loss $(V-C)/2$ where C is a constant and such that the sum of gains of the hawks is normally less than or equal to V. In other words:

$$\frac{V-C}{2}+\frac{V-C}{2}=V-C\leq V \tag{15.2.100}$$

In short, when a hawk fight another hawk, he gets on average 50% of the time the value of the resource reduced of the cost price to get it.

In summary to simplify:

1. Hawks (aggressive):
   - Always attack other individuals, taking the resource if the win
   - If a hawk encounters another hawk, it will win only half the time
   - When it loses, it will suffer and injury cost
2. Doves (non-aggressive):
   - When a dove encounters an opponent, it may put on an aggressive display, but it does not fight
   - When a dove encounters a dove, it will win the resource one half the time
   - When a dove encounters a hawk, the hawk will always win the resource
   - But since they don't fight, they don't incur any injury cost

Or in the form of a table:

J_1 \ J_2	H **(Hawk)**	D **(Dove)**
H **(Hawk)**	Hawk wins 50% of fights; is injured in 50% of fights.	Hawk always wins; dove flees.
D **(Dove)**	Dove never wins; is never injured.	Dove wins 50% of fights; is never injured.

Table 15.29: **Hawk vs Dove evolutionary game matrix explicit example**

Remark

This game can be seen as a war game between two players (or ideologies)... the interpretation of this results is therefore more than relevant. It is also an excellent comparison example between the competition that may exist between government offices (dowes) and private offices (hawks) providing the same type of product/service.

We must now consider two strategies:

1. The study of the game using a pure strategic game (without probabilities)
2. The study of the game using a mixed strategy (involving probabilities)

15.2.5.1 Dove & Hawk game in pure strategy (without probabilities)

For this type of strategy we will consider three cases:

$$V<C \qquad V=C \qquad V>C \tag{15.2.101}$$

1. If $V>C$ (higher benefit than the cost of the strategy), choosing (H,H) (which is therefore the strict Nash equilibrium of the game) we can see that the game will be a stable evolutionary strategy (SES). Indeed, we fall back on the relation:

   $$\left[U(H,H)=\frac{V-C}{2}\right]>[U(D,H)=0] \tag{15.2.102}$$

   corresponding well to:

   $$U(S_1,S_2)>U(S_2,S_1) \tag{15.2.103}$$

   and we can therefore also observe that there exist is also a weakly dominant strategy (no natural selection) in:

   $$[U(H,D)=V]>\left[U(D,D)=\frac{V}{2}\right] \tag{15.2.104}$$

   corresponding well to:

   $$U(S_1,S_2)>U(S_2,S_2) \tag{15.2.105}$$

   But that latter will not be adopted as weaker than the Nash equilibrium.

2. If $V=C$ (benefit equal to the cost), the game is also of the SES kind. Indeed, (H,H) becomes a weakly dominant strategy:

   $$[U(H,H)=0]=[U(D,H)=0] \tag{15.2.106}$$

   corresponding well to:

   $$U(S_1,S_1)=U(S_2,S_1) \tag{15.2.107}$$

   and there is therefore no evolution and we can also observe that there is also:

   $$[U(H,D)=V]=\left[U(D,D)=\frac{V}{2}\right] \tag{15.2.108}$$

   corresponding to:

   $$U(S_1,S_2)>U(S_2,S_2) \tag{15.2.109}$$

   Since we have simultaneously:

   $$U(S_1,S_1)=U(S_2,S_1) \qquad \text{and} \qquad U(S_1,S_2)>U(S_2,S_2) \tag{15.2.110}$$

   when $V=C$ the game is a SES.

3. If $V<C$ (benefit less than the cost), nor H, nor D are the dominant strategies and we do not have a SES:

$$[U(D,H)=0]>\left[U(H,H)=\frac{V-C}{2}\right] \tag{15.2.111}$$

and:

$$[U(H,D)=V]>\left[U(D,D)=\frac{V}{2}\right] \tag{15.2.112}$$

the latter two relations corresponding both to:

$$U(S_1,S_2)>U(S_2,S_2) \tag{15.2.113}$$

It is rather annoying... it's a kind of collective suicide...

Remark

The last two relations lead us to observe that the hawks will not want to necessarily reveal to others their strategy of doves predators, since: any strategy is better to be countered by another strategy rather than by itself. They may prefer to discuss among themselves which leads to the fact that the game therefore cooperative.

15.2.5.2 Dove & Hawk game in stable evolutionary strategy (with probabilities)

Let us now using the study in mixed strategy what we could do to bring the previous configuration to a SES (thus relatively to the last configuration $V<C$ to see more closely what we can do to avoid this) :

We consider a population of individuals who therefore play a mixed strategy which we denote for each:

$$\sigma(P,1-P) \tag{15.2.114}$$

with $P=P(H)$ and:

$$1-P=P(D) \tag{15.2.115}$$

If $P=1$ (pure strategy), we will therefore have:

$$\sigma(P,1-P)=\sigma(1,0)=\sigma_H \tag{15.2.116}$$

Let us now study the three cases:

$$V<C \qquad V=C \qquad V>C \tag{15.2.117}$$

- If $V>C$ with σ_H and $1>P\geq 0$ we always have:

  $$U(\sigma_H,\sigma_H)>U(\sigma,\sigma_H) \tag{15.2.118}$$

  in other words, the strategy will be always of the kind stable evolutionary (SES) if σ_H is a pure strategy and this even if σ can vary and tend to σ_H.

- If $V=C$ with σ_H and $1>P\geq 0$, we always have:

  $$U(\sigma_H,\sigma_H)=U(\sigma,\sigma_H) \qquad \text{and} \qquad U(\sigma_H,\sigma)>U(\sigma,\sigma)=\frac{V}{2} \tag{15.2.119}$$

  in other words: the strategy will always be of the non-selective type if σ_H is a pure strategy even if σ can vary and tend to σ_H.

- If $V<C$ and $1>P\geq 0$, we drop σ_H to focus only to the generalization $\sigma(P,1-P)$. Then we have:

  $$U(\sigma,D)>U(D,D) \tag{15.2.120}$$

  Indeed:

  $$\left[U(\sigma,D)=PV+(1-P)\frac{V}{2}=(1+P)\frac{V}{2}\right]>\left[U(D,D)=\frac{V}{2}\right] \tag{15.2.121}$$

  Also:

  $$U(\sigma,H)>U(H,H) \tag{15.2.122}$$

  Indeed:

  $$\left[U(\sigma,H)=P\frac{V-C}{2}+(1-P)\cdot 0=P\frac{V-C}{2}\right]>\left[U(H,H)=\frac{V-C}{2}\right] \tag{15.2.123}$$

  and we would to arrive at a SES with a mixed strategy. Is this possible?

  As part of a mixed strategy, we have proved during our study of a zero-sum game that mixed equilibrium was given by:

  $$\mathrm{E}(J_1)=-\mathrm{E}(J_2) \tag{15.2.124}$$

  It is therefore quite obvious that for a game that is not a zero-sum game, we have the mixed equilibrium given by:

  $$\mathrm{E}(J_1)=\mathrm{E}(J_2) \tag{15.2.125}$$

  Therefore we seek the relation between P, C and V such that this equilibrium is reached. So in cascade we have:

  $$\mathrm{E}(J_1)=\mathrm{E}(J_2) \tag{15.2.126}$$

  that can be written:

  $$\mathrm{E}(H)=\mathrm{E}(D) \tag{15.2.127}$$

  Which lead us to write:

  $$U(H,\sigma)=U(D,\sigma)\Leftrightarrow U(S_1,S_1)=U(S_2,S_1) \tag{15.2.128}$$

  Therefore:

  $$P\cdot U(H,H)+(1-P)\cdot U(H,D)=P\cdot U(D,H)+(1-P)\cdot U(D,D) \tag{15.2.129}$$

Knowing the utilities:

$$P\cdot\frac{V-C}{2}+(1-P)\cdot V=P\cdot 0+(1-P)\cdot\frac{V}{2} \tag{15.2.130}$$

from which we derive that the equilibrium in mixed strategy is given by:

$$P=\frac{V}{C} \tag{15.2.131}$$

and therefore that the equilibrium is given by the mixed strategy:

$$\sigma=\left(\frac{V}{C},1-\frac{V}{C}\right) \tag{15.2.132}$$

To what will this strategy lead to in practice? Well, simply in the suicidal case this mixed strategy is the best answer against itself (this is what is best done in what is worst) because it leads to the two conditions that satisfy a SES.

Remark

We strongly recommend the reader to take a look to the paper *Social penalty promotes cooperation in a cooperative society* (see [279]) that as the title says provides evidence in the case of the evolutionary Hawk-Dove game that introducing a social penalty (and even punishments) on the aggressive individual is likely to promote cooperation and never reduce cooperation. The reader can also take a look to the paper *Culture and the evolution of human cooperation* (see [71]) that explains how cultural evolution, social learning, punishment, and group norms support large-scale cooperation.

15.2.6 Cournot Competition

Cournot competition (11838 according to holocene calendar) is an economic model used to describe an industry structure in which companies compete on the amount of output they will produce, which they decide on independently of each other and at the same time.

Let us imagine two companies M and N, and two sources whose qualities are identical and that are positioned to concurrently supply the same market so that the total quantity delivered to shops consists of the sum of the quantities m, n delivered by each company at a price that is necessarily the same for each of them as there is no reason to prefer one source to another. This price is determined when the sum of the quantities m, n is completely known, because of the link between offer and demand. Let us suppose the company N has set arbitrarily, without regard to the price, quantity he n he intends to deliver, then the company M will indirectly fix the sale price on the market, that is to say the total available production (consisting of the sum of the quantities m and n for recall...), that is to say, its own production quantity m to obtain the greatest possible income.

In practice, a series of trial and error will bring the two companies in their equilibrium position, and the theory shows that this equilibrium is stable: that is to say that if one or the other owners depart momentarily from this equilibrium, he will be taken back by a series of oscillations of the kind that had originally led to constitute the balance.

Definition (#15.2.649): A "Cournot equilibrium" is therefore related to the fact that when a firm raises price,the others will stay put. If a firm reduces price,the other firms will do the same.

> Remark
>
> The Nash equilibrium is the generalization of the Cournot equilibrium. A Nash equilibrium can be interpreted as a pair of expectations about each player's choice such that, when the other person's choice is revealed, neither individual wants to change his behaviour.

OK! Let us now focus on the maths part! But for this let us first gives the hypothesis (assumptions) of the mode:

H1. There is more than one firm and all firms produce a homogeneous product, i.e. there is no product differentiation;

H2. Firms do not cooperate, i.e. there is no collusion;

H3. Firms have market power, i.e. each firm's output decision affects the good's price; The number of firms is fixed;

H4. Firms compete in quantities, and choose quantities simultaneously;

H5. The firms are economically rational and act strategically, usually seeking to maximize profit given their competitors' decisions.

We will put ourselves in the situation of a game with two plays. We will put that the price per unit P of the product is a linear function of the total quantity produced Q such that:

$$P(Q)=P(m+n)=\alpha(m+n) \tag{15.2.133}$$

where α a normalization constant of units: [price · piece^{-2}]. As it represents a price per unit divided be a global quantity.

Remark

We will see that this choice we will lead to absurd result as in reality the price per unit decrease in function of the quantity and don't increase.

We assume the marginal production costs equal and fixed and represents by the variable C, and the fixed costs as zero such that the production cost will be written respectively for the both companies:

$$C_M=C_N=C \tag{15.2.134}$$

To recognize a game in normal form, it remains for us to identify the benefit of each opponent for any pair (m,n) of strategies such that, if desired, to build the matrix of gains.

Let us denote π_i the margin of competitor i. Then we have respectively:

$$\begin{gathered}\pi_M(m,n)=mP(m+n)-mC=m\left[\alpha(m+n)-C\right]\\ \pi_N(m,n)=nP(m+n)-nC=n\left[\alpha(m+n)-C\right]\end{gathered} \tag{15.2.135}$$

The search for a Nash equilibrium leads each company to choose a production quantity that maximize profits and minimize its storage costs (see the Wilson's model in the section of Quantitative Management Techniques at page 8119), the production of his concurrent being assumed to be known.

For this purpose, we cancels the derivative of the previous two functions:

$$\begin{gathered}\frac{\partial\pi_M}{\partial m}=2\alpha m+\alpha n-C=0\\ \frac{\partial\pi_N}{\partial n}=\alpha m+2\alpha n=0\end{gathered} \tag{15.2.136}$$

System whose resolution brings leads us easily leads to the obvious solution that:

$$m_{\text{Nash}}=n_{\text{Nash}}=\frac{1}{3}\frac{C}{\alpha} \tag{15.2.137}$$

It remains to verify that these solutions are maximums, by controlling the second-order derivatives, and not minimums.

The equilibrium position of the duopoly intervenes therefore when each of the two companies produces the same quantity... (not surprising result). The is then the Nash equilibrium production quantity.

The sale price unit under a Nash equilibrium would be:

$$\boxed{P_{\text{Nash}}=\alpha(m+n)=\frac{2}{3}C} \tag{15.2.138}$$

Either a value below the marginal cost C which obviously sounds not good as the margin is then negative. Indeed: Therefore the profit is given by:

$$\begin{aligned}\max(\pi_{M,\text{Nash}})=m\left[\alpha(m+n)-C\right]=-m\frac{1}{3}C=-\frac{2}{9}\frac{C^2}{\alpha}\\ \max(\pi_{N,\text{Nash}})=n\left[\alpha(m+n)-C\right]=-n\frac{2}{3}C-mC=-\frac{2}{9}\frac{C^2}{\alpha}\end{aligned} \tag{15.2.139}$$

So it would be better that the price is not an affine function of the quantity...

These calculations are to be compared with the purely economic reasoning, for which each company would like to be alone on the market (monopoly). The profit of the company M in monopoly position would then be in the assumptions above given by:

$$\pi_M(m,0)=m\left[\alpha m-C\right]=\alpha m^2-mC \tag{15.2.140}$$

$$m_{\text{monopoly}}=\frac{1}{2}\frac{C}{\alpha} \tag{15.2.141}$$

So we see obviously that:

$$\boxed{m_{\text{monopolay}}>m_{\text{Nash}}} \tag{15.2.142}$$

and therefore that the quantity produced in case of monopoly is greater in case of duopoly (logical!) and the profit and the prices can then be higher.

The sale price unit under a monopoly would then be:

$$\boxed{P_{\text{monopoly}}=\alpha(m+n)=\alpha m=\frac{1}{2}C} \tag{15.2.143}$$

and therefore:

$$\max(\pi_{M,\text{monompoly}})=m\left[\alpha(m+n)-C\right]=-m\frac{1}{2}C=-\frac{1}{4}\frac{C^2}{\alpha} \tag{15.2.144}$$

Therefore the benefit is still negative with this affine model (...) and even worst... the benefit in case of monopoly is small that in case of duopole...

The idea would be now, if we go back to our two companies, that they establish and agreement (case named "oligopoly agreement" against the competition ... which is forbidden by the commercial laws in most countries!), that makes them share a potential majorited profit. The perfect symmetry of the situations would lead to the division by half of the market. But the difficulty is that the decision to produce:

$$m_{\text{agreement}}=n_{\text{agreement}}=\frac{1}{2}\left(\frac{1}{2}\frac{C}{\alpha}\right) \tag{15.2.145}$$

is not the best answer because it encourages to betray the agreement with the other. Thus, the best balance is that of imposing Nash equilibrium already seen above.

During the development of an agreement or a cartel, one can distinguish several levels of quantities that depend on the degree of precision of the rules defined by the companies belonging to this cartel.

The first case is that we can name a "perfect agreement"; This is the agreement that maximizes the total profit of all the companies at the same time.

The maximization of the total margin (profit) a set of companies will obviously be given by:

$$\boxed{\pi_{\text{cartel}}(q_1,q_2,\ldots,q_n)=QP(Q)-\sum_{i=1}^{n}C_iq_i} \tag{15.2.146}$$

where for recall we have the conditions:

$$C_i\geq 0 \qquad q_i\geq 0 \qquad Q=\sum_{i=1}^{n}q_i \tag{15.2.147}$$

This profit is maximized when obviously all the partial derivatives of order 1 are zero and maximum, that is:

$$\dfrac{\partial\pi_{\text{cartel}}}{\partial q_i}=0\Leftrightarrow\dfrac{\partial\left(\displaystyle\sum_{i=1}^{n}q_iP\left(\sum_{i=1}^{n}q_i\right)\right)}{\partial q_i}-\dfrac{\partial\left(C_iq_i\right)}{\partial q_i}=0 \tag{15.2.148}$$

Where the term:

$$\dfrac{\partial\left(\displaystyle\sum_{i=1}^{n}q_iP\left(\sum_{i=1}^{n}q_i\right)\right)}{\partial q_i} \tag{15.2.149}$$

expresses the change in total revenue caused by a small change in the quantity q_i produced by the manufacturer i, and:

$$\dfrac{\partial\left(C_iq_i\right)}{\partial q_i} \tag{15.2.150}$$

expresses the change in cost caused by the same variation of q_i (producer i marginal cost).

The marginal revenue caused by a given change in output Q is the same, regardless of the manufacturer which changed its production. Indeed, the influence of an additional production on the total supply and the price is the same, that this additional production comes from a producer or another one.

15.2.7 Markov Decision Processes (MDPs)

As we mentioned in the section Probability, Markov chains are also used in the field of decision making techniques. We speak then of "Markov decision processes (MDPs)" (denomination that can be found in the ISO 31010 Risk Management standard) that provide a mathematical framework for modelling decision making in situations where outcomes are partly random and partly under the control of a decision maker (MDPs are known at least as early as the 11950 according to holocene calendar). They are used in a wide area of disciplines, including robotics, automated control, economics, and manufacturing.

More precisely, a Markov Decision Process is a discrete time stochastic control process. At each time step, the process is in some state s, and the hazard may choose any action a a that is available in state s. The process responds at the next time step by randomly moving into a new state s'. The finally issue led to the possibility to help to take better decisions.

Remark

Strictly speaking, Markov decision processes are an extension of Markov chains; the difference is the addition of actions (allowing choice) and rewards (giving motivation). Conversely, if only one action exists for each state (e.g. "wait") and all rewards are the same (e.g. "zero"), a Markov decision process reduces to a Markov chain.

For example, the following simple Markov chain (state diagram) on a particular medical symptom, has a step say to "absorbing state" known by all that it is not possible to survive to this day...:

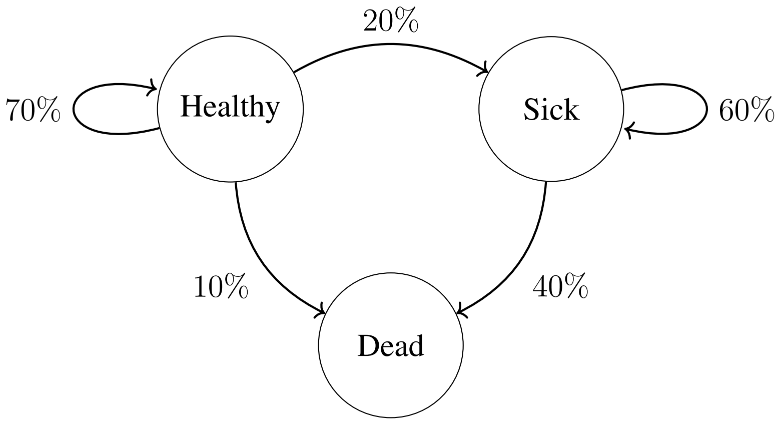


Figure 15.70: **Medical state diagram**

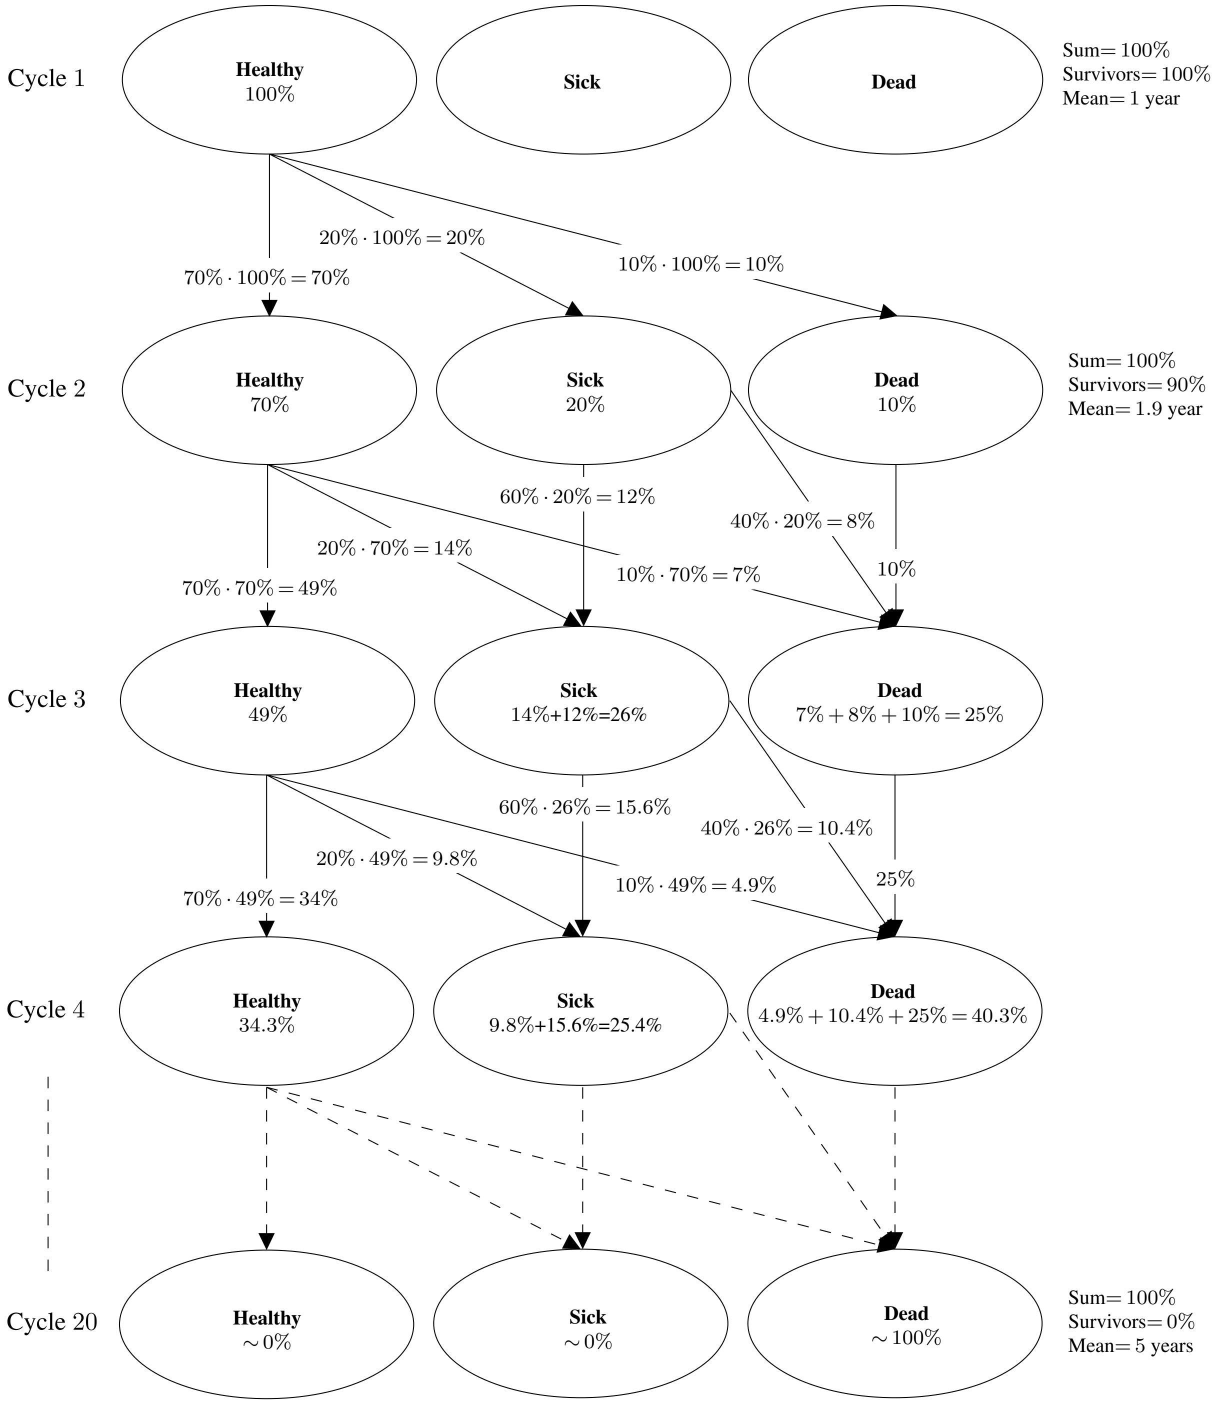
And here is the same Markov chain decomposed over 20 cycles as traditionally presented in the medical field (this assumes that the probabilities do not change over time...):



Cycle 1
Healthy
100%
Sick
Dead
Sum= 100%
Survivors= 100%
Mean= 1 year
20% · 100% = 20%
10% · 100% = 10%
70% · 100% = 70%
Cycle 2
Healthy
70%
Sick
20%
Dead
10%
Sum= 100%
Survivors= 90%
Mean= 1.9 year
60% · 20% = 12%
40% · 20% = 8%
20% · 70% = 14%
10%
10% · 70% = 7%
70% · 70% = 49%
Cycle 3
Healthy
49%
Sick
14%+12%=26%
Dead
7% + 8% + 10% = 25%
60% · 26% = 15.6%
40% · 26% = 10.4%
20% · 49% = 9.8%
25%
10% · 49% = 4.9%
70% · 49% = 34%
Cycle 4
Healthy
34.3%
Sick
9.8%+15.6%=25.4%
Dead
4.9% + 10.4% + 25% = 40.3%
Cycle 20
Healthy
∼ 0%
Sick
∼ 0%
Dead
∼ 100%
Sum= 100%
Survivors= 0%
Mean= 5 years

We can also consider the following example applied to finance:

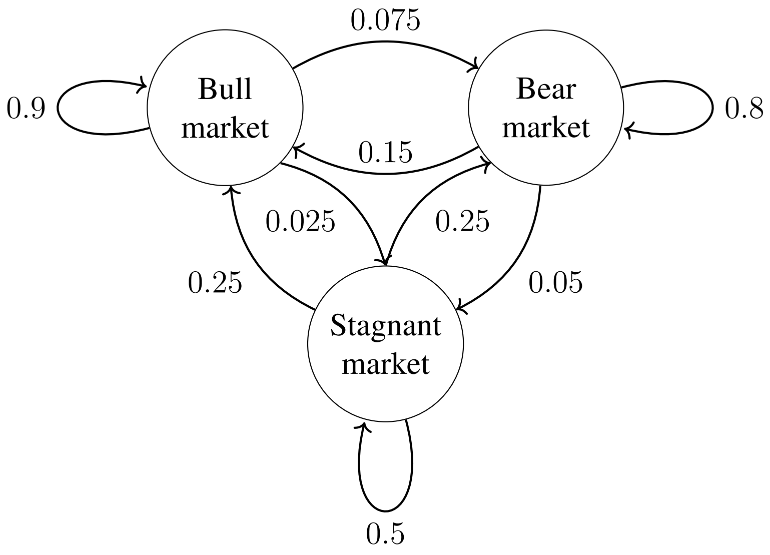


Figure 15.71: Financial state diagram (source: Wikipedia, author: Gareth Jones)

where a bull week[11] is followed by another bull week 90% of the time, a bear week 7.5% of the time, and a stagnant week the other 2.5% of the time. Labelling the state space 1 = bull, 2 = bear, 3 = stagnant the transition matrix (see section Probabilities page 538) for this example is:

$$P=\begin{bmatrix}0.9 & 0.075 & 0.025\\ 0.15 & 0.8 & 0.05\\ 0.25 & 0.25 & 0.5\end{bmatrix} \tag{15.2.151}$$

The distribution over states can be written as a stochastic row vector p with the relation:

$$x(n+1)=x(n)P \tag{15.2.152}$$

So if at time n the system is in state $p(n)$, then three time periods later, at time $p+3$ the distribution is:

$$\begin{aligned}p^{(n+3)}&=p^{(n+2)}P=\left(x^{(n+1)}P\right)\,P\\ &=p^{(n+1)}P^2=\left(p^{(n)}P\right)\,P^2\\ &=p^{(n)}P^3\end{aligned} \tag{15.2.153}$$

In particular, if at time n the system is in state 2 (bear), then at time $n+3$ the distribution is:

$$\begin{aligned}p^{(n+3)}&=\begin{bmatrix}0 & 1 & 0\end{bmatrix}\begin{bmatrix}0.9 & 0.075 & 0.025\\ 0.15 & 0.8 & 0.05\\ 0.25 & 0.25 & 0.5\end{bmatrix}^3\\ &=\begin{bmatrix}0 & 1 & 0\end{bmatrix}\begin{bmatrix}0.7745 & 0.17875 & 0.04675\\ 0.3575 & 0.56825 & 0.07425\\ 0.4675 & 0.37125 & 0.16125\end{bmatrix}\\ &=\begin{bmatrix}0.3575 & 0.56825 & 0.07425\end{bmatrix}\end{aligned} \tag{15.2.154}$$

---

[11] "Bearish" and "Bullish" are simply terms used to characterize trends in the currency, commodity or stock markets. If prices tend to be moving upward, it is a bull market. If prices are moving downward, it is a bear market.

Using the transition matrix it is possible to calculate, for example, the long-term fraction of weeks during which the market is stagnant, or the average number of weeks it will take to go from a stagnant to a bull market. Using the transition probabilities, the steady-state probabilities indicate that 62.5% of weeks will be in a bull market, 31.25% of weeks will be in a bear market and 6.25% of weeks will be stagnant, since:

$$\lim_{N\to+\infty} P^N = \begin{bmatrix} 0.625 & 0.3125 & 0.0625 \\ 0.625 & 0.3125 & 0.0625 \\ 0.625 & 0.3125 & 0.0625 \end{bmatrix} \qquad (15.2.155)$$

Obviously it is possible to perform the same calculation directly in matrix form... again the transition matrix (stochastic matrix) is easy to identify. It is (see section Probabilities page 538):

$$P = \begin{bmatrix} p_{11} & p_{12} & p_{13} \\ p_{21} & p_{22} & p_{23} \\ p_{31} & p_{32} & p_{33} \end{bmatrix} = \begin{bmatrix} 0.7 & 0.2 & 0.1 \\ 0 & 0.6 & 0.4 \\ 0 & 0 & 1 \end{bmatrix} \qquad (15.2.156)$$

The initial probability vector $p(0)$ is obviously in the most common cases of disease ...:

$$p(0) = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} \qquad (15.2.157)$$

Every time we multiply the transpose of the transition matrix by the vector of initial probabilities, we then get the probability of being in a given state at a given cycle !:

$$p(n+1) = P^T p(n) \qquad (15.2.158)$$

With the Microsoft® Excel® 14.0.7173 the modelling is quite simple to reproduce:

Figure 15.74: **Medical Markov decision process far time states in Microsoft® Excel® 14.0.7173**

It is very common in companies to synthesize the evolution graphically (more meaningful to management...):

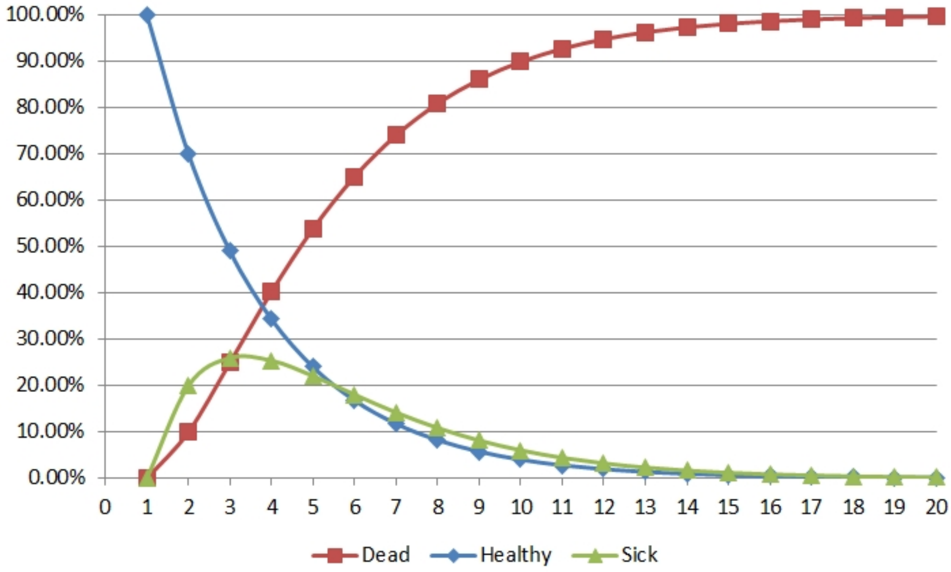

Figure 15.75: **Medical Markov decision process far time states in Microsoft® Excel® 14.0.7173**

So we see that the state "death" is an absorbing state because all probabilities converges to it (unfortunately ...). We also see that the total life expectancy if of 4.99 cycles. If we assimilate a cycle to one year, then life expectancy is 4.99 years. We immediately see that the stationary measure (see section Probabilities page 540) of the chain is:

$$\pi=\begin{pmatrix}0\\0\\1\end{pmatrix} \tag{15.2.159}$$

15.2.8 Multi-Criteria Decision Making (MCDM)

The field of "multi-criteria decision making" (MCDM) studies (among other topics) the problem of how to select the best alternative among a number of competing alternatives. This is an important task in decision making. In such a setting each alternative is described in terms of a set of evaluative criteria. These criteria are associated with weights of importance. Intuitively, one may think that the larger the weight for a criterion is, the more critical that criterion should be. However, this may not be the case. It is important to distinguish here the notion of "criticality" with that of "importance". By "critical", we mean that a criterion with small change (as a percentage) in its weight, may cause a significant change of the final solution. It is possible criteria with rather small weights of importance (i.e., ones that are not so important in that respect) to be much more critical in a given situation than ones with larger weights.

In our daily lives, we usually weigh multiple criteria implicitly and we may be comfortable with the consequences of such decisions that are made based on only intuition. On the other hand, when stakes are high, it is important to properly structure the problem and explicitly evaluate multiple criteria. In making the decision of whether to build a nuclear power plant or not, and where to build it, there are not only very complex issues involving multiple criteria, but there are also multiple parties who are deeply affected from the consequences.

The are dozens of MCDM models but we will here focus only on the most widely used one and also available in specialized decision softwares: the AHP.

MCDM has been an active area of research since the 11970s (holocene calendar). There are several MCDM-related organizations including the International Society on Multi-criteria Decision Making, Euro Working Group on MCDA and INFORMS Section on MCDM

15.2.8.1 Analytic Hierarchy Process (AHP)

The "analytic hierarchy process" (AHP) is a MCDM structured technique for organizing and analysing complex decisions, based on mathematics and psychology. It was developed by Thomas L. Saaty in the 11970s (holocene calendar) and has been extensively studied and refined since then. It is used almost exclusively in large US multinationals and in governments where politician know well the issue of human decision bias to make complex deterministic decisions.

In the large majority of books, AHP is wrongly introduced (also in Wikipedia still in 12015... according to holocene calendar). So let us see exactly what are the mathematical concepts behind (you can check and apply this model with a free software like `R` - see our companion book on this software that has more details).

Remark

In the AHP, each element in the hierarchy is considered to be independent of all the others at the opposite of the ANP (Analytic Network Process).

We know that traditional voting or score / rank systems can not be used in multi-criteria and multi-level complex decisions because they do not trivially take into account the relative importance of components. Moreover, even if a weight was affected the problem lies in the choice of an empirical value of that latter which makes the approach totally unscientific and opens the door to endless debates in practice.

To introduce the technique of the AHP it seems pertinent to study this technique with a companion example of naive analysis of a sum of scores:

Alternative / **Criteria**	**Choice X**	**Choice Y**	**Choice Z**	**Range**
Factor A	1	4	5	0 to +5
Factor B	20	70	50	+1 to +100
Factor C	-2	0	1	-2 to $+2$
Factor D	0.4	0.75	0.4	0 to +1
Sum	19.4	74.75	56.4	
Normalized score	12.9%	49.7%	37.5%	

Table 15.30: **Naive ranged scoring decision analysis approach**

However, the reader will notice that the range of values for each factor of the product / project is not the same. It is then quite unfair to summarize all the values of several criteria and compare the result. It is clear that factor B is dominant because the range has a higher value. To be fair, we can propose at least two trivial solutions:

- Instead of using arbitrary values for each factor, we position just the choice for each factor: the smaller rank value is more preferable than the higher rank value (this is psychology in relation to the daily use of The majority of humans).
- We transform the score value of each factor as a function of the range value so that each factor will have the same extent (normalization of the scores).

Let us try the two solutions, starting with the first:

Alternative / **Criteria**	**Choice X**	**Choice Y**	**Choice Z**
Factor A	3	2	1
Factor B	3	1	2
Factor C	3	2	1
Factor D	2	1	2
Sum	11	6	6
Normalized score	26.09%	36.96%	36.96%

Table 15.31: **Naive ranged scoring decision analysis approach**

Where since the smallest rank value is the best, we have renormalized the codes in the following logical way:

1. Since the sum of all ranks is always equal, subtracting from the total of the ranks R_T the sum of the ranks of a column automatically has the effect of giving it the inverse

importance (indeed if the total sum of the ranks is equal to 23 as above, then $23-6=17$ whereas $23-11=12$ so we have the desired effect). We then have the following sum of ranks (SR) for each criterion (C):

$$SR_{N_i}=R_T-R_{C_i} \tag{15.2.160}$$

2. We want a percentage, so it is natural to write:

$$\%SR_{N_i}=\frac{R_T-R_{C_i}}{R_T}=1-\frac{R_{C_i}}{R_T} \tag{15.2.161}$$

3. The problem of this last calculation is that it gives systematically, summed for all the columns, the value of 200%. It must then be multiplied by 0.5 such that in the end:

$$\%SR_{N_i}=0.5\left(1-\frac{R_{C_i}}{R_T}\right) \tag{15.2.162}$$

Now it is important to notice that working with the ranks no longer gives the same result as in the antecedent table. Indeed, the choices Y and Z become indifferent and so we lost information!

Reason why it is recommended to work on scores rather than ranks because not only working on the ranks can lead to equalities that did not need have to exist to be but in some cases it even reverses the final rank of some elements of a choice (we speak then of "inversion effect of rank by the scores").

Now let us see what happen if we transform the score value of each factor in such a way such that all factors have the same range value. Say, we choose all factors to have range to be 0 to 1. To convert linearly the score of each factor from the table below into the next one, we use the following formula which is based on simple geometric of a line segment:

$$\begin{aligned}\text{New Score}&=\frac{\text{New Upper Bound}-\text{New Lower Bound}}{\text{Original Upper Bound}-\text{Original Lower Bound}}(\text{Original Score}-\text{Original Lower Bound})+\text{New Lower Bound}\\&=\frac{\text{NUB}-\text{NLB}}{\text{OUB}-\text{OLB}}(\text{OS}-\text{OLB})+\text{NLB}\end{aligned} \tag{15.2.163}$$

Alternative **Criteria**	**Choice X**	**Choice Y**	**Choice Z**	**Range**
Factor A	1	4	5	0 to +5
Factor B	20	70	50	+1 to +100
Factor C	−2	0	1	−2 to +2
Factor D	0.4	0.75	0.4	0 to +1
Sum	19.4	74.75	56.4	
Normalized score	12.9%	49.7%	37.5%	

For instance, Factor A has originally range 0 to 5. To make score of choice Y from 4 into a range of 0 to 1 we have OLB $=0$, OUB $=5$, NLB $=0$, NUB $=5$ and Original Score $=5$ thus:

$$\text{New Score}=\frac{1-0}{5-0}(4-0)+0=\frac{4}{5}=0.8 \tag{15.2.164}$$

Another example, for choice X in factor B has original score of 20 and original range 1 to 100. Thus we have OLB $=1$, OUB $=100$, NLB $=0$, NUB $=1$ and Original Score $=20$ thus:

$$\text{New Score} = \frac{1-0}{100-1}(20-1)+0 = \frac{19}{99} = 0.192 \qquad (15.2.165)$$

Therefore becomes:

Criteria \ **Alternative**	**Choice X**	**Choice Y**	**Choice Z**
Factor A	0.109	0.436	0.545
Factor B	0.035	0.127	0.090
Factor C	0.000	0.091	0.136
Factor D	0.036	0.068	0.036

Clearly the transformation of score value is a little bit more complicated than rank but we get better results.

Now let us see a naturally more advanced version inspired by financial portfolios including weights to criteria. Obviously the result of the example that follows will no longer be comparable to the previous ones.

So consider the following table of weights:

	Factor A	**Factor B**	**Factor C**	**Factor D**	**Sum**
Weight	6	2	2	1	11
Relative Weight	54.5%	18.2%	18.2%	9.1%	100%

Our table of normalized scores therefore becomes:

Criteria \ **Alternative**	**Weight**	**Choice X**	**Choice Y**	**Choice Z**
Factor A	54.5%	0.109	0.436	0.545
Factor B	18.2%	0.035	0.127	0.090
Factor C	18.2%	0.000	0.091	0.136
Factor D	9.1%	0.036	0.068	0.036
Sum	100%	0.180	0.722	0.808
Normalized score		10.5%	42.2%	47.2%

Well now that these basic decisional techniques have been presented let us now strictly speaking introduce the AHP which has a different complementary approach!

Remark

Notice that the author of this method (Thomas Saaty) has edited a software that allows to automate complex decision-making procedures based on his method and which can be found at `http://www.superdecisions.com`. The reader interested can also see a real application example in our R companion book.

The AHP approach is obviously quite more mathematical that previous methods. Thus, we can already say that the normalized scores are actually the components of a weight vector of preference, whose sum of component are equal to 100%:

$$\vec{w}=\begin{pmatrix} w_1 \\ \vdots \\ w_n \end{pmatrix} \tag{15.2.166}$$

therefore with $\sum_i w_i = 100\%$.

Then the second idea is to compare via a matrix for a given factor the choices that are available (obviously to have an approach using the power of Linear Algebra). For example, by taking our tables above and focusing on Factor A, we would have:

Factor A	**Choice A**	**Choice B**	**Choice C**
Choice A	1	$?$	$?$
Choice B	$?$	1	$?$
Choice C	$?$	$?$	1

The values (scores) of the diagonal are obvious because each choice can not be preferred to itself than in a relation other than a strict unitary equality.

Already two questions can be raised at this level:

Q1. Knowing that the scores (sometimes named "stimuli") must have a form of symmetry, how many scores according to the number of choices n will have to make a "judge".

Q2. Which scale of the score ("stimuli") do we have to choose and what relation of symmetry (for example between Choice B-Choice A and Choice A-Choice B because if we have to choose one, the other must follow automatically)

To answer the first question we can construct a simple table (it is therefore simply the number of cases above or respectively below the diagonal of the matrix of preference):

Number of choices	1	2	3	4	5	6	7	$\ldots$	n
Number of comparisons	0	1	3	6	10	15	$\ldots$	21	$\dfrac{n(n-1)}{2}$

To answer the second question it is better to put ourselves in the shoes of a mathematician, engineer or statistician. First, knowing that equality is logically equal to "1" it would be inappropriate to take the set of real number $\mathbb{R}$ with negative values for the reciprocal knowing that in this case the equality should be zero and not 1. Taking a matrix of preference whose diagonal would be zeros, would consist to use techniques specific to Data Mining (see section Numerical Methods page 6768) since this is equivalent to have a matrix of distances. But the problem of matrices of distances in the context that interests us here is that the components are symmetrical and in the case of preferences this is a non-sense!

So let us denote the square matrix of the scores in the following way:

$$A=(a_{ij})=\begin{bmatrix}1 & a_{12} & \cdots & a_{1n}\\ a_{21} & 1 & \cdots & a_{2n}\\ \vdots & \vdots & \ddots & \vdots\\ a_{n1} & a_{n2} & \cdots & a_{nn}\end{bmatrix} \tag{15.2.167}$$

A possible way would be to say that since we have a vector of weights $\vec{w}$, one would have to operate between the matrix of preferences and this vector of weights in one way or another. Now, thinking of the fact that in the domain of Statistics we often find the concept of eigenvector and eigenvalue (see section Linear Algebra page 1997) then, the choice of multiplication is quite natural:

$$\begin{bmatrix}1 & a_{12} & \cdots & a_{1n}\\ a_{21} & 1 & \cdots & a_{2n}\\ \vdots & \vdots & \ddots & \vdots\\ a_{n1} & a_{n2} & \cdots & a_{nn}\end{bmatrix}\begin{pmatrix}w_1\\ w_2\\ \vdots\\ w_n\end{pmatrix} \tag{15.2.168}$$

Now, having taken the multiplication gives us an idea on the choice of the components of the matrix of preferences to make. Indeed, if we take:

$$\begin{bmatrix}1 & a_{12} & \cdots & a_{1n}\\ a_{21} & 1 & \cdots & a_{2n}\\ \vdots & \vdots & \ddots & \vdots\\ a_{n1} & a_{n2} & \cdots & a_{nn}\end{bmatrix}\begin{pmatrix}w_1\\ w_2\\ \vdots\\ w_n\end{pmatrix}=\begin{bmatrix}w_1/w_1 & w_1/w_2 & \cdots & w_1/w_n\\ w_2/w_1 & w_2/w_2 & \cdots & w_2/w_n\\ \vdots & \vdots & \ddots & \vdots\\ w_n/w_1 & w_n/w_2 & \cdots & w_n/w_n\end{bmatrix}\begin{pmatrix}w_1\\ w_2\\ \vdots\\ w_n\end{pmatrix}=n\begin{pmatrix}w_1\\ w_2\\ \vdots\\ w_n\end{pmatrix} \tag{15.2.169}$$

we have a relation between an eigenvector and an eigenvalue via a matrix (linear application) whose components are preferences. Notice also that the sum of the values of a column i is equal to $1/w_i$. And if we observe well we have in fact:

$$\left(\begin{bmatrix}w_1/w_1 & w_1/w_2 & \cdots & w_1/w_n\\ w_2/w_1 & w_2/w_2 & \cdots & w_2/w_n\\ \vdots & \vdots & \ddots & \vdots\\ w_n/w_1 & w_n/w_2 & \cdots & w_n/w_n\end{bmatrix}-1\right)\begin{pmatrix}w_1\\ w_2\\ \vdots\\ w_n\end{pmatrix}=\begin{pmatrix}0\\ 0\\ \vdots\\ 0\end{pmatrix} \tag{15.2.170}$$

This is equivalent to have a problem with eigenvectors and eigenvalues (see section Linear Algebra page 1997):

$$(A-n\mathbb{1})\vec{w}=\vec{0} \tag{15.2.171}$$

Given the following characteristic polynomial (see section Linear Algebra page 1998):

$$\det(A-\lambda\mathbb{1}_2)=\begin{vmatrix}a_{11}-\lambda & a_{12}\\ a_{21} & a_{22}-\lambda\end{vmatrix}=\lambda^2-\underbrace{(a_{11}-a_{22})}_{\text{tr}(A)}\lambda+\underbrace{(a_{11}a_{22}-a_{21}a_{12})}_{\det(A)} \tag{15.2.172}$$

or also the following one (see section Linear Algebra page 1967):

$$\begin{aligned}\det(A-\lambda\mathbb{1}_3)&=\begin{vmatrix}a_{11}-\lambda & a_{12} & a_{13}\\ a_{21} & a_{22}-\lambda & a_{23}\\ a_{31} & a_{32} & a_{33}-\lambda\end{vmatrix}\\ &=-\lambda^3+\underbrace{(a_{11}+a_{22}+a_{33})}_{\text{tr}(A)}\lambda^2-(a_{11}a_{33}+a_{22}a_{33}+a_{11}a_{22}-a_{32}a_{23}-a_{12}a_{21}-a_{31}a_{13})\lambda\\ &+\underbrace{(a_{11}a_{22}a_{33}-a_{11}a_{32}a_{23}-a_{12}a_{21}a_{33}+a_{31}a_{23}a_{12}+a_{13}a_{21}a_{32}-a_{13}a_{31}a_{22})}_{\det(A)}\end{aligned}\tag{15.2.173}$$

Knowing the construction of the preference matrix, we see that:

$$\det(A-\lambda\mathbb{1}_2)=\lambda^2-2\lambda+1-1=\lambda^2-2\lambda=0\tag{15.2.174}$$

and therefore there is only one eigenvalue, it is an integer and is well equal to $\lambda=n=2$. We then say that every square matrix of dimensions 2 is "consistent matrix".

Let us move on to a higher dimension:

$$\begin{aligned}\det(A-\lambda\mathbb{1}_3)&=-\lambda^3+3\lambda^2+(1-1-1+a_{31}a_{23}a_{12}+a_{13}a_{21}a_{32}-1)\\ &=-\lambda^3+3\lambda^2+a_{31}a_{23}a_{12}+a_{13}a_{21}a_{32}-2=0\end{aligned}\tag{15.2.175}$$

We say in this case that any square matrix of dimensions 3 is "not necessarily consistent". For this to happen, it would be necessary to have:

$$a_{31}a_{23}a_{12}+a_{13}a_{21}a_{32}-2=0\tag{15.2.176}$$

and only in this case will we have a unique eigenvalue $\lambda=n=3$. Notice that if we write this last relation in the form:

$$a_{jk}a_{ij}a_{ki}+a_{kj}a_{ik}a_{ji}-2=0\tag{15.2.177}$$

Then if:

$$a_{jk}a_{ij}=a_{ik}\tag{15.2.178}$$

the matrix is consistent! We will see later the practical impact of this last equality.

It is obviously necessary, if necessary, to normalize the eigenvector so that the sum of the preference weights is unitary such that:

$$\vec{w}_N=\frac{\vec{w}}{\sum_i w_i}\tag{15.2.179}$$

So this leads us to have if we judge our preference on a scale of the following type for our three choices of the Factor A:

$$\begin{gathered}[\text{Choice } A]\;9\,8\,7\,6\,5\,4\,3\,2\,1\,2\,\mathbf{3}\,4\,5\,6\,7\,8\,9\;[\text{Choice } B]\\ [\text{Choice } A]\;9\,8\,7\,6\,\mathbf{5}\,4\,3\,2\,1\,2\,3\,4\,5\,6\,7\,8\,9\;[\text{Choice } C]\\ [\text{Choice } B]\;9\,8\,\mathbf{7}\,6\,5\,4\,3\,2\,1\,2\,3\,4\,5\,6\,7\,8\,9\;[\text{Choice } C]\end{gathered}\tag{15.2.180}$$

and by taking care to put the direct preferences in the upper part of the matrix and the inverse in the lower part (otherwise the eigenvector will not be the same and in extenso the weights too!):

Factor A	**Choice A**	**Choice B**	**Choice C**
Choice A	1	**1/3**	**5**
Choice B	3	1	**7**
Choice C	$1/5$	$1/7$	1

In the above example the preferences are consistent because if B is preferred to A ($B \succ A$) and A is preferred to C ($A \succ C$) then we should logically have $B \succ C$ what is indeed the case here. If not, we say that: the choices are inconsistent. This consistency is summarized by the relation seen above where in the ideal case we should have:

$$a_{jk}a_{ij}=a_{ik} \tag{15.2.181}$$

So to be consistent we will be interested in the combination involving the choices C and B, that is to say:

$$a_{j3}a_{2j}=a_{23}\Rightarrow a_{AC}a_{BA}=5\cdot 3=15 \tag{15.2.182}$$

So to be totally consistent we should have for a_{BC} the value of 15 but that is not something we can practically request strictly speaking... However, the deviation to the perfect consistency will generate additional eigenvalues other than the unique eigenvalue which is n when the consistency is perfect. Hence, a possible measure of inconsistency, denoted IC for "index of inconsistency", is the average of the eigenvalues other than the principal one:

$$\text{IC}=\frac{1}{n-1}\sum_{i=2}^{n}\lambda_i \tag{15.2.183}$$

which in the case of perfect consistency is therefore zero.

To simplify the calculation of IC, we will use the fact that we have proved in the section of Linear Algebra that the trace of a matrix is equal to the sum of these eigenvalues. So we can write:

$$\text{tr}(A)=n=\sum_{i=1}^{n}\lambda_i=\lambda_{\max}+\sum_{i=2}^{n}\lambda_i\Leftrightarrow\sum_{i=2}^{n}\lambda_i=n-\lambda_{\max} \tag{15.2.184}$$

Hence a possible choice to measure the inconsistency:

$$\text{IC}=\frac{n-\lambda_{\max}}{n-1} \tag{15.2.185}$$

But by tradition we take the negative value of this relation as a definition of the "criterion of consistency":

$$\boxed{\text{IC}=\frac{\lambda_{\max}}{n-1}} \tag{15.2.186}$$

Thus above, for example, the choice B has been noted 3 with respect to the choice A (therefore B is preferred to A). Determine the weight of the preferences is thus equivalent to a problem of eigenvectors and eigenvalues:

$$\left(\begin{bmatrix} 1 & 1/3 & 5 \\ 3 & 1 & 7 \\ 1/5 & 1/7 & 1 \end{bmatrix} - n\mathbb{1}\right)\begin{pmatrix} w_1 \\ w_2 \\ w_3 \end{pmatrix} = \left(\frac{1}{n}\begin{bmatrix} 1 & 1/3 & 5 \\ 3 & 1 & 7 \\ 1/5 & 1/7 & 1 \end{bmatrix} - \mathbb{1}\right)\begin{pmatrix} w_1 \\ w_2 \\ w_3 \end{pmatrix} = \vec{0} \qquad (15.2.187)$$

where we must not forget that multiplying a matrix with a scalar is equivalent to multiply the eigenvalues by this same scalar (and not directly the components of the eigenvectors!). This is why were seeking the eigenvectors of the matrix of preferences or of the matrix of preferences normalized by $1/n$ since the eigenvectors will be the same!

So by calculating by hand (see section Linear Algebra page 1924) or by computer, we get:

$$\vec{w} = \begin{pmatrix} w_1 \\ w_2 \\ w_n \end{pmatrix} = \begin{pmatrix} 0.397989 \\ 0.914031 \\ 0.1012818 \end{pmatrix} \qquad (15.2.188)$$

Therefore:

$$\vec{w}_N \cong \begin{pmatrix} 27.895\% \\ 64.911\% \\ 7.192\% \end{pmatrix} \qquad (15.2.189)$$

But the three eigenvalues are not null because we have:

$$\lambda_1 = 3.06488 \qquad \lambda_2 = -0.324438 + 0.447702\mathrm{i} \qquad \lambda_3 = -0.0324438 - 0.447702\mathrm{i} \qquad (15.2.190)$$

And we know that this is due to the low non-consistency of our preferences matrix. We then have as a criterion of consistency:

$$\text{IC} = \frac{3.06488 - 3}{3 - 1} = 0.03244 \qquad (15.2.191)$$

OK it's close to 0 so a priori it's a good consistency. But to have a scientific judgement on this value the best still remains to make thousands of simulations of matrices with random judgements consistent or not and calculate their average consistency. Thus, according to the original article, with $50,000$ simulations we obtain for each of the matrices of preference of size n a "random index of consistency" (denoted RI for "random index"):

n	1	2	3	4	5	6	7	8	9	10
RI	–	0	0.52	0.89	1.11	1.25	1.35	1.40	1.45	1.49

Remark

In practice it is advised to not to exceed $n = 7$ because beyond the human mind has trouble to conceptualize quickly at the opposite of artificial intelligence.

So in the case of our example, we have the consistency ratio:

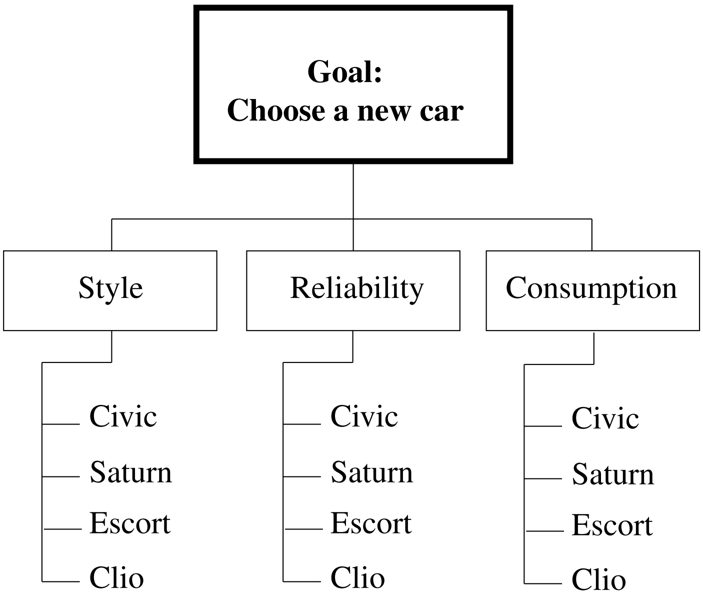
$$\text{CR} = \frac{\text{IC}}{\text{RI}} = \frac{0.03244}{0.52} \cong 0.0623 \qquad (15.2.192)$$

And of course the smaller is the ratio (in the sense: smaller than the unit!) the better it is. It is common practice to say that if this ratio is less than 0.1 then the inconsistency is acceptable (and therefore the consistency is good).

Let us now consider a multi-level case of the AHP.

✍**Example:**

Let us consider that we must choose from 4 cars on the basis of 3 criteria:



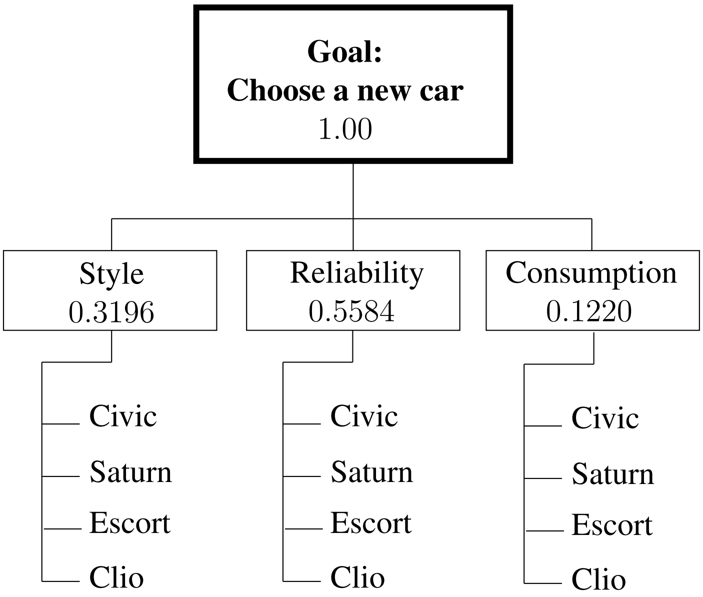
Goal:
Choose a new car
Style
Reliability
Consumption
Civic
Saturn
Escort
Clio
Civic
Saturn
Escort
Clio
Civic
Saturn
Escort
Clio

Figure 15.76: **AHP starting decision tree example**

Let us suppose that the matrix of preferences is the following based on three technical criteria:

Criteria	**Style**	**Reliability**	**Consumption**
Style	1	**1/2**	3
Reliability	2	1	4
Consumption	$1/3$	$1/4$	1

By doing the same calculations as above or with the help of a software, we get:



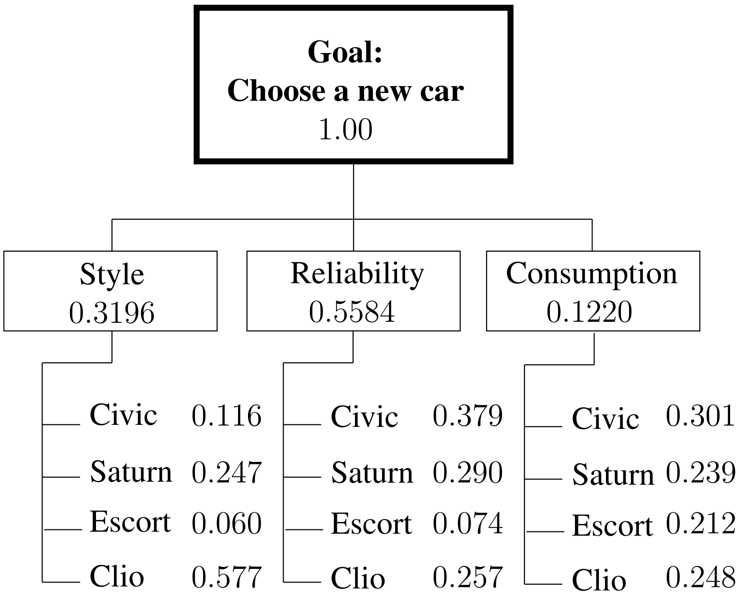
Goal:
Choose a new car
1.00
Style
0.3196
Reliability
0.5584
Consumption
0.1220
Civic
Saturn
Escort
Clio
Civic
Saturn
Escort
Clio
Civic
Saturn
Escort
Clio

Figure 15.77: **AHP decision tree example with weights**

Now we do the second level, that is to say the matrix of preferences of the cars for the style (comparison by pair of styles therefore...):

Car Style	**Civic**	**Saturn**	**Escort**	**Clio**
Civic	1	1/4	4	1/6
Saturn	4	1	4	1/4
Escort	1/4	1/4	1	1/5
Clio	6	4	5	1

And we do the same for the other two criteria to get:



Goal:
Choose a new car
1.00
Style
0.3196
Reliability
0.5584
Consumption
0.1220
Civic 0.116
Saturn 0.247
Escort 0.060
Clio 0.577
Civic 0.379
Saturn 0.290
Escort 0.074
Clio 0.257
Civic 0.301
Saturn 0.239
Escort 0.212
Clio 0.248

It is now a question of combining these two levels! For this it seems intuitive to make the following matrix multiplication (weighting):

$$\begin{bmatrix}0.1160 & 0.3790 & 0.3010\\ 0.2470 & 0.2900 & 0.2390\\ 0.0600 & 0.0740 & 0.2120\\ 0.5770 & 0.2570 & 0.2480\end{bmatrix}\begin{pmatrix}0.3196\\ 0.5584\\ 0.1220\end{pmatrix}=\begin{pmatrix}0.3060\\ 0.2720\\ 0.0940\\ 0.3280\end{pmatrix}=\begin{pmatrix}\text{Civic}\\ \text{Saturn}\\ \text{Escort}\\ \text{Clio}\end{pmatrix} \tag{15.2.193}$$

So the Clio is the winner of this AHP!

15.2.9 Electoral systems

An "electoral system" or "voting system" is a set of rules that determine how elections and referendums are conducted and how their results are determined. Electoral systems are used in politics to elect governments, while non-political elections may take place in business, non-profit organisations and informal organisations. These rules govern all aspects of the voting process: when elections occur, who is allowed to vote, who can stand as a candidate, how ballots are marked and cast, how the ballots are counted, how votes translate into the election outcome, limits on campaign spending, and other factors that can affect the result. Political electoral systems are defined by constitutions and electoral laws, are typically conducted by election commissions, and can use multiple types of elections for different offices.

Some electoral systems elect a single winner to a unique position, such as prime minister, president or governor, while others elect multiple winners, such as members of parliament or boards of directors. When electing a legislature, areas may be divided into constituencies with one or more representatives or the electorate may elect representatives as a single unit. Voters may vote directly for an individual candidate or for a list of candidates put forward by a political party or alliance. There are many variations in electoral systems, the most common being Party-list proportional representation, first-past-the-post voting, plurality block voting, the two-round (runoff) system and ranked voting (STV or Instant-runoff voting). Mixed systems and some other electoral systems attempt to combine the benefits of non-proportional and proportional systems.

The study of formally defined electoral methods is called social choice theory or voting theory, and this study can take place within the field of political science, economics, or mathematics, and specifically within the subfields of game theory and mechanism design. Impossibility proofs such as Arrow's impossibility theorem demonstrate that when voters have three or more alternatives, no preferential voting system can guarantee the race between two candidates remains unaffected when an irrelevant candidate participates or drops out of the election.

We will focus here on "positional voting" is a ranked voting electoral system in which the options or candidates receive points based on their rank position on each ballot and the one with the most points overall wins. The lower-ranked preference in any adjacent pair is generally of less value than the higher-ranked one. Although it may sometimes be weighted the same, it is never worth more. A valid progression of points or weightings may be chosen at will (Eurovision Song Contest) or it may form a mathematical sequence such as an arithmetic progression (Borda count), a geometric one (positional number system) or a harmonic one (Nauru/Dowdall method). The set of weightings employed in an election heavily influences the rank ordering of the candidates. The steeper the initial decline in preference values with descending rank, the more polarised and less consensual the positional voting system becomes.

"Positional voting" should be distinguished from "score voting": in the former, the score that each voter gives to each candidate is uniquely determined by the candidate's rank; in the latter, the each voter is free to give any score to any candidate.

As a companion example, let us suppose Alice, Becca, and Carly are running for president. The personal preferences of the 54 members are given by:

1st :	A	A	B	B	C	C
2nd :	B	C	A	C	A	B
3rd :	C	B	C	A	B	A
	13	0	19	0	17	5

So who should be president?

Method 1: Vote for your first choice:

A	B	C
13	19	22

Carly wins!

This is also named a "first-past-the-post electoral system" (FPTP or FPP), formally named "single-member plurality voting" (SMP) when used in single-member districts or informally choose-one voting in contrast to ranked voting.

Method 2: Tell us your full ranking, and we will pair them off:

$A > B$	$B > C$	$A > C$
30	32	32
$A < B$	$B < C$	$A < C$
24	22	22
$A > B$,	$B > C$,	$A > C$

Alice wins!

This is the "Condorcet method" and the winner is named the "Condorcet winner" (11785 according to holocene calendar). The winner, if there is one, is therefore the candidate who, compared in turn to each of the other candidates, turns out to be the preferred candidate each time. In other words, he beats everyone else in a duel.

A "Condorcet cycle" (i.e. "Condorcet paradox") is likely to occur with this method, best explained through an example. Suppose an election involves three candidates - A, B, and C, with 30 voters such that ten vote C–B–A, ten vote B–A–C, and ten vote A–C–B. In this case, no Condorcet winner exists. Specifically, A cannot be a Condorcet winner as two-thirds of voters prefer B over A. Similarly, B cannot be the winner as two-thirds prefer C over B, and C cannot win as two-thirds prefer A over C. This forms a cycle where the search for a Condorcet winner fails to find one.

Method 3: Tell us your full ranking, and we will run an "instant-runoff voting" also named "alternative vote" or "ranked-choice voting" in the U.S.A. :

Round 1:

A	B	C
13	19	22

Alice loses.

Round 2:

B	C
32	22

Becca wins!

Method 4: Tell us your full ranking, and we'll give points according to the candidates' positions, i.e. 1 for 1st, t for 2nd, 0 for 3rd.

Let us recall that:

1^{st} :	A	A	B	B	C	C
2^{nd} :	B	C	A	C	A	B
3^{rd} :	C	B	C	A	B	A
	13	0	19	0	17	5

Thanks to this table we build the following one (where $36=19+17$ and $18=13+5$):

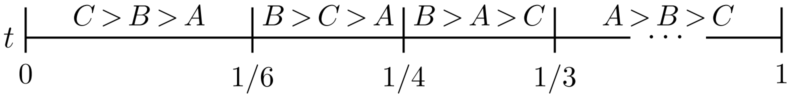
A	B	C
$13+36t$	$19+18t$	$22+0t$

$(0\leq t\leq 1)$

Therefore:

	A	B	C
$(0\leq t\leq 1)$	$13+36t$	$19+18t$	$22+0t$
$t=0$:	13	19	**22**
$t=0.25$:	22	**23.5**	22
$t=0.5$:	**31**	28	22
$t=0.75$:	**40**	32.5	22
$t=1$:	**49**	37	22

Hence:



Method 5: Tell us your full ranking, and we we'll give points according to candidates' positions, i.e. n for the first $n-1$ for the second and so on until the n-th candidate that will have 0 points. This is the "Borda method" (11770 according to holocene calendar).

Remember that we have:

1^{st} :	A	A	B	B	C	C
2^{nd} :	B	C	A	C	A	B
3^{rd} :	C	B	C	A	B	A
	13	0	19	0	17	5

Therefore

we have:

$$\begin{aligned}A&=13\cdot 3+0\cdot 3+19\cdot 2+0\cdot 0+17\cdot 2+5\cdot 0=111\\B&=13\cdot 2+0\cdot 0+19\cdot 3+0\cdot 3+17\cdot 0+5\cdot 2=93\\C&=13\cdot 0+0\cdot 2+19\cdot 0+0\cdot 2+17\cdot 3+5\cdot 3=66\end{aligned}\tag{15.2.194}$$

So finally:

$$A > B > C$$

Notice that the score of each candidate k above is given by:

$$S_k = \sum_{i=1}^{n} b_{k,i}(n-i+1)$$

where $b_{k,i}$ is the number of times the candidate k is ranked in position i.

In the case where the number of candidate is very large and everyone can stop their ranking list wherever they want, we find the system of "voting by approval".

The Borda method is used for elections to one seat or several seats. This voting system is popular in the United States for awarding sports prizes. It is by this method that, among others, the best player in Major League Baseball and the champion American college football team are elected. This method is known in Europe thanks to the Eurovision song contest.

We find this voting system for the parliamentary elections in Nauru and only to nominate, within the Maneaba ni Maungatabu (Parliament), the three or four candidates for the presidential election of Kiribati

✍**Example:**

In 12000 (holocene calendar), in Florida, $2,912,790$ people voted for Bush, $2,912,253$ voted for Gore, $97,488$ voted for Nader, and $40,575$ for other. Neglecting the “others”, suppose we had asked the rest of the voters for their full rankings of the top three candidates:

1st :	B	G	G	N
2nd :	G	N	B	G
3rd :	N	B	N	B
	2.902 mil.	1.421 mil.	1.481 mil.	0.118 mil.

So who should have been president?

Method 1: Vote for your first choice.

B	G	N
2.90 mil.	2.90 mil.	0.11 mil.

Bush won!

Method 2: Tell us your full ranking, and we’ll pair them off.

$B > G$	$G > N$	$B > N$
2.90 mil.	5.80 mil.	4.32 mil.
$B < G$	$G < N$	$B < N$
3.02 mil.	0.12 mil.	1.60 mil.
$G > B,$	$G > N,$	$B > N$

Gore wins!

Method 3: Tell us your full ranking, and we’ll run an instant run off.

Round 1:

B	G	N
2.90 mil.	2.90 mil.	0.12 mil.

Nader loses.

Round 2:

B	G
2.90 mil.	3.02 mil.

Gore wins!

Method 4: Tell us your full ranking, and we'll give points according to the candidates' positions - 1 for 1st, t for 2nd, 0 for 3rd (the values 1.421, 1.481 and $3.020 = 1.421 + 1.481 + 0.118$ are in the table just above).

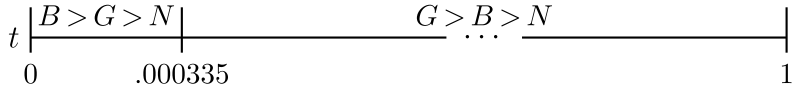
B	G	N
$2.902 + 1.421\,t$	$2.902 + 3.020\,t$	$0.118 + 1.481\,t$

$(0 \leq t \leq 1)$

Therefore:

	A	B	C
$(0 \leq t \leq 1)$	$2.902 + 1.421\,t$	$2.902 + 3.020\,t$	$0.118 + 1.481\,t$
$t = 0:$	**2.90** mil.	2.90 mil.	0.19 mil.
$t = 0.25:$	3.26 mil.	**3.66** mil.	0.49 mil.
$t = 0.5:$	3.61 mil.	**4.41** mil.	0.86 mil.
$t = 0.75:$	3.97 mil.	**5.17** mil.	1.23 mil.
$t = 1:$	4.32 mil.	**5.92** mil.	1.60 mil.

Hence:



We can see above, as Condorcet highlighted it long time before the fact that an ordinary election may very well not represent the desires of voters!

There are a number of formalised voting system, here is a non-exhaustive list:

- Schulze
- Ranked pairs
- Tideman's Alternative
- Kemeny–Young
- Copeland
- Nanson
- Black
- Instant-runoff voting
- Smith/IRV
- Borda
- Baldwin
- Bucklin
- Plurality
- Contingent voting
- Coombs
- MiniMax
- Anti-plurality
- Sri Lankan contingent voting
- Supplementary voting
- Dodgson

Arrow's impossibility theorem (the theorem is named after economist and Nobel laureate Kenneth Arrow who proved it in 11951 according to holocene calendar) is an impossibility theorem in social choice theory that states that when voters have three or more distinct alternatives (options), no ranked voting electoral system can convert the ranked preferences of individuals into a community-wide (complete and transitive) ranking while also meeting the specified set of criteria. Arrow's theorem posits the impossibility of devising a system that operates without fail in every conceivable scenario.

15.2.10 Ethics and Moral

Where did morality come from and why don't we just all constantly backstab each other? It is common knowledge that morality is an important part of human society. Consequently, morality has been widely explored and discussed in the past as philosophers have debated the necessity of morality for centuries. Animals can either betray each other or not betray each other (see [81]), and the payoff is most of the time improvement in survival and reproduction.

Definition (#15.2.650): "Morality" is the value of the discount factor δ (see further below) based on the mathematical proof of the "golden rule" (Tit for Tat) of Game and Decision Theory which makes consensus in a population/culture, or by the authority that represents it, at a given moment in time to decide whether an act is reprehensible or not in order to compensate for the physical, mental, psychological, societal or numerical utility cost (i.e. payoff) of the action considered.

We may for example ask ourselves if it is moral that in the old testament in genesis the son of Adam and Eve had to commit incest with their own mother or that the prophet of islam consummated his marriage with a nine years old girl? Or the fact the that the old testament doesn't vorbid slavery is moral or not? There are plenty of questionable moral concepts in all religion scriptures anyway! That's because animals morality evolves depending on the context and the constraints of the environment (but the morality of an omniscient divinity shouldn't evolve by definition!).

The dominant strategy in the prisoner's dilemma was to always betray each other. However, real life is more complicated than that. Real life is more like an iterated prisoner's dilemma (Evolutionary Game Theory (EGT)) where the game can be played multiple times and players remember the previous rounds of the game! If all players just betray each other in the games, then there will be a cycle of betraying that causes distrust, social ostracization, and evolutionarily lower rates of survival. With repeated games, co-operation can become a Nash equilibrium and can lead to better payoffs with increased rates of survival.

Evolutionary Game Theory (EGT) has also been successfully applied to the field of evolutionary biology where species and/or genes are treated as agents/players from a game theoretical viewpoint. In EGT, moves amongst a choice of possible options are not arrived at by economically rational agents. Instead, agents are disposed to particular strategies by their very nature, and the success and failure of a particular strategy is determined by the number of copies of itself that it will have to play in the games of succeeding generations, given a population in which other kinds of strategies that an agent acts are also distributed at particular frequencies. In this approach, the players represent strategies and the individuals are the executors of these strategies who get the benefits/costs associated with the different outcomes.

Maynard Smith's work *Evolution and the Theory of Games* appeared in 11982 (holocene calendar) summarises well the subsequent developments of these applications and their success in evolutionary biology (see [498]). Indeed, *Evolution and the Theory of Games* demonstrated how game theory could help to offer the most insightful explanations of the theory of evolution and the principles of behaviour of animals and plants when they are analysed in a context where they can mutually interact. In the end, most likely evolutionary biology turned out to provide the most promising applications of game theory (see [541]).

Richard Braithwaite was the first professional philosopher to formally employ game theory in the analysis of a problem of ethics. In his 11954 (holocene calendar) lecture *Theory of Games as a Tool for the Moral Philosopher* (published in 11955 according to holocene calendar), Braithwaite used Nash's bargaining problem to argue for a particular resolution to the fair division problem (see [73]). He also conjectured that game theory might transform moral philosophy, much as statistics had transformed the social sciences. Although this transformation has not taken place in philosophy in the way that it has for some of the other social sciences, game theory has made significant inroads into moral and political philosophy in the years since Braithwaite's lecture. David Gauthier's *Morals by Agreement* (11986 according to holocene calendar) and Ken Binmore's *Game Theory and the Social Contract* (2 volumes, 11994, 11998 according to holocene calendar) are arguably the first two works to present systematic moral theories built from game-theoretic foundations (see [198] and [59]).

An important criticism that has been pointed at the application of EGT to ethical decision making is the idea of the rational agent; this criticism can be thought of as a general criticism relating to the application of the whole of game theory to our understanding of ethical norms. A rational agent is a kind of one-dimensional entity who is supposed to determine preference rankings over possible outcomes. However, differences of character and other psychological variables concerning the agent are not really considered in the application process. Recent developments in game theory have made efforts to incorporate the notion of the player's "reputation" to explain the emergence of cooperation in iterated plays of games.

15.2.10.1 Golden Rule of morality (Tit for Tat)

In Game Theory, the concept that closely aligns with the principle of "*don't do to others what you don't want people to do to you*" is known as the "Golden Rule of morality" or "Tit for Tat" (an English saying meaning "equivalent retaliation") strategy also named "ethical reciprocity" (what objectively grounds moral values, right and wrong beyon evolutionary survival). The strategy was first introduced by Anatol Rapoport in Robert Axelrod's two tournaments, held around 11980 (holocene calendar). Notably, it was (on both occasions) both the simplest strategy and the most successful in direct competition. Few have extended the game theoretical approach to other applications such as finance. In that context the Tit for Tat strategy was shown to be associated to the trend following strategy.

The Tit for Tat strategy is a classic example of a strategy used in repeated games, such as the prisoner's dilemma. In this strategy, a player initially cooperates and then mimics the opponent's previous action in subsequent rounds. Essentially, it means if you want cooperation and fair play from others, you should start by cooperating and respond in kind to their actions. If they cooperate, you continue to cooperate; if they defect, you retaliate by defecting as well.

This strategy promotes mutual cooperation and discourages negative behavior on a rational basis. This result may help explain how groups of animals, especially human societies, have developed to live in mostly or fully cooperative ways, rather than in the fiercely competitive and aggressive manner one might expect from individuals living in a natural state of constant conflict. This, and particularly its application to human society and politics, is the subject of Robert Axelrod's book *The Evolution of Cooperation* (see [32]).

Take for example the following infinitely repeated prisoners dilemma game[12] (the letter "**D** denoting "Defect" and the letter "**C**" denoting "Collaborate"):

	C	**D**
C	$6,6$	$2,9$
D	$9,2$	$3,3$

More generally denoted:

	C	**D**
C	R,R	S,T
D	T,S	P,P

where:

- R is the reward for mutual cooperation
- T is the temptation payoff
- P is the punishment for mutual defection
- S is the sucker's payoff (cooperate while the other defect)

The Tit for Tat strategy copies what the other player previously chose. If players cooperate by playing strategy $(\mathbf{C},\mathbf{C})$ they cooperate forever:

	1	**2**	**3**	**4**	...
p_1	**C**	**C**	**C**	**C**	...
p_2	**C**	**C**	**C**	**C**	...

Cooperation gives the following payoff (where $\delta \in [0,1]$ is the "discount factor", i.e. you value today's income more than tomorrow[13]) in the above example:

$$6+6\delta+6\delta^2+6\delta^3\ldots \tag{15.2.195}$$

---

[12] It can also be seen as an infinitely repeated hawk-dove game.

[13] When the delta is 1 the players don't care when they get their payoff. But with $\delta=0$ they only care about the first round, because later rounds don't give them any payoff.

a geometric series summing to (see section Sequences and Series page 1679):

$$6+6\delta+6\delta^2+6\delta^3\ldots=\frac{6}{1-\delta} \tag{15.2.196}$$

If a player deviates to defecting (**D**), then the next round they get punished (it's a serious problem of mutual destruction - cycles of retaliation). To get out of this the players involved have to recognize their failure to stand a new cooperation cycles.

Remark

Keep in mind that Tit for Tat mean that if a player continues to cooperate then its opponent will do the same for the rest of the game. So **C-C**, **C-C**, **C-C** forever.

On the other hand, "off the path", if a player deviate its opponent will do the same to punish him, so he also starts to deviate. So the series is: at first **C**, **C**. Then one player will deviate, so it will be **C-C**. Then the opponent, in order to punish the first player, start to deviate as well. So **D-D**. Then, the first player that deviated may note that the deviation equilibria isn't so profitable as the initial one, so it start to cooperate again, so **D-C**. Finally, the opponent, seeing that he first player wants to cooperate again, starts to cooperate with me and restore the initial situation. So **C-C**.

To summarize we have **C-C** ; **C-D** ; **D-D**; **D-C**; **C-C** and so on.

Alternate between outcomes where p_1 cooperates and p_2 deviates, and vice versa (remember that this is the definition of "Tit for Tat" the player mimic the previous strategy of the other player!):

	1	**2**	**3**	**4**	...
p_1	C	D	C	D	...
p_2	D	C	D	C	...

The question we have is: is their any kind of equilibrium and under what conditions?

Deviation gives the following payoff flip-flop:

$$9+2\delta+9\delta^2+2\delta^3+9\delta^4+2\delta^5\ldots \tag{15.2.197}$$

a sum of two geometric series that comes to:

$$9+2\delta+9\delta^2+2\delta^3+9\delta^4+2\delta^5\ldots=\frac{9}{1-\delta^2}+\frac{2\delta}{1-\delta^2} \tag{15.2.198}$$

So we expect collaboration if payoff of deviation is no better than cooperation! That is:

$$6+6\delta+6\delta^2+6\delta^3\ldots\geq 9+2\delta+9\delta^2+2\delta^3+9\delta^4+2\delta^5\ldots \tag{15.2.199}$$

Or more generally denoted:

$$\boxed{\frac{R}{1-\delta}\geq\frac{T}{1-\delta^2}+\frac{S\delta}{1-\delta^2}\Rightarrow\frac{\text{reward for mutual cooperation}}{1-\delta}\geq\frac{\text{temptation payoff}}{1-\delta^2}+\frac{\text{sucker's payoff}\cdot\delta}{1-\delta^2}} \tag{15.2.200}$$

Or in human language:

$$\text{payoff for always cooperating} \overset{?\delta}{\geq} \text{flip-flop payoff} \tag{15.2.201}$$

Let us check under what condition this is satisfied in our example above:

$$\begin{aligned}\frac{6}{1-\delta} &\geq \frac{9}{1-\delta^2}+\frac{2\delta}{1-\delta^2}\\ \frac{6}{1-\delta} &\geq \frac{9+2\delta}{1-\delta^2}\\ (1-\delta^2)\cdot\frac{6}{\cancel{1-\delta}} &\geq \frac{9+2\delta}{\cancel{1-\delta^2}}\cdot\cancel{1-\delta^2}\\ (1+\delta)\cancel{(1-\delta)}\cdot\frac{6}{\cancel{1-\delta}} &\geq 9+2\delta\\ 6+6\delta &\geq 9+2\delta\\ 4\delta &\geq 3\\ \delta &\geq \frac{3}{4}\end{aligned} \tag{15.2.202}$$

Continue cooperating (Nash equilibrium subgame) if we have the following cutpoint:

$$\delta \geq \frac{3}{4} \tag{15.2.203}$$

So if δ is greater than this value the players are happy to continue to cooperate.

However they will continue defecting if:

$$\delta < \frac{3}{4} \tag{15.2.204}$$

Or more generally:

$$\boxed{\delta_{\text{moral threshold}} = \frac{T-R}{T-S}} \tag{15.2.205}$$

Or in human language:

$$\begin{aligned}\delta_{\text{moral threshold}} &= \frac{\text{temptation payoff} - \text{reward payoff}}{\text{temptation payoff} - \text{sucker's payoff}}\\ &= \frac{\text{how tempting it is to betray cooperation}}{\text{how costly it is to lose future cooperation}}\end{aligned} \tag{15.2.206}$$

This value depends of the initial weights. If we started from:

	C	**D**
C	$2,2$	$0,3$
D	$3,0$	$1,1$

We would have get continue cooperating (Nash equilibrium subgame) if:

$$\delta \geq \frac{1}{2} \tag{15.2.207}$$

Continue defecting if:

$$\delta < \frac{1}{2} \tag{15.2.208}$$

While Axelrod has empirically shown that the strategy is optimal in some cases of direct competition, two agents playing Tit for Tat remain vulnerable. A one-time, single-bit error in either player's interpretation of events can lead to an unending "death spiral": if one agent defects and the opponent cooperates, then both agents will end up alternating cooperate and defect, yielding a lower payoff than if both agents were to continually cooperate. This situation frequently arises in real world conflicts, ranging from schoolyard fights to civil and regional wars.

In 11979 (holocene calendar), Robert Axelrod (professor of political science at this time) organized a tournament between autonomous software programs capable of behaving like living beings. There was only one constraint: each program had to be equipped with a communication subroutine allowing it to discuss and interact with its neighbours (see [31]).

Robert Axelrod received 14 diskettes of programs sent by university colleagues who were also interested in this tournament. Each program stated different laws of behaviour (for the most simplistic, two lines of code of conduct, for the most complex, a hundred), the goal being to accumulate the maximum number of points.

Some programs have the rule of exploiting their neighbours as quickly as possible, seizing their points by force or trickery, then quickly changing partners to continue this accumulation of points.

Others try to manage alone, carefully guarding their points and avoiding any contact with those likely to steal them. Rules stipulate: « *If the other is hostile, warn him that he must change his behavior and then proceed to a punishment.* » Or again: « *Cooperate and then obtain surprise defections caused by a random system.* » Each program was opposed 200 times to each of the other competitors. Anatol Rapoport's, equipped with the CRP behavior (Cooperation-Reciprocity-Forgiveness), **dominates all the others**.

Even stronger, the CRP program, placed this time in the middle of the others in bulk, initially proves to be the loser to the aggressive thief programs, but ends up being victorious and even "contagious": after a certain time, as time passes, the neighboring programs, noting that it is the most effective at accumulating points, end up aligning their attitude with its own.

The Tit for Tat strategy has also been observed by other animals who don't have sophisticated cognition. Plenty of scientific papers describe these observations for example on guppies (fish) and rats.

So to summarize at its core, Tit for Tat operates on reciprocity: you start cooperatively, but if the other player defects, you retaliate in kind. If they cooperate again, you also return to cooperation. This resembles moral concepts like fairness, justice, and even forgiveness - people often believe in rewarding good behavior and punishing betrayal. It reflects the idea that trust must be maintained but not blindly given.

Philosophically, Tit for Tat aligns with ethical theories like contractualism or rule-based morality, where people follow norms based on mutual benefit. It also connects to moral intuitions about proportional responses - whether in personal relationships, justice systems, or even international diplomacy.

However, morality often pushes beyond simple reciprocity. While Tit for Tat encourages fairness, ethical systems sometimes emphasize mercy, altruism (see [544]), or turning the other cheek, which don't always align with pure retaliation. Some moral principles advocate unconditional kindness, whereas Tit for Tat is strictly reactive.

For more on morality and Game and Decision Theory see *The Irrelevance of Moral Uncertainty* ([230]), *Moral Uncertainty and Its Consequences* ([355]) and *Moral uncertainty and the principle of equity among moral theories* ([489]).

15.3. Economy

ECONOMICS is the study of how humans make decisions in the face of scarcity. These can be individual decisions, family decisions, business decisions or societal decisions. If you look around you carefully, you will see that scarcity is a fact of life. Scarcity means that human wants an amount of goods, services and resources that exceed what is available. Resources, such as labour, tools, land, and raw materials are necessary to produce the goods and services we want but they exist in limited supply. Of course, the ultimate scarce resource is time - everyone, rich or poor, has just 24 hours in the day to try to acquire the goods they want. At any point in time, there is only a finite amount of resources available.

Think about it this way: In 12015 (holocene calendar) the labour force in the United States contained over 158.6 million workers, according to the U.S. Bureau of Labor Statistics. Similarly, the total area of the United States is $9,834$ square kilometers. These are large numbers for such crucial resources, however, they are limited. Because these resources are limited, so are the numbers of goods and services we produce with them. Combine this with the fact that an important proportion of what human want seems to be virtually infinite, and you can understand why scarcity is a problem...

The "Economy", that we assimilate in this textbook to the domain encompassing the "theory of goods", the "financial mathematics", the "financial analysis", the "portfolio theories", aims to reach a settlement, model and determine the origins, dynamics and optimum prices for exchange goods or values "of economic agents" (market actors) in rational competition (...) according to theoretical statistics models (simplified and idealized ...) of markets.

The mathematical tools related to Economy are responsible for the implementation of concepts that are an integral part to political decisions, financial modelling, forecasting, analysis of investments that without the support of mathematics would be very difficult to propose, evaluate and benchmark.

Remark

So far... the best book that we have read about Economy (including portfolio management, assets management, microeconomics, macroeconomics, project management), is not a book but as set of books! For the people that want to in-deep their knowledge, we strongly recommend the following reference [276].

15.3.1 Concepts

An economic agent to live will have to satisfy two types of needs that may require to obtain them one or more exchanges:

1. The set B_p of "primary needs" or physiological needs (finite and countable)
2. The set B_s of "secondary needs" (which are not vital and not necessarily finite and countable) and are subjectively unique to every individual (and not only human either!)
3. The "opportunity cost" is what must be given up to obtain something that is desired.

Remark

Secondary needs are very difficult to define and measure, but if we reason in terms of set theory, we can simply say that "secondary needs" B_s are anything that is excluded from all primary needs B_p so that $B_s = \bar{B}_s$.

Definitions (#15.3.651):

D1. We say that need is an "economic need" when it concerns a "rare good" whose obtention requires several exchanges. They are oppose to "free goods" that are goods available in abundance to all, no work (typically...) and no exchanges being assumed necessary to benefit of them.

The large quantity of goods requires us to propose a classification like the following one:

C1. "Material goods" that have a physical reality, palpable and can that can be stored

C2. "Intermediate goods" or "services" whose production and consumption are considered as simultaneous

C3. "Virtual goods" which have a mathematical existence and often limited in time

Remark

The number of goods in most sophisticated macro models is equal to five: commodities, labour, bonds, money and foreign exchange.

D2. A "market" is a system consisting of the meet between supply and demand which relates to a particular good.

We are thus led to state the following assumptions:

P1. The market is supposed to be an isolated and isotropic system.

P2. Any active agent is rational and in competition

P3. Any agent respects market rules

D3. "Microeconomics" is the branch of economics that analyses the economic behaviour at the level of individual entities such as consumer or firms. Consumers are regarded as labour suppliers and goods seekers. Firms are, in turn, seeking for work and goods suppliers.

D4. "Macroeconomics" is the theoretical approach that studies the economy through the relations between the major economic aggregates: income, investment, consumption, unemployment, inflation, etc.

15.3.1.1 Microeconomics

Definition (#15.3.652): The "exchange value" of a specific product specifies for each good the amount of other goods that are equivalent to it. Usually, we consider that the "price" (or "currency") P is the monetary form of exchange value (we will come back later on the concept of money).

> **Remark**
>
> The "price" is a parameter which is of interest in the economy. Any tangible good or human resource and a given currency have a price whose (relative) value must be determined either empirically or with more or less complex mathematical statistics models.

There are different types of prices for which we give here a sample in the order of a classic economic process (the definitions are specific to this textbook!):

Definitions (#15.3.653):

D1. The "price of manufacturing P_F" of a good at time t is determined by the sum of direct manufacturing costs (not necessarily constant!) C_D at the same time t (salaries, raw materials, machinery, patents, licenses,...):

$$P_F(t)=\sum C_D(t) \tag{15.3.1}$$

D2. The "factory price P_U" of a good at time t is the sum of manufacturing costs plus indirect costs C_I at the same time t (taxes, administrative costs, storage costs, advertising, etc.). To be able to model a little bit this theoretically price, we will assume that the market is "lean" or balanced if you prefer (we will see later that it is implicit in the "Say's law"). In other words, the goods are produced directly in line with demand, no storage and no time gap between the availability on the market and sales (that is a rough approximation, but we are obliged). Since then:

$$P_U(t)=P_F(t)+\sum C_I(t) \tag{15.3.2}$$

D3. The "net selling price P_{VN}" of a good at time t (or seen by the side of buyer: the "net buying price" P_{AN}) is factory price at the same time t plus the "safety margin" (named also "gross profit" or "profit margin") B_b of the factory such as:

$$P_{VN}(t)=P_U(t)+B_b(t) \tag{15.3.3}$$

> **Remark**
>
> The gross profit will be invested in many areas by the manufacturer (research and development, redistribution to investors, etc.) and the balance is to help protect themselves against various direct market fluctuations, that is to say: wages, taxes, commodity prices, unanticipated events.

We can then consider at least two trivial cases:

(a) The gross profit is greater than the sum of general expenses and unanticipated expenses (so there will be a net benefit).

(b) The gross profit is smaller than the general expenses (so there will be a deficit or a net loss).

D4. The "net income B_n" is given by the portion of the safety margin which was scheduled for a period and that ultimately was not used by unanticipated expenses C_Δ during this period as:

$$B_n = B_b - C_\Delta \tag{15.3.4}$$

Remark

If sales are higher than expected and that the general and unforeseen expenses were addressed to customers, we talk then for this unexpected additional about "overactivity bonus" which obviously increases the expected net income. Otherwise, we speak of "cost of partial inactivity", which obviously reduces the net income expected. These are very important concepts within the enterprise project estimate.

D5. The "call price P_{AP}" at time t is the factory price multiplied by a sentimental and artistic factor F_{SA} (fashion, gossip, subjective reasons, etc.) also sometimes named "B.F.I. index" (for "Big Fake Index"...). This factor can be quantified statistically from the uniqueness of the property, the lifetime of the good, the number of potential buyers and this as nobody operates so as to change the original after the manufacturing. We have therefore:

$$P_{AP}(t) = F_{SA}(t) \cdot P_U(t) \tag{15.3.5}$$

D6. The "gross selling price P_{VB}" at time t or seen by the buyer as the "gross purchase price" P_{AB} is the Call price augmented by the profit margin of the seller (intermediate between the factory and the purchaser) plus the general sales expenses F_G. The seller margin may be included initially in direct expenses but overheads are not deterministic apart in a lean market where there are none overheads and as we have hypothesized a lean market, we thus have:

$$P_{VB}(t) = P_{AB}(t) = P_{AP}(t) + B_b(t) + F_G(t) \cong P_{AB}(t) + B_b(t) \tag{15.3.6}$$

Remark

The gross purchase price is also sometimes named "catalogue price".

D7. The "cost price P_R " at time t is the gross sales price (or purchase price depending from the point of view...) minus various possible or obligatory deductions D (being a negative value) made by the seller such that:

$$P_R(t) \cong P_{VB}(t) + D(t) \tag{15.3.7}$$

The agents of goods market exchange sometimes accept a discount on the catalogue price. Reductions exist in two main know forms:

1. The "remission R" which is a price bonification (negative value) given to an agent who buys goods in large quantities N or to a retailer which is charged a branded item sale price imposed by the manufacturer (strategic factor business, promotion, etc.). The discount depends on the time t and the amount n bought or ordered.
2. The "prompt payment discount E" which is a deduction at time t granted to the buyer agent for cash payment or prepayment or for payment for an agreed period (we will formally come back on this topic later below during our study of simple interest in Actuarial Calculation).

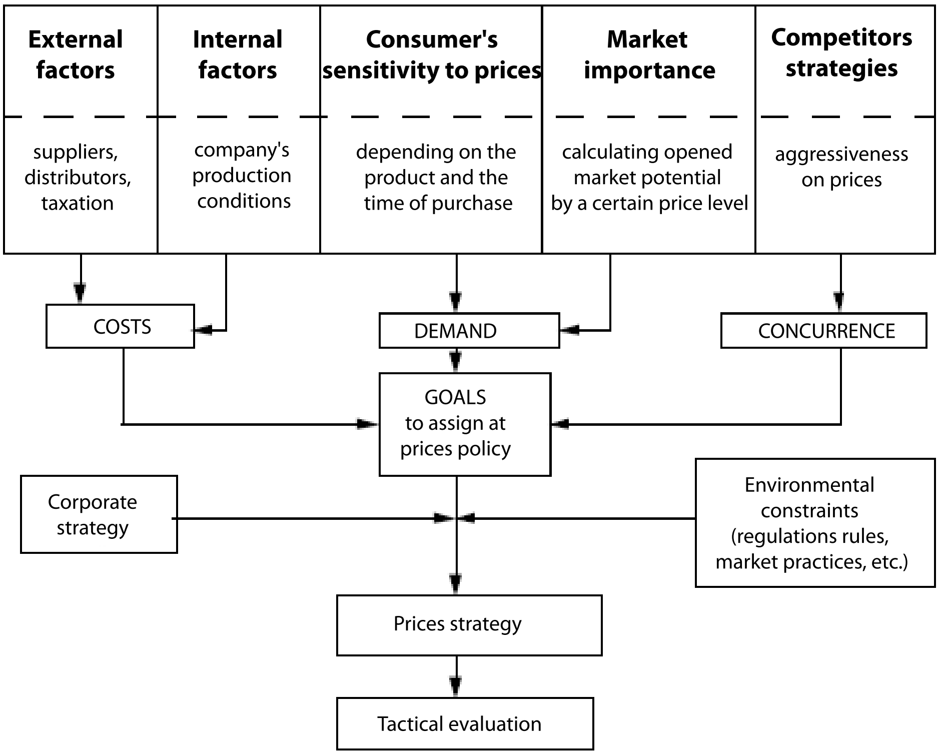
In the most general case we talk at a given time t of "exercise price" (or "invoice price") to which the good can be bought or sold as:

$$\boxed{P_E(t)=R(t,N)+E(t)+n\left\{F_{SA}(t)\left[\sum C_D(t)+\sum C_I(t)+B_b(t)+F_G(t)+D(t)\right]\right\}} \tag{15.3.8}$$

Remark

All the terms of these relations usually take their values in $\mathbb{R}$...

The factors to be considered when developing a pricing policy are synthesized without being exhaustive in the following diagram:



External factors
suppliers, distributors, taxation
Internal factors
company's production conditions
Consumer's sensitivity to prices
depending on the product and the time of purchase
Market importance
calculating opened market potential by a certain price level
Competitors strategies
aggressiveness on prices
COSTS
DEMAND
CONCURRENCE
GOALS to assign at prices policy
Corporate strategy
Environmental constraints (regulations rules, market practices, etc.)
Prices strategy
Tactical evaluation

Figure 15.78: **Simplified schematic summary to develop a pricing policy**

Definitions (#15.3.654):

D1. The "propensity to consume P_C" equation is the part of the income R of an agent that is devoted to consumption of an amount C (primary and secondary consumption):

$$P_C=\frac{C}{R} \tag{15.3.9}$$

D2. The difference between consumption expenditure and the income is defined as "savings E" while contributions and revenues on services represent "social transfers":

$$E=R-C \tag{15.3.10}$$

D3. The "income elasticity" is the ratio of the change in consumption on the change in income:

$$E_r=\frac{\Delta C}{\Delta R} \tag{15.3.11}$$

The concept of income elasticity propose to classify goods in supplementary categories:

1. "Inferior goods" are consumer goods whose income elasticity is negative and therefore whose consumption decreases with increasing income as $E_r<0$ (bread, flour, etc.).
2. "Superior goods" which are luxury consumer goods whose income elasticity is positive and therefore of which the consumption increases with an increase in income as $E_r>0$ (health, leisure, etc.).
3. "Normal goods": which are goods that are neutral and with a coefficient of elasticity with respect to income is a little different from 0 such that $E_r\cong 0$.

D4. The "price elasticity" is the ratio of the change in the amount of demand $D(P)$ for a good on the change in its price P, both assumed non-negative, continuous and differentiable, and is given by:

$$E_r=\frac{\Delta D}{\Delta P} \tag{15.3.12}$$

or at the limit, written:

$$E_r=\frac{\mathrm{d}D}{\mathrm{d}P}=D'(P) \tag{15.3.13}$$

and "arc-elasticity" is defined by:

$$e_D=-\frac{\%D}{\%P}=-\frac{\Delta D/\bar{D}}{\Delta P/\bar{P}} \tag{15.3.14}$$

or at the limit, written:

$$e_D=\frac{\mathrm{d}D/D}{\mathrm{d}P/P}=\frac{P\mathrm{d}D}{D\mathrm{d}P}=D'(P)\frac{P}{D} \tag{15.3.15}$$

The arc-elasticity gives the value of elasticity at the midpoint over a range of change.

Remarks

R1. A demand is named "price sensitive" when the percentage change in quantity demanded is greater than the percentage change in price. If we talk about "rigid price" demand.

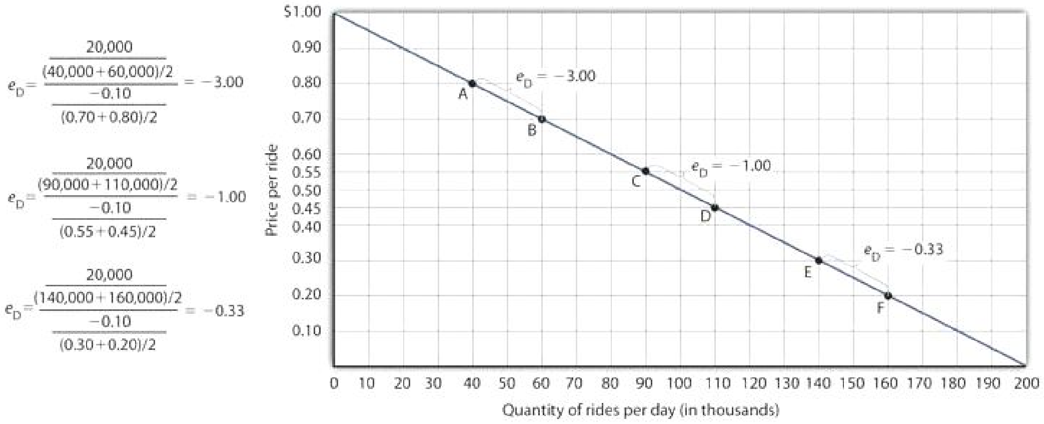
R2. Notice (useful for later) that as:

$$\frac{\mathrm{d}\ln(D)}{\mathrm{d}D}=\frac{1}{D}\Leftrightarrow\frac{\mathrm{d}D}{D}=\ln(D)\qquad\text{and}\qquad\frac{\mathrm{d}\ln(P)}{\mathrm{d}P}=\frac{1}{P}\Leftrightarrow\frac{\mathrm{d}P}{P}=\ln(P)\tag{15.3.16}$$

Therefore:

$$e_D=-\frac{\mathrm{d}D/D}{\mathrm{d}P/P}=\frac{\ln(D)}{\ln(P)}\tag{15.3.17}$$

What happens to price elasticity of demand when we travel along a demand curve depends on the nature of the demand curve itself. On a linear demand curve, such as the one in the figure below elasticity becomes smaller (in absolute value) as we travel downward and to the right:



D5. An "investment I" is the operation performed by an economic agent whose objective is to obtain produced goods in exchange.

D6. A "transaction T" is the exchange of a quantity of goods at a specified price between a "seller" and "buyer". It concludes on the market whose form is determined by the number of economic agents who are involved which determines the "concurrence".

The table below shows the different types of contracts:

	Suppliers		
Seekers	multitude	some	only one
multitude	perfect competition	oligopoly	monopoly
some	oligopsony	bilateral oligopoly	upset monopoly
only one	monopsony	upset monopsony	bilateral monopoly

Table 15.32: **Different forms of market competition**

When the actors of an ogilopoly work together to fix prices, we speak then of "cartel".

✍**Examples:**

E1. Lysine, a $600 million-a-year industry, is an amino acid used by farmers as a feed additive to ensure the proper growth of swine and poultry. The primary U.S. producer of lysine is Archer Daniels Midland (ADM), but several other large European and Japanese firms are also in this market. For a time in the first half of the 11990s (holocene calendar), the world's major lysine producers met together in hotel conference rooms and decided exactly how much each firm would sell and what it would charge. The U.S. Federal Bureau of Investigation (FBI), however, had learned of the cartel and placed wire taps on a number of their phone calls and meetings. From FBI surveillance tapes, following is a comment that Terry Wilson, president of the corn processing division at ADM, made to the other lysine producers at a 11994 (holocene calendar) meeting in Mona, Hawaii:

«I wanna go back and I wanna say something very simple. If we're going to trust each other, okay, and if I'm assured that I'm gonna get 67,000 tons by the year's end, we're gonna sell it at the prices we agreed to... The only thing we need to talk about there because we are gonna get manipulated by these [expletive] buyers-they can be smarter than us if we let them be smarter. ...They [the customers] are not your friend. They are not my friend. And we gotta have 'em, but they are not my friends. You are my friend. I wanna be closer to you than I am to any customer. Cause you can make us ... money. ... And all I wanna tell you again is let's - let's put the prices on the board. Let's all agree that's what we're gonna do and then walk out of here and do it.»

The price of lysine doubled while the cartel was in effect. Confronted by the FBI tapes, Archer Daniels Midland pled guilty in 11996 (holocene calendar) and paid a fine of $100 million. A number of top executives, both at ADM and other firms, later paid fines of up to $350, 000 and were sentenced to 24-30 months in prison.

In another one of the FBI recordings, the president of ADM told stated the slogan of its company this way: «*Our competitors are our friends. Our customers are the enemy*».

E2. French antitrust authorities in 12014 (holocene calendar) issued two fines of a cumulative amount of some 951 million euros against 13 of the main manufacturers of the maintenance sector, hygiene and beauty for having coordinated their marketing policy with the mass retailers and to have agreed on the price increases between 12003 and 12006 (holocene calendar). The first fine of concerns Colgate-Palmolive, Henkel, Unilever, Procter & Gamble, the second one concerns the same + Gillette and L'Oréal.

This case was revealed 3 years after another important decision of the Authority on the laundry sector, already containing some of the same companies. The four major manufacturers of laundry detergents - Unilever, Procter & Gamble, Colgate-

Palmolive and Henkel - secretly agreed during 6 years on their prices and promotions in France, resulting in a 4% surcharge of 6% for consumers. These manufacturers were then sentenced to pay only 361 million euros in fines...

A competition is qualified of "pure competition" (P.P.C.: pure and perfect competition) or "perfect competition" if it meets the next five following hypothesis:

H1. Atomicity: Buyers and sellers are numerous to the point that no one alone can influence the prices.

H2. Homogeneity: The goods traded are identical and interchangeable with each other. They can satisfy the same need.

H3. Free entry: There is no barrier to entry and exit of new economic agents.

H4. Free movement: Economic agents can move freely (from a market to the other one).

H5. Perfect information: Everyone knows at the same time and for free all quantities supplied and demanded by all the agents at different prices (see section Game and Decision Theory page 7400).

D7. The "intermediate management balances" are parts of the overall result of market activity period that are significant to the financial analyst. There are multiple definitions which arise from elementary algebraic operations on concepts defined above as (non exhaustive list!):

- The "gross margin" or "gross profit" is the difference between the proceeds of sales of goods and the purchase cost of goods sold (the sales margin is specific to trading activities, that is to say to companies with a distribution activity).
- The "operating income" is the difference between the gross margin less the operating expenses.
- The "net income" (also named "earning before interest and taxes" abbreviated EBIT[14]) is the difference between the operating income and other expenses (interest expenses) and taxes.
- The "production of the fiscal period" which is the sum of production sold, stored and immobilized (production of exercise is specific to production activities, that is to say companies with an industrial activity).
- The "turnover", which is the sum of revenue from sales of goods and sales of goods and services.
- The "added value" which is defined as the difference between production for the fiscal period and the intermediate consumption by the economic agents (the manager considers it created wealth resulting from the real business of the company and the added value also of national importance because it is an aggregate).
- The "degree of operating leverage" (DOL) is a numerical measure that helps an analyst compare the situation of two firms or of one firm over a period of time. When a proportionate change in EBIT, due to a change in sales, is more than the proportionate change in sales, operating leverage exists. Degree of Operating Leverage is the

---

[14] There is also the EBITDA that stands for the earnings before interest, depreciation, taxes, and amortization...

magnification factor by which % change in EBIT exceeded the % change in sales. It is defined by:

$$\text{DOL} = \frac{\text{\% change in Operating Income}}{\text{\% Change in Sales}} \tag{15.3.18}$$

- The "gross operating surplus" (G.O.S.) is the result of the current activity of the company and is defined as:

$$\begin{aligned}\text{G.O.S.} =&\text{Added Value} + \text{Amortization \& Provisions}+\\ &\text{Other Products} - \text{Other Expenses} + \text{Charges transfer}\end{aligned} \tag{15.3.19}$$

✍**Examples:**

E1. Consider the following non-standardized and naive income statement:

Imaginary Corp & Co.	
Income statement	
Sales	\$105,000
Less: Cost of Sales	\$20,000
Gross Profit	\$85,000
Less: Operating Expenses	\$15,000
Operating Income	\$70,000
Less: Other Expenses and Taxes	\$20,000
Net Income	\$50,000

E2. To introduce the DOL (degree of operating leverage), let us consider the two following income statements (the years are given based on the holocene calendar):

Imaginary Corp & Co.		
Income Statement	**11998**	**11999**
Sales	\$85,000	\$105,000
Cost of Operations	\$45,000	\$35,000
Operating Income	\$40,000	\$70,000

The percentage change in sales and in operating income is:

$$\begin{aligned}\text{\% change in sales} &= \frac{105,000-85,000}{85,000} \cong 23.5\%\\ \text{\% change in operating income} &= \frac{70,000-40,000}{40,000} \cong 75\%\end{aligned} \tag{15.3.20}$$

We can see that a 23.5% increase in sales results in a 75% increase in operating income. Using the definition above, the Degree Of Operating Leverage is:

$$\text{DOL} = \frac{\text{\% change in Operating Income}}{\text{\% Change in Sales}} = \frac{75\%}{23.5\%} = 3.19 \tag{15.3.21}$$

15.3.1.1.1 Willingness-To-Pay

The "willingness-to-pay" (W.T.P.) approach assumes that each potential customer has a maximum willingness to pay (sometimes named a "reservation price") for a product or service. A customer will purchase if and only if the price is less than her maximum willingness to pay (we will use willingness to pay, sometimes to mean "maximum willingness to pay"). For example, a customer with a willingness to pay of \$ 253 for an airline ticket from New York to Miami will purchase the ticket if the price is less than or equal to \$ 253 but not if it is \$ 253.01 or more. In this case, $D(253)$ equals the number of customers whose maximum willingness to pay is at least \$ 253. A customer with a maximum willingness to pay of \$ 0 (or less) will not buy at any price.

Define the function $w(x)$ as the W.T.P distribution across the population. Then, for any values $0 \leq P_1 \leq P_2$:

$$\int\limits_{P_1}^{P_2} w(x)\mathrm{d}x = \text{fraction of the population that has W.T.P. between } P_1 \text{ and } P_2 \tag{15.3.22}$$

We note that $0 \leq w(x) \leq 1$ for all non-negative values of x, therefore it is quite obvious that $w(x)$ is just a probability density function! Let:

$$D_{\max} = D(0) \tag{15.3.23}$$

be the maximum demand achievable. Then we can derive $D(P)$ from the W.T.P distribution from:

$$\boxed{D(P) = D_{\max} \int\limits_{P}^{+\infty} w(x)\mathrm{d}x} \tag{15.3.24}$$

Denoting the primitive of $w(x)$ by $W(x)$ that latter can be written:

$$D(P) = D_{\max}\left(W(+\infty) - W(P)\right) \tag{15.3.25}$$

Assuming:

$$w(+\infty) \rightarrow 0 \tag{15.3.26}$$

We can take the derivative of the corresponding price-response function to obtain:

$$D'(P) = D_{\max}\left(W(+\infty) - W(P)\right)' = D_{\max}\left(w(+\infty) - w(P)\right)' - D_{\max}w(P) \tag{15.3.27}$$

which is non-positive, as required by the downward-sloping demand curve property. Conversely, we can derive the willingness-to-pay distribution from the price-response function using:

$$w(P) = -\frac{D'(P)}{D_{\max}} = -\frac{D'(P)}{D(0)} \tag{15.3.28}$$

We will see further below what is the purpose to build such a W.T.P. function!

15.3.1.1.2 Pricing optimization

The scope of "pricing and revenue optimization" (PRO) is to set and update the prices for each combination of product, customer segment and channel. Due to market condition change over time, the PRO is responsible to update the prices. The basic element of a PRO is the price-response function or the price-response curve given by $D(P)$.

We are going here to compare three different types of demand models for homogeneous products and how to find optimal prices for each one of them.

For the linear model, demand is given by:

$$D(P)=\alpha P+\beta \tag{15.3.29}$$

and as we have seen earlier, the arc elasticity goes for infinity to zero in absolute value.

Remark

It is easy to verify that for this model:

$$D(0)=\alpha\cdot 0+\beta=\beta \tag{15.3.30}$$

And therefore:

$$w(x)=-\frac{D'(P)}{D(0)}=-\frac{\alpha}{\beta}=c^{te} \tag{15.3.31}$$

ie a uniform distribution!

Another very common demand model is the "constant arc-elasticity model" (CAEM), defined by:

$$\ln\left(D(P)\right)=\alpha\ln(P)+\beta \tag{15.3.32}$$

or if we take the exponential:

$$D(P)=e^{\beta}P^{\alpha}=C^{te}P^{\alpha} \tag{15.3.33}$$

Proof 15.2.2. Let us prove that the arc-elasticity is indeed constant for the specific model:

$$\begin{aligned}e_D&=\frac{\mathrm{d}D/D}{\mathrm{d}P/P}=\frac{\mathrm{d}D}{\mathrm{d}P}\frac{P}{D}=\left[\frac{\mathrm{d}}{\mathrm{d}P}\left(C^{te}P^{\alpha}\right)\right]\frac{P}{D}\\&=C^{te}\alpha P^{\alpha-1}\frac{P}{D}=C^{te}\alpha P^{\alpha-1}\frac{P}{C^{te}P^{\alpha}}=C^{te}P^{\alpha-1}\frac{P}{P^{\alpha}}\\&=C^{te}P^{\alpha-1}PP^{-\alpha}=C^{te}P^{\alpha-1}P^{-\alpha+1}=C^{te}\end{aligned} \tag{15.3.34}$$

As e_D should be positive or null, this assumes that $C^{te}\leq 0$ (once again this will make sense a bit later).

■ Q.E.D.

Remark

It is easy to verify that for this model:

$$D(0)=C^{te}\cdot 0^{\alpha}=0 \tag{15.3.35}$$

And therefore:

$$w(x)=-\frac{D'(P)}{D(0)}=+\infty \tag{15.3.36}$$

So this is a quite unrealistic probability density function...

A much more interesting demand curve is given by the logistic/sigmoid function (i.e. the logit price-response function):

$$D(P)=C^{te}\frac{e^{\alpha P+\beta}}{1+e^{\alpha P+\beta}}=\frac{C^{te}}{1+e^{-\alpha P-\beta}}=\frac{C^{te}}{1+e^{-\alpha(P+\beta/\alpha)}}=\frac{C^{te}}{1+e^{-\alpha(P-P_0)}} \tag{15.3.37}$$

Where:

$$P_0=-\frac{\beta}{\alpha} \tag{15.3.38}$$

is the inflection point of the demand and C^{te} is a scale factor and α measures price sensitivity.

Proof 15.2.3. Let us prove the value of the inflection point. For this we determine the first derivative before:

$$D'(P)=\left(C^{te}\left(1+e^{-\alpha P-\beta}\right)^{-1}\right)'=-C^{te}\left(1+e^{-\alpha P-\beta}\right)^{-2}\left(-\alpha e^{-\alpha P-\beta}\right) \tag{15.3.39}$$

Then the second derivative is then quite immediate:

$$D''(P)=2C^{te}\left(1+e^{-\alpha P-\beta}\right)^{-3}\left(-\alpha e^{-\alpha P-\beta}\right)^{2}-C^{te}\left(1+e^{-\alpha P-\beta}\right)^{-2}\left(\alpha^{2}e^{-\alpha P-\beta}\right) \tag{15.3.40}$$

to find the inflection point we therefore only have to solve (see section Differential and Integral Calculus page 1454):

$$2C^{te}\left(1+e^{-\alpha P-\beta}\right)^{-3}\left(-\alpha e^{-\alpha P-\beta}\right)^{2}-C^{te}\left(1+e^{-\alpha P-\beta}\right)^{-2}\left(\alpha^{2}e^{-\alpha P-\beta}\right)=0 \tag{15.3.41}$$

Very simple algebraic simplification then gives (abscissa value of the inflection point):

$$P=-\frac{\beta}{\alpha} \tag{15.3.42}$$

Hence the ordinate is given by:

$$D\left(-\frac{\beta}{\alpha}\right)=\frac{C^{te}}{1+e^{-\alpha(-\beta/\alpha)-\beta}}=\frac{C^{te}}{1+e^{0}}=\frac{C^{te}}{2} \tag{15.3.43}$$

■ Q.E.D.

Remark

It is easy to verify that for this model:

$$D(0)=\frac{C^{te}e^{\beta}}{1+e^{\beta}}=\frac{C^{te}}{1+e^{-\beta}} \tag{15.3.44}$$

And therefore:

$$\begin{aligned}w(x)&=-\frac{D'(P)}{D(0)}=-\frac{-C^{te}\left(1+e^{-\alpha P-\beta}\right)^{-2}\left(-\alpha e^{-\alpha P-\beta}\right)}{\dfrac{C^{te}}{1+e^{-\beta}}}=\frac{C^{te}\left(1+e^{-\alpha P-\beta}\right)^{-2}\left(-\alpha e^{-\alpha P-\beta}\right)}{\dfrac{C^{te}}{1+e^{-\beta}}}\\&=\frac{-\alpha e^{-\alpha P-\beta}\left(1+e^{-\beta}\right)}{\left(1+e^{-\alpha P-\beta}\right)^2}=K\frac{e^{-\alpha P-\beta}}{\left(1+e^{-\alpha P-\beta}\right)^2}\end{aligned} \tag{15.3.45}$$

This is a far more realistic W.T.P. distribution than those associated with either the constant-elasticity or linear price-response functions. For that reason, the logit is usually preferred to linear or constant-elasticity price-response functions.

It is important to notice that the price sensitivity α is almost always negative (excepted for luxury on limited edition products and some other obvious special cases) for all these three models:

$$\begin{aligned}D(P)&=\alpha P+\beta\\D(P)&=e^{\beta}P^{\alpha}\\D(P)&=\frac{C^{te}}{1+e^{-\alpha(P-P_0)}}\end{aligned} \tag{15.3.46}$$

In a quite general setting, one have for the total profit function:

$$L(P)=D(P)(P-C) \tag{15.3.47}$$

where L gives the profit, D is still the demand function that depends of the price and C is the marginal cost. Taking the derivative with respect to price we have:

$$\begin{aligned}L'(P)&=(D(P)(P-C))'=D'(P)(P-C)+D(P)(P-C)'=D'(P)(P-C)+D(P)P'\\&=D'(P)(P-C)+D(P)\end{aligned} \tag{15.3.48}$$

Making $L'(P)=0$ to calculate the optimum price P^* (first order condition), we have:

$$D'(P^*)(P^*-C)+D(P^*)=0 \tag{15.3.49}$$

Hence:

$$D'(P^*)P^*+D(P^*)=D'(P^*)C \tag{15.3.50}$$

Now for the linear model introduced just earlier above, we have obviously:

$$D'(P^*_{\text{lin}})=\alpha \tag{15.3.51}$$

Hence:

$$D'(P_{\text{lin}}^*)P_{\text{lin}}^* + D(P_{\text{lin}}^*) = D'(P_{\text{lin}}^*)C \rightarrow \alpha P + (\alpha P_{\text{lin}}^* + \beta) = \alpha C \tag{15.3.52}$$

Therefore the optimal price is given by:

$$P_{\text{lin}}^* = \frac{\alpha C - \beta}{2\alpha} \tag{15.3.53}$$

To deal now with the constant arc-elasticity model, let us first recall that:

$$D'(P^*)(P^* - C) + D(P^*) = 0 \tag{15.3.54}$$

Hence:

$$-\frac{D'(P^*)}{D(P^*)} = \frac{1}{P^* - C} \tag{15.3.55}$$

Multiplying both sides by P^*, we get:

$$-\frac{D'(P^*)P^*}{D(P^*)} = \frac{P^*}{P^* - C} \tag{15.3.56}$$

And according to our definition of arc-elasticity:

$$e_D(P^*) = \frac{P^*}{P^* - C} \tag{15.3.57}$$

Hence after rearranging:

$$P^* = \frac{e_D(P^*)C}{1 - e_D(P^*)} = \frac{C}{1 - 1/e_D(P^*)} \tag{15.3.58}$$

And as:

$$e_D = \frac{\mathrm{d}D/D}{\mathrm{d}P/P} = \frac{\ln(D)}{\ln(P)} = \frac{\alpha \ln(P) + \beta}{\ln(P)} = \alpha \tag{15.3.59}$$

Therefore:

$$P_{\text{CAEM}}^* = \frac{C}{1 - 1/e_D(P^*)} = \frac{C}{1 - 1/\alpha} \tag{15.3.60}$$

It is interesting to note that one needs $|\alpha| > 1$, otherwise the profit function will be convex with respect to price and the optimal price will be $+\infty$. If one have a monopolistic market, normally this assumption holds.

For the logistic model. we have for recall:

$$D'(P) = C^{te}\left(1 + e^{-\alpha P - \beta}\right)^{-2}\left(\alpha e^{-\alpha P - \beta}\right) \tag{15.3.61}$$

And if we put it into:

$$D'(P^*)(P^* - C) + D(P^*) = 0 \tag{15.3.62}$$

We get:

$$C^{te}\left(1+e^{-\alpha P^*-\beta}\right)^{-2}\left(\alpha e^{-\alpha P^*-\beta}\right)(P^*-C)+\frac{C^{te}}{1+e^{-\alpha P^*-\beta}}=0 \qquad (15.3.63)$$

Simplifying a bit we get:

$$\frac{C^{te}}{1+e^{-\alpha P^*-\beta}}\left(\alpha e^{-\alpha P^*-\beta}(P^*-C)+1\right)=0 \qquad (15.3.64)$$

With a further simple simplification:

$$\alpha e^{-\alpha P^*-\beta}(P^*-C)+1=0 \qquad (15.3.65)$$

Since the last equation above does not seems to have an analytical solution, one can easily find the result with a Newton-step algorithm or minimization problem (see section of Numerical Methods page 6662):

$$\min_{P^*\in\mathbb{R}}\left(\alpha e^{-\alpha P^*-\beta}(P^*-C)+1\right)^2 \qquad (15.3.66)$$

Remark

To see how to implement this on a computer software the reader can refer to the `R` companion book.

15.3.1.1.3 Average & Marginal Cost/Revenue

Let us introduce the subject directly by an example:

Suppose an amateur cook (and economist) invites his friends to his table and proposes to do their a tomato salad. It evaluates the work he has to do this job and figure it in monetary value. It considers that a minute of his time spent in the preparation of the salad corresponds to an expense of 1.-.

So the data are:

1. Each minute of work value is 1.-
2. Each tomato is 1.-/unit
3. Prepare the salad takes 15 minutes

If each of his friends is satisfied with a single tomato, prepare dinner for five friends (the cook does not eat) will cost in total:

$$C_T = 5.- + 15.- = 20.- \tag{15.3.67}$$

Mathematically, the "total cost function" will looks like following if we write q as the number of friends (in practice it is often a strictly increasing polynomial function):

$$C_T(q) = (1.-)\, q + 15.- \tag{15.3.68}$$

Definition (#15.3.655): The "average cost" or "average cost function" for each guest is of 20.- divided by 5 thus 4.-. This corresponds to:

$$\boxed{C_m(q) = \frac{C_T(q)}{q}} \tag{15.3.69}$$

which is not necessarily an increasing function!

Theorem 15.3. We can see that as q tends to infinity, under the assumption of constant production effort, the average cost C_m tends to the unit cost C_U. That is so to say:

$$\lim_{q \to +\infty} C_m(q) = C_U \tag{15.3.70}$$

Proof 15.3.1. Indeed, if we denote C_F the assumed fixed cost and C_U the unit cost, we have:

$$C_m(q) = \frac{C_T(q)}{q} = \frac{C_U q + C_F}{q} \tag{15.3.71}$$

and when $q \to +\infty$ then as $C_U q \gg C_F$ we can write:

$$C_m(q) = \frac{C_U q + C_F}{q} \cong \frac{C_U q}{q} = C_U \tag{15.3.72}$$

■ Q.E.D.

Remark

According to the books (and authors), the average cost is denoted by a lowercase m or uppercase M and the marginal cost (see further below) too.

If our cook invites a sixth friends, the total cost will be 21.-. In fact the preparation time will remain, at least we assume ... constant! In this case, the marginal cost of the sixth guest is:

$$(21.\text{-}) - (20.\text{-}) = 1.\text{-} \qquad (15.3.73)$$

while the average cost for all guests is now:

$$\frac{21.\text{-}}{6} = 3.5.\text{-} \qquad (15.3.74)$$

We notice in this situation that the average cost goes down of 0.5.- indefinitely as the number of guests increases. This quantity of 0.5.- is the marginal revenue!

This example illustrates the return scale and shows that we often have an incentive to increase production to reduce the average cost of production (but this does not mean that our amateur cook will appreciate the reasoning when reaching its physical limit...).

Moreover, it this not however a general rule! While the bowl of our economist can contain only 6 tomatoes, the 7th guest will force him to prepare a second bowl. In this case, the marginal variation will be greater than the previous one.

We must also be aware that the total cost function is in fact rarely a continuous function (because you have to buy machinery or engage staff in stepwise quantities) and even more it is the market that dictates the quantities to a factory and not the inverse.

Definition (#15.3.656): Mathematically, the "marginal cost" is defined by the variation of the total cost function $C_T(q)$, relative to the quantity produced q:

$$C_M = \frac{\Delta C_T(q)}{\Delta q} \qquad (15.3.75)$$

or if the total cost function is differentiable (anyway in economics, even if it is not continuous we makes abstraction of this fact...):

$$\boxed{C_M = \frac{\mathrm{d}C_T(q)}{\mathrm{d}q}} \qquad (15.3.76)$$

The marginal cost corresponds thus to the cost of producing one more or less unit (in the example above it is equal to 1.-). In practice, we are more interested in the cost of an additional series.

In addition, the reader will notice that as the total cost is a strictly increasing function, the marginal cost is also a constant or increasing function.

Remark

If the marginal cost increases as the quantity q increases, we say that the returns are diminishing. In contrast, they are increasing if the marginal cost is decreasing as the amount increases.

The marginal cost corresponds thus to the cost of producing one more or less unit. In practice, we are more interested in the cost of an additional series.

In addition, the reader will notice that as the total cost is a strictly increasing function, the marginal cost is also a constant or increasing function.

Theorem 15.4. Let us show now that if the average cost goes through an extremal value, the marginal cost is equal to it at that point. We name this particular situation a "technical optimum".

Recall previously that if a continuous and differentiable function $f(x)$ has a minimum (or maximum), its derivative at that point is equal to zero (see section Differential and Integral Calculus page 1453).

Proof 15.4.1. Apply this property to the average cost function. But recall that previously (see section Differential and Integral Calculus page 1475):

$$\left(\frac{u}{v}\right)'=\frac{u'v-uv'}{v^2} \tag{15.3.77}$$

So we have if the derivative of the average cost is zero:

$$\frac{\mathrm{d}C_m}{\mathrm{d}q}=0\Rightarrow\frac{\mathrm{d}}{\mathrm{d}q}\left(\frac{C_T}{q}\right)=\left(\frac{C_T}{q}\right)'=0 \tag{15.3.78}$$

So this is the derivative of the ratio of two functions. therefore:

$$\left(\frac{C_T}{q}\right)'=\frac{\dfrac{\mathrm{d}C_T}{\mathrm{d}q}q-C_T\dfrac{\mathrm{d}q}{\mathrm{d}q}}{q^2}=0\Rightarrow\frac{\mathrm{d}C_T}{\mathrm{d}q}q-C_T=C_T'q-C_T=0 \tag{15.3.79}$$

Hence we deduce:

$$C_T'q=C_T \tag{15.3.80}$$

Thus:

$$C_T'=\frac{C_T}{q} \tag{15.3.81}$$

■ Q.E.D.

This result tell us that in this situation, the marginal cost is equal to average cost (we find the definition of each cost on the to left or on the right respectively of equality).

In other words, where the average cost reaches an optimum (minimum in our case), then the marginal cost equals average cost.

Definition (#15.3.657): Mathematically, the "marginal revenue" is defined by the additional margin relative to the quantity produced q (it is the additional revenue that will be generated by increasing product sales by one unit):

$$\boxed{C_R = \Delta C_m(q) = \frac{C_T(q)}{q} - \frac{C_T(q-1)}{q-1}} \tag{15.3.82}$$

Theorem 15.5. As $q \rightarrow +\infty$ the marginal revenue C_R tends to zero. In other words, more we produce a given product the smaller is the margin variation.

Proof 15.5.1. As we have:

$$C_R = \frac{C_T(q)}{q} - \frac{C_T(q-1)}{q-1} = \frac{C_F + qC_U}{q} - \frac{C_F + (q-1)C_U}{q-1} \tag{15.3.83}$$

Then when $q \rightarrow +\infty$ we have:

$$q \cong q-1 \tag{15.3.84}$$

and therefore:

$$C_R = \frac{C_F + qC_U}{q} - \frac{C_F + (q-1)C_U}{(q-1)} \cong \frac{C_F + qC_U}{q} - \frac{C_F + qC_U}{q} = 0 \tag{15.3.85}$$

■ Q.E.D.

For our above example the tabulated values give in a spreadsheet software:

	A	B	C	D	E	F	G
1	Quantity	Production Cost	Tomato Costs	Total Cost	Average Cost	Marginal Cost	Marginal Revenue
2	1	15	1	16	16	1.00

25	8388608	15	8388608	8388623	1.000001788	1.00	1.78814E-06
26	16777216	15	16777216	16777231	1.000000894	1.00	8.9407E-07

✍**Example:**

A factory has calculated that the cost of producing q units of a product can be modelled by the following function within the yield capacity limits of a machine and manpower it has at its disposal:

$$C_T(q)=2,600+2q+0.001q^2 \tag{15.3.86}$$

Let us calculate the cost, the average cost and marginal cost of the production of $1,000$, $2,000$ and $3,000$ units. We then have the following information:

$$\begin{aligned}C_T(q)&=2,600+2q+0.001q^2\\C_m(q)&=\frac{C_T(q)}{q}=\frac{2,600}{q}+2+0.001q\\C_M(q)&=\frac{\mathrm{d}C_T(q)}{\mathrm{d}q}=2+0.002q\end{aligned} \tag{15.3.87}$$

Then we have:

Quantity	**Total Cost**	**Average Cost**	**Marginal Cost**
$1,000$	$5,600$.-	5.60.-	4.00.-
$2,000$	$10,600$.-	5.30.-	6.00.-
$3,000$	$17,600$.-	5.87.-	8.00.-

Table 15.33: **Various costs**

And for the average cost to be as low as possible, it is necessary that the marginal cost is equal to average cost:

$$\frac{\mathrm{d}C_T(q)}{\mathrm{d}q}=\frac{C_T(q)}{q}\Rightarrow\frac{2,600}{q}+2+0.001q=2+0.001q \tag{15.3.88}$$

We conclude:

$$q=\sqrt{\frac{2,600}{0.001}}\cong 1,612 \tag{15.3.89}$$

By injecting this value in the total cost function, we deduce that the minimum average cost is 5.22.-.

In reality, we make Monte Carlo simulations that gives not only the possibility to work in an uncertain and quantities, but that an also take into account non-continuous functions! For more information on Monte Carlo modelling, the reader can refer to the section of Numerical Methods at page 6708.

Revenue is wrong.
2
How do you define revenue?
3
Gross revenue
Net revenue
Adjusted revenue
Revenue excluding returns
The number from the old report

15.3.1.2 Macroeconomics

"Aggregates" are synthetic variables developed by nations for their national accounting and measuring the result of their entire economy. Some of the main aggregates are defined by:

Definitions (#15.3.658):

D1. The "gross national product" (G.N.P.) whose purpose is to measure domestic production (considered as isolated), that is to say all the monetary values of goods and services produced in a given period (the term "Gross" indicates that the value of G.N.P. is not deducted from different existing taxes on production).

D2. The "gross domestic product" (G.D.P.) whose role is to measure national production (such as G.N.P.) and take into account the income of the rest of the world. In other words, G.D.P. is the G.N.P. which we sum the capital coming from outside and which is subtracted from capital going outside.

D3. The "gross fixed capital formation" (G.F.C.F.) measures the value of acquisitions of new or existing fixed assets by the business sector, governments and "pure" households (excluding their unincorporated enterprises) less disposals of fixed assets and it is a component of the expenditure on gross domestic product (G.D.P.), and thus shows something about how much of the new value added in the economy is invested rather than consumed.

D4. The "national income" (N.I.) whose role is to measure all the incomes received by economic agents.

D5. The "consumption" whose role is to represent the value of goods and services used for the direct needs of economic agents.

D6. The "consumer price index" (C.P.I.) measures changes in prices of goods and services representative of the consumption of private households. It indicates how much consumers have to increase or decrease their expenses to maintain the same volume of consumption.

D7. The "inflation" (I) is defined as the increase in prices or the purchasing power of money the most common way to calculate the inflation rate is by recording the prices of goods and services over the years, take a base year and then determine the percentage rate changes of those prices over the years. For example with C.P.I. we get:

$$\mathrm{I}=\frac{\mathrm{CPI}_y-\mathrm{CPI}_{y-1}}{\mathrm{CPI}_{y-1}} \tag{15.3.90}$$

D8. The "purchasing power standard" (P.P.S.) is an artificial common reference currency unit used in the European Union which eliminates the differences of price levels between countries. So, a P.P.S. allows to buy the same volume of goods and services in all the countries. This unit allows significant comparisons in volume of economic indicators between countries.

D9. The "purchasing power parity" (P.P.P.) is the exchange rate that equalizes the prices of internationally traded goods across countries. A group of economists at the International Comparison Program, rub by the World Bank, have calculated the PPP exchange rate for all countries, based on detailed studies of the prices and quantities of internationally tradable goods. The PPP is often used in any international comparison involving prices or amounts of money!!!

D10. The "added value" (A.V.) of a company whose role is to represent the difference between the value of goods and services produced by it with the value of goods and services used to produce these goods and services.

and so on...

Remark

Never forget that when you read macro-economics indicators in papers that first there is a margin error on them (even if it is not indicated) and second that these indicator are given with a time lag of months or years sometimes. So when you see a good macroeconomic indicator this year it is in fact the macroeconomics wealth of previous year and furthermore because sells of major Fortune 500 are done on customers orders of prior-previous year (typical for machines and some food stuff) it is in fact with two years late!

15.3.1.2.1 Cobb-Douglas Model

In 11928 (holocene calendar), Charles Cobb and Paul Douglas published a study in which appeared the modelling of the growth of the US economy between 11899 (holocene calendar) and 11922 (holocene calendar). They had adopted a simplified view of the economy in that the quantity produced of goods is based that the amount of work done and the amount of capital invested.

Although many other factors affect economic performance, their model has shown to be remarkably accurate. The function they used to model production was of the form:

$$P(L,K)=bL^{\alpha}K^{1-\alpha} \tag{15.3.91}$$

where P is the total production (the monetary value of all goods produced in one year), L the amount of work (the total number of hours worked in a year) and K the amount of investment (the monetary value of all machinery, equipment and buildings). The factor b is a "collector" constant that represents technology, efficiency, and other things not accounted for by K and L.

Although this model has been applied primarily to economy, we can find it in many scientific articles in biology or human resources. It seemed appropriate to show in detail (since it is the purpose of this textbook to see things in details!) where does this strange function comes from because the approach is relatively great.

First, if we have a function of two variables $P(L,K)$, the partial derivative $\partial P/\partial L$ indicates the rate of change in production with respect to the amount of labour only. This is what economists name the "marginal production in relation to labour" or "marginal productivity of labour". Similarly, the partial derivative $\partial P/\partial K$ indicates the rate of change in production relative to capital and is named the "marginal productivity of capital".

If we increase the number of machines K, will we be able to produce more cookies? Of course! What if we increase the amount of labour L? Same thing. We can observe this mathematically as well:

$$\begin{aligned}\frac{\partial Y}{\partial K}=b(\alpha K^{\alpha-1})L^{1-\alpha}>0\\ \frac{\partial Y}{\partial K}=b(\alpha K^{\alpha-1})L^{1-\alpha}>0\end{aligned} \tag{15.3.92}$$

In these terms, the hypothesis (assumptions) of Cobb and Douglas (to confront to historical measures and adapt to these measures in individual cases) are as follows:

- H1. Without labour L or without capital K no production.
- H2. The marginal productivity of labour is proportional to the amount produced P per unit of labour L.
- H3. The marginal productivity of capital is proportional to the amount produced P per unit of capital K

Given that the production per work unit is the P/L, hypothesis 2 can be written as:

$$\frac{\partial P}{\partial L}=\alpha\frac{P}{L} \tag{15.3.93}$$

for a given constant α.

If the case where the invested capital K is constant ($K=K_0$), the partial differential equation becomes an ordinary differential equation:

$$\frac{\mathrm{d}P}{\mathrm{d}L}=\alpha\frac{P}{L} \tag{15.3.94}$$

This gives us:

$$\frac{1}{P}\mathrm{d}P=\alpha\frac{1}{L}\mathrm{d}L \tag{15.3.95}$$

So solving this differential equation gives:

$$\ln(P)=\alpha\ln(L)+c^{te}\Rightarrow e^{\ln(P)}=e^{\alpha\ln(L)}e^{c^te}=C^{te}e^{\ln(L^\alpha)} \tag{15.3.96}$$

Therefore:

$$P(L,K_0)=C^{te}(K_0)L^\alpha \tag{15.3.97}$$

because as we fixed K it is obvious that the constant depends on K_0.

By doing exactly the same for the third hypothesis:

$$\frac{\partial P}{\partial K}=\beta\frac{P}{K} \tag{15.3.98}$$

Therefore:

$$P(L_0,K)=C^{te}(L_0)K^{\beta} \tag{15.3.99}$$

So we have at the end:

$$\begin{gathered}P(L,K_0)=C^{te}(K_0)L^{\alpha}\\P(L_0,K)=C^{te}(L_0)K^{\beta}\end{gathered} \tag{15.3.100}$$

and identifying term by term, we get immediately:

$$P(L,K)=c^{te}K^{\beta}L^{\alpha} \tag{15.3.101}$$

Let us observe the implications of this last relation if capital and labour are both multiplied by a constant factor m:

$$P(mL,mK)=c^{te}(mK)^{\beta}(mL)^{\alpha}=c^{te}m^{\alpha+\beta}K^{\beta}L^{\alpha}=c^{te}m^{\alpha+\beta}P(K,L) \tag{15.3.102}$$

If we impose:

$$\alpha+\beta=1 \tag{15.3.103}$$

then the production is multiplied by the same factor m. And we are in a proportionality assumption of production which seemed was consistent Cobb and Douglas assumption. since then:

$$\boxed{P(L,K)=c^{te}K^{\beta}L^{\alpha}} \tag{15.3.104}$$

The economic data used by Cobb and Douglas are those of the following table published by the U.S.A. Government (the years in the table below are given according to the holocene calendar):

Year	P	L	K
11899	100	100	100
11900	101	105	107
11901	112	110	114
11902	122	117	122
11903	124	122	131
11904	122	121	138

Table 15.34: **U.S. data in % used by Cobb and Douglas**

They deliberately took 11899 (holocene calendar) as a base, that is to say, they attributed the level 100 to each factor and expressed the values of other years as a percentage of that year.

To determine the Cobb-Douglas coefficients, we just have to make a linear regression by the least squares method (see section Numerical Methods page 6324). If we take the logarithm:

$$\begin{aligned}\ln(P)&=\ln\left(c^{te}K^{1-\alpha}L^{\alpha}\right)=\ln\left(c^{te}K^{1}K^{-\alpha}L^{\alpha}\right)=\ln\left(c^{te}K\left(\frac{L}{K}\right)^{\alpha}\right)\\&=\ln\left(c^{te}\right)+\ln(K)+\ln\left(\left(\frac{L}{K}\right)^{\alpha}\right)=\ln\left(c^{te}\right)+\ln(K)+\alpha\ln\left(\frac{L}{K}\right)\end{aligned} \tag{15.3.105}$$

and after rearranging, still using the properties of logarithms (see section Functional Analysis page 2284):

$$\ln\left(\frac{P}{K}\right)=\ln(c^{te})+\alpha\ln\left(\frac{L}{K}\right) \tag{15.3.106}$$

We put now to simplify:

$$x=\ln\left(\frac{L}{K}\right)\qquad y=\ln\left(\frac{P}{K}\right) \tag{15.3.107}$$

Therefore we just end up with a linear function:

$$y=\alpha x+\ln\left(c^{te}\right) \tag{15.3.108}$$

We then just adapt the table to inject it into a spreadsheet or statistical software to obtain (see section Numerical Methods page 6324):

$$\alpha\cong 0.75 \qquad c^{te}\cong 1.01 \tag{15.3.109}$$

Therefore:

$$P(L,K)\cong 1.01K^{0.25}L^{0.75} \tag{15.3.110}$$

By testing compared to the data table we get:

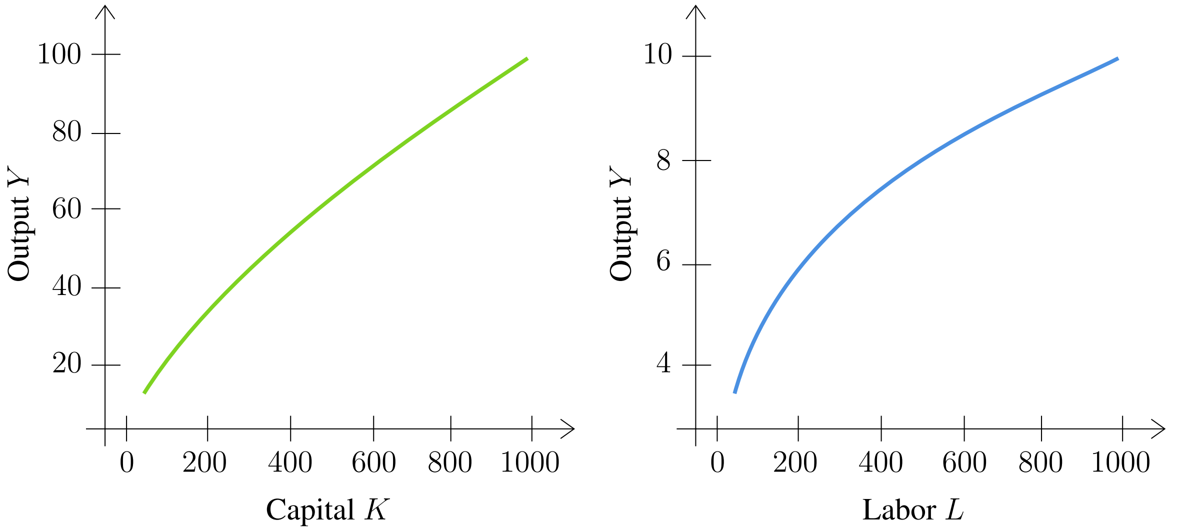
$$\begin{gathered}P_{11908}(123,185)\cong 137\\ P_{11910}(147,208)\cong 161\\ P_{11920}(194,407)\cong 235\\ P_{11922}(161,431)\cong 207\end{gathered} \tag{15.3.111}$$

So we see that the model... is a model... with some errors as every model. For example a typical "evolutionary" error (that a lot of economists still ignore and also politicians) of this model can illustrated by the following assumption:

If we keep increasing the number of machines K and hold labour L constant, economists say that we will produce less and less cookies per machine added. Same goes for labour if you hold capital constant. Why? Diminishing marginal returns! If we have too many machines but not enough workers, the machines will be idle. If we have too many workers for the machines, they overcrowd. Simple as that. But economists and politicians forget that now machine are "intelligent" and can manage and learn by themselves!

How can we prove mathematically this previous fact (that marginal returns diminish when increasing of the variable)?

Mathematically, we say that Y is increasing in K, but at a declining rate. Y is also increasing L, but at a declining rate. Indeed here is a plot of this:



(a) Plot of Y against K holding L constant (a) Plot of Y against L holding K constant

Figure 15.79: Y **Increasing in** K **and** L **at a declining rate**

This requires us to find the second derivatives:

$$\begin{aligned}\frac{\partial^2 Y}{\partial K^2} &= b(\alpha(\alpha-1)K^{\alpha-2})L^{1-\alpha}<0\\ \frac{\partial^2 Y}{\partial L^2} &= bK^{\alpha}((1-\alpha)(-\alpha)L^{-\alpha-1})<0\end{aligned} \quad (15.3.112)$$

as $(\alpha-1)$ is negative, since we stipulated that $0<\alpha<1$.

The assumptions H2 and H3 implies what economists name the "constant return to scale". In other words, we are taking our original K and L, and multiplying them both by the same proportion c^{te}. Then we investigate what happens to output.

So originally, we have:

$$Y_0 = bK^{\alpha}L^{1-\alpha} \quad (15.3.113)$$

After increases in input by a constant c^{te}, we have:

$$Y_1 = b(c^{te}K)^{\alpha}(c^{te}L)^{1-\alpha} = c^{te}Y_0 \quad (15.3.114)$$

We have just shown that if we increase both K and L by a same constant, then Y gets increased by the same factor. In fact we know it is much more interesting to invest in machines rather than in humans. So this model and through the assumptions H2 and H3 was valid only at the time computers (and defacto machines) were not able to do the work of humans.

15.3.2 Monetary Model

It is funny for an engineer to see at least once in his life how an idealistic macroeconomic Monetary Model can be build. We can see that the whole is just a summation of obvious assumptions that has for only purpose to try to have the most complicated mathematical formula at the end to makes it look like a pure science...

To build a macroeconomic monetary model in a pure and perfect competition market (remember above the five assumptions of such a market) we will assume that the "monetary utility" can be defined a priori by four properties:

- P1. It is a counting unit
- P2. It is a medium of payment (via trade)
- P3. It is a reserve value
- P4. It is in relative value a conservative quantity

This description approach is however insufficient to mathematical analysis: we need a comprehensive explanatory system because here we only formalized facts. We must therefore establish the link between money and monetary theory.

Apart from the value that represents currency, it derives its utility of the property it provides exchanges of goods. This is what we name the "derived utility".

Let us note O_u the available money on the market. It therefore depends on the existing total quantity of money Q_u minus the "cash" e kept by economic agents (who exchanged goods against money). We can then write the following relation named "money supply according to Walras":

$$\boxed{O_u = Q_u - e \Leftrightarrow Q_u = O_u + e} \tag{15.3.115}$$

The cash e is also in some way that of households and is a real demand for goods, which can be expressed necessarily in monetary form.

Remark

If all people really knew how modern money creation process works (the one used since the majority of states around the world allow banks to create "debt money" - that is to say, to create the money from a debt repayment promise) the system would probably not last long. Moreover, the contemporary system is relatively fragile and vicious in reality as we will see later (it will probably crash down soon or later).

Sales agents, when they sale their goods, a priori desire a given sum of monetary value against the sale of these goods, value named "desired monetary amount" and denoted by D_u. The problem is that D_u can be expressed as working hours, gold, air, animals, vegetables, etc. This is why it is important to convert this value into common artificial price measure of the monetary value.

We express this desired monetary amount in "cash" and for this we introduce a price to monetary value (because there exist different way to pay a cash value of a good having a given desired monetary amount). The desired monetary amount is then written over all market balances. The cash serves to express the relative prices for the overall balance. There is a cash desired by the agents for the realization of general equilibrium. These are actually real goods in monetary form:

$$\boxed{e = p_u D_u} \tag{15.3.116}$$

where p_u is the "monetary cash price" (factor variable over time and that brings in a market that is not "flow" to speculate). In a flow-market p_u will always assumed to be equal to unity. We can then write for different currencies in a global heterogeneous market:

$$\boxed{p_u D_u = \sum_{i=1}^{n} p_i D_i} \tag{15.3.117}$$

where p_i is the relative monetary cash price of currency i relatively to p_u

Remarks

R1. In an isotropic single currency market this relations would not need to be written.

R2. "Parity" is the term used when we look for equivalence of foreign currencies exchange rate and it is dependent (among others) of time and it is important to consider its variations in the context of goods market where the currency is not unique and payments not immediate.

The desired monetary amount by agents can then be define using the relation:

$$D_u = \frac{1}{p_u} \sum_{i=1}^{n} p_i D_i \tag{15.3.118}$$

Returning back to O_u but this time in the point of view of the companies (firms). They need money to make payments and to operate (wages, investments, etc.) and the desired monetary amount D'_u of all these companies at a given moment in time is in an ideal case necessarily equal to the total money available on the market such that:

$$D'_u := \frac{1}{p_u} O_u \tag{15.3.119}$$

since companies (firms) sell goods on the quantity of money Q_u of agents of the economic market minus the cash margins of these agent e.

The last relation implies that:

1. The aggregate demand necessarily creates an equal quantity of aggregate production ("Say Law").
2. The selling price of goods tends to be equal to their cost price (this is for simplification purposes and also a condition for what will follow!).

Remark

This last relation also means that the whole offer is satisfied only by the demand from the economic agents and the aforementioned amount of monetary value consists only of goods outside the companies (producers/firms/manufactures) and that they therefore have no stocks!

This also corresponds to a certain quantity of goods since the idea is to propose goods to get money (seen of the point of view of companies/firms/manufactures!). Therefore we can write:

$$D'_u := \frac{1}{p_u} O_u = \frac{1}{p_u}\left[\sum_{j=1}^{n} p_j D'_j\right] \tag{15.3.120}$$

But as the goods already in possession by the economic agents will also have to be renewed, the companies (firms) have finally as potential total amount of money available in the market:

$$Q_u = D'_u + D_u = \frac{1}{p_u}\left[\sum_{j=1}^{n} p_j D'_j + \sum_{i=1}^{n} p_i D_i\right] = O_u + e \tag{15.3.121}$$

The sum in brackets corresponds to the total money available in the market in the form of household assets and potential cash in the restriction of goods with a common currency cash price p_u. This is named the "money supply". It is restrictive as a model but sufficient in the context of determining the price of a given type good.

We write then by definition for the money supply according to Walras:

$$Q_u = D'_u + D_u = \frac{1}{p_u} H_u = O_u + e \tag{15.3.122}$$

This last relation implies that economic agents may not collectively choose to increase the amount of money e they hold...

In view of the foregoing, the reader will have noticed that this model considers that money is neutral in the sense that the total amount of money in circulation exerts no influence on the relative prices of products from each to others, nor on the level of supply and demand for products. The currency is not desired for itself...

15.3.2.1 Monetary base conservation

In economics, the "monetary base" in a country is defined as the portion of a commercial bank's reserves that consist of the commercial bank's accounts with its central bank plus the total currency circulating in the public, plus the currency, also known as vault cash, that is physically held in the bank's vault.

Remark

The monetary base should not be confused with the "money supply" which consists of the total currency circulating in the public plus the non-bank deposits with commercial banks.

The previous relations that we have obtained assume therefore that the money supply is constant. What is interesting to know then is that when a central bank print out money at time t, since it keep this money inside the bank and don't tell anyone it print it out, the relative value of money will remain constant such that:

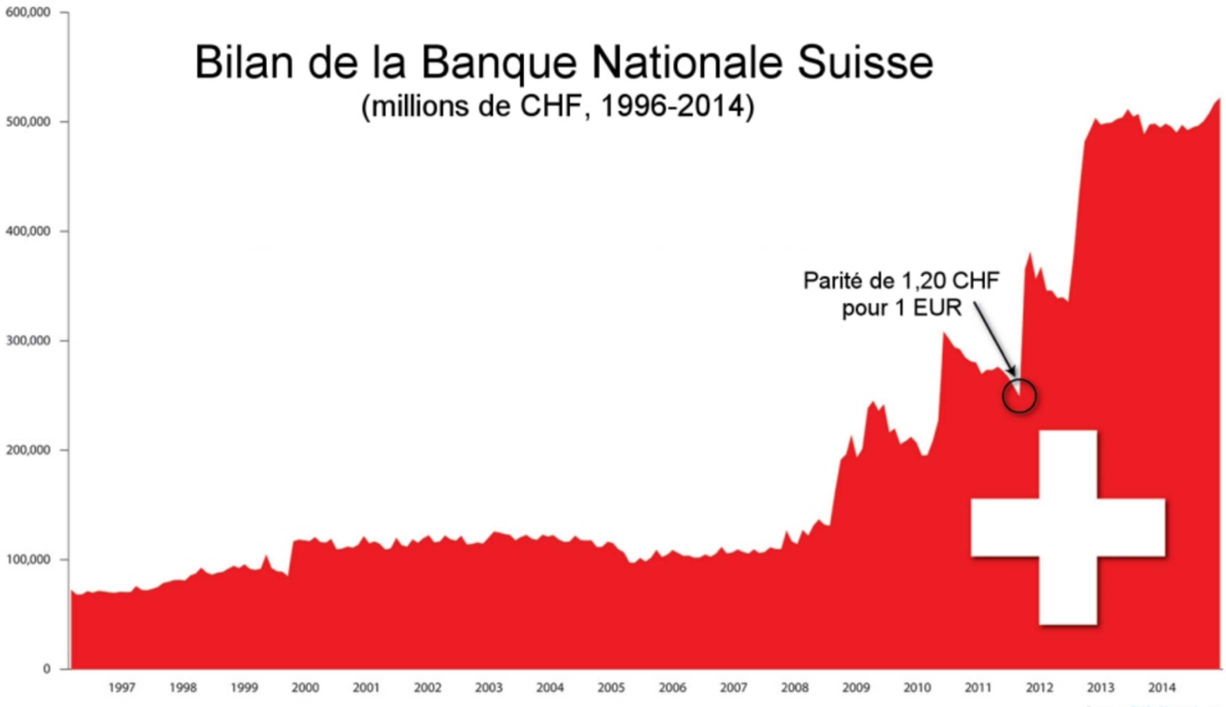
$$p_i(t)=p_i(t-\Delta t)\Leftrightarrow\frac{p_i(t-\Delta t)}{p_i(t)}=1 \tag{15.3.123}$$

But if the central bank put the new quantity of money on the market, then by conservation of the value p_i should be re-evaluated. That means that all the prices, wages, etc. in the country where the bank has printed out the money should be multiplied by a factor:

$$\boxed{\frac{p_i(t-\Delta t)}{p_i(t)}=\frac{Q_u(t)}{Q_u(t-\Delta t)}} \tag{15.3.124}$$

So there is no "law of conservation of money" or "law of monetary base conservation" on the long time term at work but.... rather a "law of relative money price value to the monetary base"!

However it is funny to notice that some Governments, hands in the hands with the Central bank ("monetary policy") don't do such corrections depending on the situations and therefore violates the monetary base conservation principle. For example in Switzerland, the monetary base in 12012 (holocene calendar) had increased by a factor 6, from 100 billion to 600 billions (we speak then of "money dilution"), without saying to the banks, shops and individuals that everything should have therefore been multiplied by a factor 6 (the amount in the bank accounts, the wages, GDP, and so on...) since the value of the Swiss money therefore lost a value of a factor 6 in an international point of view (deflation).



Source: SNB, Bloomberg

Figure 15.80: **Swiss National Banks reserve (source: Bloomberg)**

But in this case the Swiss Central Bank has argued during a conference (using random bullshit language...) that this was:

1. Because the Swiss money was over-evaluated of the point of view of the international market.
2. The wages, and individual bank account are not included in the measurement of the monetary base (this last statement being given without surprise with no mathematical proof...)

It is common in Governments to split the monetary base in three "monetary aggregates" (some split it in four):

M1. Money (banknotes and coins)
M2. Household savings (private saving accounts, deposits <2 years)
M3. Corporates savings (debts <2 years, bonds, shares)

And we have (the M_1 and M_2 as previously mentioned are sometimes ignored and the argument - when the mathematical proof shows the opposite... - is that they can be neglected):

$$M_1 \subset M_2 \subset M_3 \quad (15.3.125)$$

Here are some plots showing a monetary policy for a country (still Switzerland) for M_1, M_2 and M_3:

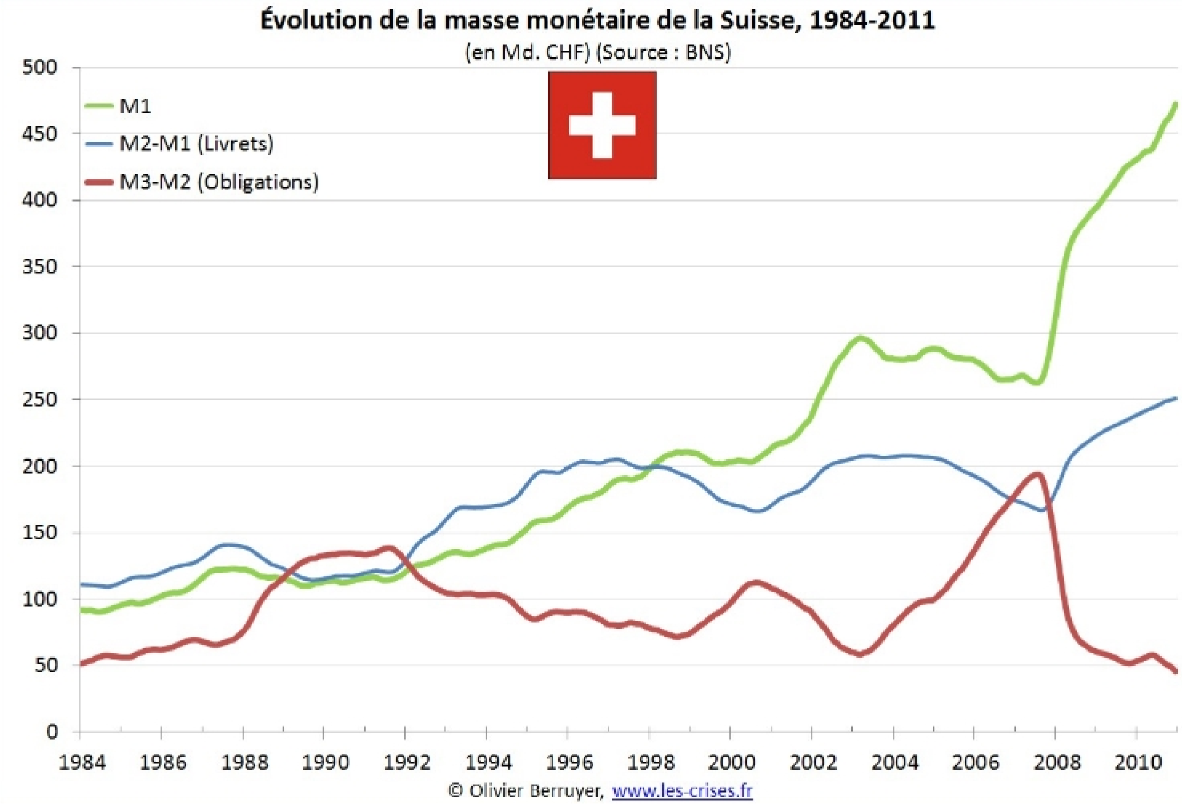


Figure 15.81: **Evolution of monetary base in Switzerland (source: `www.les-crises.fr`, author: Olivier Berruyer)**

and in relative value:

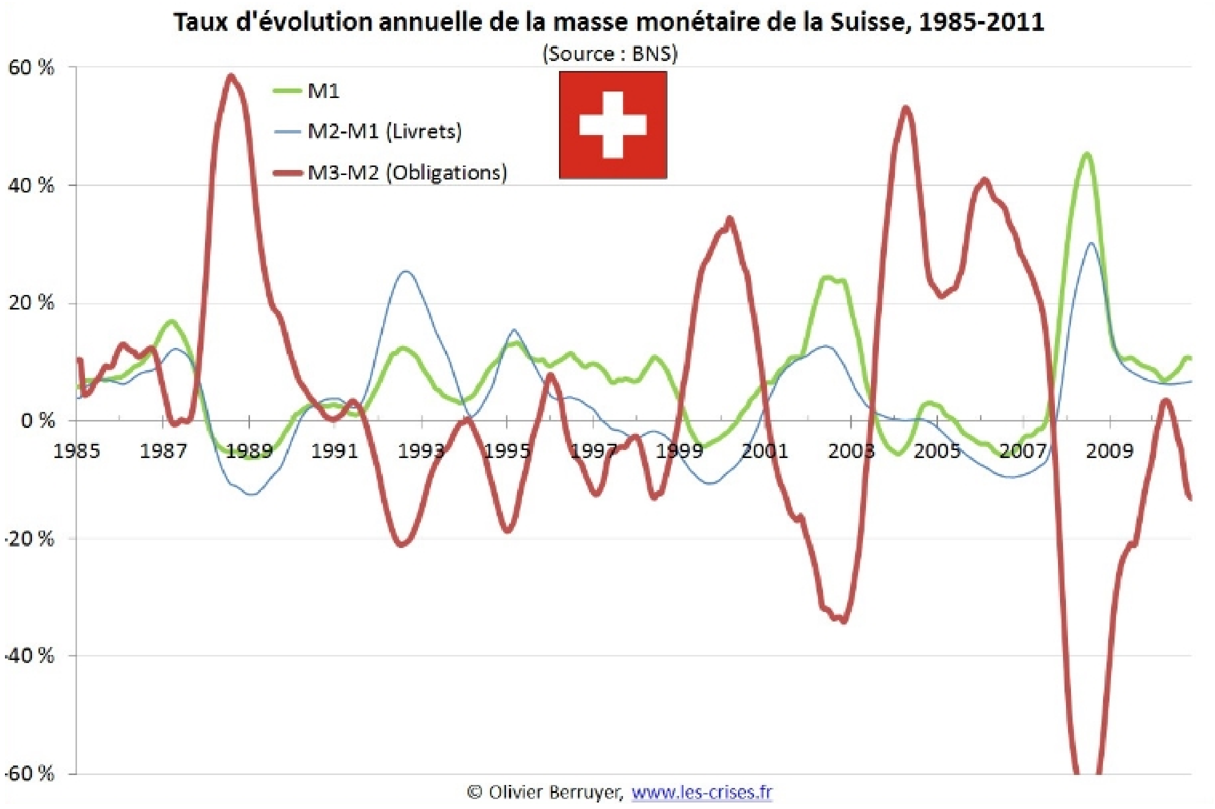

Figure 15.82: **Relative evolution of monetary base in Switzerland (source: `www.les-crises.fr`, author: Olivier Berruyer)**

15.3.2.2 Walras' law

Walras' Law is a principle in general equilibrium theory asserting that budget constraints imply that the values of excess market demands (or, conversely, excess market supplies) must sum to zero in a pure and perfect competition market where economic agents do not increase the amount of money they hold and where the value of money is equal...

Moving from the particular to the general, the money value of what the j-th agent transactor plans to purchase (Demand) can be written symbolically as:

$$p_1 D_{1j} + p_2 D_{2j} + \ldots + p_n D_{nj} = \sum_{i=1}^{n} P_i D_{ij} \tag{15.3.126}$$

where $p_1, \ldots, p_n$ are the prices of the n goods, and $D_{1j}, \ldots, D_{nj}$ are the quantities of those goods that the j-th agent plans to purchase.

Similarly, the money value of what the j'th individual plans to Sell can be written symbolically as:

$$p_1 S_{1j} + p_2 S_{2j} + \ldots + p_n S_{nj} = \sum_{i=1}^{n} P_i S_{ij} \tag{15.3.127}$$

where $p_1, \ldots, p_n$ are the prices of the n goods, and $S_{1j}, \ldots, S_{nj}$ are the quantities of those goods that the j'th agent plans to sell.

Now let us adopt Say's Law that is to say that the money value of all the goods that the j-th individual plans to buy must always be equal to the money value of all the goods that individual plans to sell, we may write:

$$\sum_{i=1}^{n} p_i D_{ij} \equiv \sum_{i=1}^{n} p_i S_{ij} \tag{15.3.128}$$

This condition is obviously written as an identity (remember that an identity is a proposition which is true by definition and is usually written with a $\equiv$ rather than an $=$ sign in it), since we assume that no individual transactor in our model will be so misguided as to suppose that he or she can acquire something for nothing (tacitly, our model assumes that transactors are not thieves, extortioners, embezzlers - or philanthropists!).

Remark

The changes in the currency prices do not affect the actual balance if and only if all these relative prices change in the same proportion (and thus excess demand should no increase or decrease).

Granted that each individual's planned market transactions in goods satisfy condition the previous identity, it follows as a matter of simple arithmetic that the money value of the quantities demanded by all individuals must be equal to the money value of the quantities offered for sale by all individuals. Therefore, summing previous identity over all individuals (as supposed to be independent!) we obtain:

$$\sum_{j=1}^{m} \sum_{i=1}^{n} p_i D_{ij} \equiv \sum_{j=1}^{m} \sum_{i=1}^{n} p_i S_{ij} \tag{15.3.129}$$

when we assume that there are m individual transactors.

Factoring out the price variables from this expression yields:

$$\sum_{i=1}^{n} p_i \left(\sum_{j=1}^{m} D_{ij} \right) \equiv \sum_{i=1}^{n} p_i \left(\sum_{j=1}^{m} S_{ij} \right) \tag{15.3.130}$$

However, the expression in parentheses on the left-hand side is simply the total market demand for the i-th good, since it is the sum of the individual transactors' demands for that good. We will write this total market demand as D_i. Similarly, the expression in parentheses on the right-hand side is simply the total market supply of the i'th good, since it is the sum of the individual transactors' supplies of that good. We will write this total market supply as S_i.

Thus, we arrive at the conclusion:

$$\boxed{\sum_{i=1}^{n} p_i D_i \equiv \sum_{i=1}^{n} p_i S_i} \tag{15.3.131}$$

Which is a proposition known as "Walras' identity". It states that the money value of all planned market purchases are identically equal to the money value of all planned market sales and it is valid whether or not market prices equate demand with supply for each individual type of good.

We can find also sometimes the identity with the following rearrangement:

$$\sum_{i=1}^{n} p_i D_i - \sum_{i=1}^{n} p_i S_i \equiv 0 \tag{15.3.132}$$

But this result is trivial and is not what interest in reality! What interest us is two very important and obvious implications that can be written in a mathematical way (do not forget that it is the main purpose of economists even if the level is a pre-school one). One implication relates to the generality of equilibrium. The other refers to states of dis-equilibrium. We will deal with each in turn using maths (even if it is trivial by the Say's Law).

Theorem 15.6. We will prove that if all but one of the markets in an economy are in equilibrium (+some other assumptions already communicated before!), then that other market also must be in equilibrium.

Proof 15.6.1. Assume that a set of prices has been established which will equate demand with supply in every market except the n-th market. Since all $n-1$ markets are in equilibrium, then if the market is big enough we can always find and indexation of goods such that:

$$D_1 = S_1, D_2 = S_2, \ldots, D_{n-1} = S_{n-1} \tag{15.3.133}$$

Next, multiply through by the set of prices that put these $n-1$ markets in equilibrium. Then:

$$p_1 D_1 = p_1 S_1, p_2 D_2 = p_2 S_2, \ldots, p_{n-1} D_{n-1} = p_{n-1} S_{n-1} \tag{15.3.134}$$

And we apply Say's law we get:

$$\sum_{i=1}^{n-1} p_i D_i \equiv \sum_{i=1}^{n-1} p_i S_i \tag{15.3.135}$$

If this is now subtracted from Walras' Identity we obtain:

$$p_n D_n \equiv p_n S_n \tag{15.3.136}$$

Which implies immediately that the n-th market is also in equilibrium. It also follows in an isotropic single currency market that:

$$D_n \equiv S_n \tag{15.3.137}$$

To recapitulate verbally, we have shown that if all but one of the markets in an economy are in equilibrium (+some other assumptions already communicated before!), then that other market also must be in equilibrium. This result is known as "Walras' law":

$$\boxed{\sum_{i=1}^{n-1} p_i D_i \equiv \sum_{i=1}^{n-1} p_i S_i \Rightarrow p_n D_n = p_n D_n} \tag{15.3.138}$$

■ Q.E.D.

We now look at some implications of Walras' Identity for dis-equilibrium.

Corollary 15.6.1. Assume that one market (the n-th market) is in dis-equilibrium. This may take the form of (positive) excess demand (where $p_nD_n > p_nS_n$) or excess supply, also known as "negative excess demand" (where $p_nD_n < p_nS_n$).

Proof 15.6.2. It is an implication of Walras' Identity that for all markets taken as a whole there can be neither excess supply nor excess demand when we sum over all markets. We can see this by rearranging Walras's Identity as follows (without forgetting assumptions!):

$$\sum_{i=1}^{n}(p_iD_{ij}-p_iS_{ij})\equiv 0 \tag{15.3.139}$$

In order for this condition to be satisfied in the presence of disequilibrium in the n-th market, it must be the case that there is on off-setting dis-equilibrium in at least one other market. Form this result emerge the basic idea of "demand & supply equilibrium".

■ Q.E.D.

To resume this pseudo-proof, Walras' and Say's laws are like the conservation energy in physics in a closed thermodynamic system but where mass are goods and the constant normalizing factor to conversion in energy is the money...

Corollary 15.6.2. Let us see now another pseudo-proof that shows that equilibrium (Say's Law) is not affected by the change in price if we suppose that the demand and supply are proportional (or inversely proportional) to the price. That is to say that the demand/supply is a homogeneous function of degree 1 of the price such that:

Proof 15.6.3.

$$\begin{aligned}D_i(\alpha p_1,\alpha p_2,\ldots,\alpha p_n)=\alpha^1D_i(p_1,p_2,\ldots,p_n)=\alpha D_i(p_1,p_2,\ldots,p_n)\\ S_i(\alpha p_1,\alpha p_2,\ldots,\alpha p_n)=\alpha^1S_i(p_1,p_2,\ldots,p_n)=\alpha S_i(p_1,p_2,\ldots,p_n)\end{aligned} \tag{15.3.140}$$

Study this fact is interesting only to have once again at look on how economists try to formalize idealistic concepts using scientific words and mathematical methods. For this purpose we start from Walras's identity:

$$\sum_{i=1}^{n}p_iD_i\equiv\sum_{i=1}^{n}p_iS_i \tag{15.3.141}$$

That we rewrite to indicate that D_i and P_i depends on prices $p_1,\ldots,p_n$ of their own components:

$$\sum_{i=1}^{n}p_iD_i(p_1,\ldots,p_n)=\sum_{i=1}^{n}p_iS_i(p_1,\ldots,p_n) \tag{15.3.142}$$

Now consider a change α on prices of components:

$$\sum_{i=1}^{n}p_iD_i(\alpha p_1,\ldots,\alpha p_n)=\sum_{i=1}^{n}p_iS_i(\alpha p_1,\ldots,\alpha p_n) \tag{15.3.143}$$

Using the assume property of homogeneity we can write this:

$$\sum_{i=1}^{n} p_i \alpha D_i(p_1,\ldots,p_n) = \sum_{i=1}^{n} p_i \alpha S_i(p_1,\ldots,p_n) \tag{15.3.144}$$

This result for the moment just means that a change in prices of the components of a goods is impacted on the global price of the good (trivial!). Therefore:

$$\alpha \sum_{i=1}^{n} p_i D_i(p_1,\ldots,p_n) = \alpha \sum_{i=1}^{n} p_i S_i(p_1,\ldots,p_n) \tag{15.3.145}$$

And obviously we can eliminate α from the two side of the equality (identity). This finish the proof.

■ Q.E.D.

Therefore the equilibrium is not affected by movements in prices under the assumptions given before. We can therefore understand why in such a simple market wages that are the monetary price of work decrease in implicit value in proportion to the increase of supplied goods (at least in theory...) because everything should be in equilibrium and work being a good like any other... (if something increase in monetary value, something must decrease in monetary value).

Here, relations are based on equations. Walras, however, distinguish two procedures to ensure balance between supply and demand:

1. A theoretical algebraic method. But... we can not easily determine individual needs in advance to know when there will be demand and prepare to build the offer. This system only works if and only if the economic agents are reasonable and agree to wait or that we have a huge database with all information about all products and all economic agents supply and offers.

2. An empirical method that searches the solution by tests/errors operations. There is the presence of a kind of market secretary, "auctioneer". This last announce the prizes for each type of goods that could exist. The economic agents react to this prices: they ask and they offer based on that prices. For the good i, there is a price p_i, we therefore have D_i, S_i. We then compare the supply and demand. In case of equality, the price is an equilibrium price. In case of non-equilibrium, the auctioneer starts the procedure again and so on until there is equilibrium. That is basically the procedure that is used in the stock market and is often named the "invisible hand of the market" !!!

However, the equations show us that we need the price of currency to measure supply and demand and it should be remembered that we have considered money as a given quantity fixed merchandise because the system is in equilibrium between supply and demand. But precisely, agents can not indefinitely divide the total amount of money if the number of goods is increasing. Therefore, for the process of offer and demand to be possible, we must be prepared to inject money in the market (otherwise it could become immobile which is probably not good on the long term...). We must of course also be prepared to withdraw also money and this is where the government intervenes in the economy to regulate the quantity of money in every possible way (through taxes for example).

Thus, according to the Walras model, the quantity of money available in the market is only depending on the number of economic agents. But should we therefore develop a new model for a more general framework of money demand?

In fact, it is not necessary. We know that if there is a general equilibrium for n goods, there is general equilibrium for $n+1$ goods (and recursively for $n-1$ as well); the last market being simply that of the currency. The Walras model explains therefore why for a given level of quantity of currency there is a corresponding monetary value to goods!

15.3.3 Price Index and GDP

Many people and also sometimes junior politicians when speaking about retirement pension amount forget to take into account that the value of money is not the same across time. Indeed (!) 1.- today is not equal to 1.- tomorrow because of inflation (variation of price of goods). The same occur with many project manager that in their calculation of the Net Present Value (see section Quantitative Management page 8050) forget to take this into account for big project whose development range on 10-20 years or sometimes even more (30 years!).

So a useful (but not unique) way to take this into account is the use of price index that is most of times a normalized average (typically a weighted average) of price relatives for a given class of goods or services in a given region, during a given interval of time.

Also when as consultant and trainer for business analysts of Fortune 500 companies that make market analysis (of consumption, of counterfeits or others) or appoint auditing companies like KPMG or Ernst & Young in the purpose to compare year by year indicators I see always the common undergraduate error that they don't take into account the National Price Index (NPI) or Gross Domestic Product (GDP) to make things really comparable (among other awful errors)...

Definition (#15.3.659): A "price index" is a statistic designed to help to compare how the prices relatives, taken as a whole, differ between time periods or geographical locations. The index can be said to measure the economy's general price level or a cost of living. More narrow price indices help producers with business plans and pricing and are always useful in helping to guide investment.

A naive approach is to consider a $\mathcal{C}$ of goods and services, the total market value of transactions in $\mathcal{C}$ in some period T would be:

$$\sum_{c\in\mathcal{C}} p_{c,T}q_{c,T} \qquad (15.3.146)$$

where $p_{c,T}$ represents the prevailing price of c in period T and $q_{c,T}$ represents the quantity of c sold in period T.

If, across two periods T_0 and T_n, the same quantities of each good or service were sold, but under different prices, then:

$$q_{c,T_n} = q_c = q_{c,T_0} \qquad \forall c \qquad (15.3.147)$$

and:

$$P = \frac{\sum p_{c,T_n} q_c}{\sum p_{c,T_0} q_c} \qquad (15.3.148)$$

would be a reasonable measure of the price of the set in one period relative to that in the other, and would provide an index measuring relative prices overall, weighted by quantities sold.

Of course, for any practical purpose, quantities purchased are rarely if ever identical across any two periods. As such, this is not a very practical index formula.

One might be tempted to modify the formula slightly to:

$$P = \frac{\sum p_{c,T_n} q_{c,T_n}}{\sum p_{c,T_0} q_{c,T_0}} \qquad (15.3.149)$$

This new index, however, doesn't do anything to distinguish growth or reduction in quantities sold from price changes. To see that this is so, consider what happens if all the prices double between T_0 and T_n while quantities stay the same: P will double. Now consider what happens if all the quantities double between T_0 and T_n while all the prices stay the same: P will double. In either case the change in P is identical. Various indices have therefore been constructed in an attempt to compensate for this difficulty.

Of course, for any practical purpose, quantities purchased are rarely if ever identical across any two periods. As such, this is not a very practical index formula.

15.3.3.1 Paasche and Laspeyres price indices

The two most basic formulae used to calculate price indices are the "Paasche index" (after the economist Hermann Paasche) and the "Laspeyres index" (after the economist Etienne Laspeyres).

The Paasche index is computed as:

$$\boxed{P_\text{P} = \frac{\sum p_{c,T_n} q_{c,T_n}}{\sum p_{c,T_0} q_{c,T_n}}} \qquad (15.3.150)$$

while the Laspeyres index is computed as:

$$\boxed{P_\text{L} = \frac{\sum p_{c,T_n} q_{c,T_0}}{\sum p_{c,T_0} q_{c,T_0}}} \qquad (15.3.151)$$

When applied to bundles of individual consumers, a Laspeyres index equal to 1 would state that an agent in the current period can afford to buy the same bundle as he consumed in the previous period, given that income has not changed; a Paasche index of 1 would state that an agent could have consumed the same bundle in the base period as he is consuming in the current period under the same assumption!!!

The Laspeyres index tends to overstate inflation (in a cost of living framework), while the Paasche index tends to understate it, because the indices do not account for the fact that consumers typically react to price changes by changing the quantities that they buy.

As can be seen from the definitions above, if one already has price and quantity data (or, alternatively, price and expenditure data) for the base period, then calculating the Laspeyres index for a new period requires only new price data. In contrast, calculating many other indices (e.g., the Paasche index) for a new period requires both new price data and new quantity data (or, alternatively, both new price data and new expenditure data) for each new period. Collecting only new price data is often easier than collecting both new price data and new quantity data, so calculating the Laspeyres index for a new period tends to require less time and effort than calculating these other indices for a new period.

In practice, price indexes regularly compiled and released by national statistical agencies are of the Laspeyres type, due to the above-mentioned difficulties in obtaining current-period quantity or expenditure data.

15.3.3.2 Fisher index and Marshall–Edgeworth index

A third index, the "Marshall–Edgeworth index" (named for economists Alfred Marshall and Francis Ysidro Edgeworth), tries to overcome these problems of under- and overstatement by using the arithmetic means of the quantities:

$$\boxed{P_{\text{ME}}=\frac{\sum\left[p_{c,T_n}\cdot\dfrac{1}{2}\cdot(q_{c,T_0}+q_{c,T_n})\right]}{\sum\left[p_{c,T_0}\cdot\dfrac{1}{2}\cdot(q_{c,T_0}+q_{c,T_n})\right]}=\frac{\sum[p_{c,T_n}\cdot(q_{c,T_0}+q_{c,T_n})]}{\sum[p_{c,T_0}\cdot(q_{c,T_0}+q_{c,T_n})]}} \tag{15.3.152}$$

A fourth, the "Fisher index" (after the American economist Irving Fisher and not the statistician!!!), is calculated as the geometric mean of P_{P} and P_{L}:

$$\boxed{P_{\text{F}}=\sqrt{P_{\text{P}}P_{\text{L}}}} \tag{15.3.153}$$

However, there is no guarantee with either the Marshall–Edgeworth index or the Fisher index that the overstatement and understatement will exactly cancel the other.

While these indices were introduced to provide overall measurement of relative prices, there is ultimately no way - as far as we know - of measuring the imperfections of any of these indices (Paasche, Laspeyres, Fisher, or Marshall–Edgeworth) against reality.

The Fisher index is used by the Canada statistics since 12001 (holocene calendar) instead of the Laspeyres formula to calculate the estimate of real GDP (Gross Domestic Product) in terms expenditure. The Switzerland OFS use the Laspeyres index (but they don't say since how many years...).

15.3.3.3 Gross domestic product (GDP)

Definition (#15.3.660): The "gross domestic product" (GDP) is a monetary measure of the market value of all final goods and services produced in a period (quarterly or yearly). Nominal GDP estimates are commonly used to determine the economic performance of a whole country or region, and to make international comparisons. Nominal GDP, however, does not reflect differences in the cost of living and the inflation rates of the countries; therefore using a "gross domestic product (at purchasing power parity) per capita" (GDP PPP). Such calculations are prepared by various organizations, including the International Monetary Fund and the World Bank. As estimates and assumptions have to be made, the results produced by different organizations for the same country are not hard facts and tend to differ, sometimes substantially, so they should be used with caution (some companies use the McDonald burger index[15] as element of comparison!).

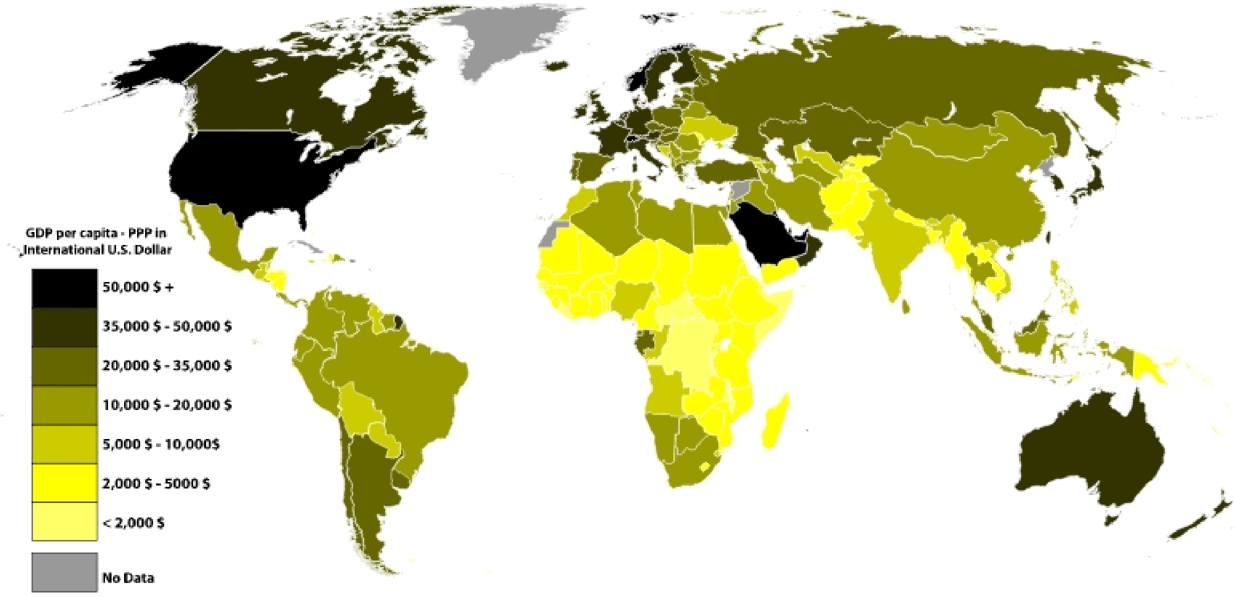

Figure 15.83: **Countries by GDP (PPP) Per Capita in 12015 (source: Wikipedia)**

The basic formula for calculating GDP is:

$$\boxed{\text{GDP} = C + I + E + G} \tag{15.3.154}$$

This formula is almost self-evident (if you take time to think about it)!

GDP is a measure of all the goods and services produced domestically. Therefore, to calculate the GDP, one only needs to add together the various components of the economy that are a measure of all the goods and services produced.

Many of the goods and services produced are purchased by consumers. So, what consumers spend on them (C) is a measure of that component.

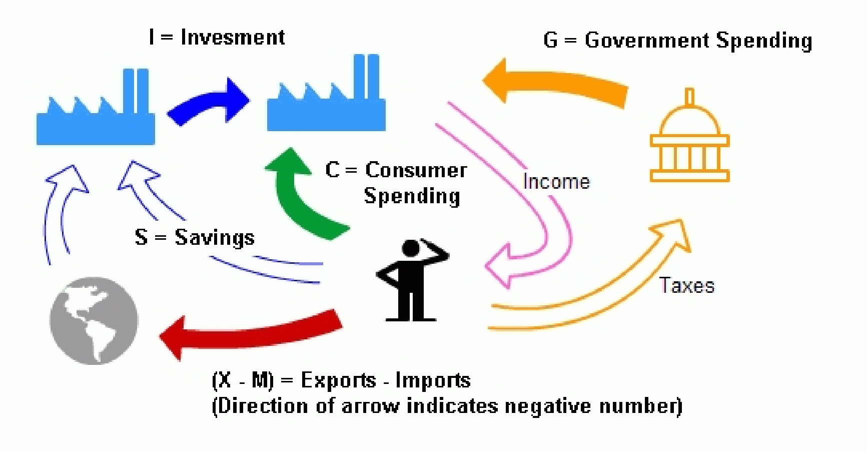
The next component is the somewhat mysterious quantity "I," or investment made by industry. However, this quantity is mysterious only because investment does not have its ordinary meaning. When calculating the GDP, investment does NOT mean what we normally think of in the case of individuals. It does not mean buying stocks and bonds or putting money in a savings account (S in the diagram). When calculating the GDP, investment means the purchases made by industry in new productive facilities, or, the process of "buying new capital and putting it to use". This includes, for example, buying a new truck, building a new factory, or purchasing new software. This is indicated in the diagram by an arrow pointing from one factory (enterprise) to another. In essence, it shows the factory "reproducing itself" by buying new goods and services that will produce still more new goods and services.

---

[15] published by The Economist as an informal way of measuring the purchasing power parity

The next component is E, or the difference between the value of all exports and the value of all imports. If Exports exceeds imports, it adds to the GDP. If not, it subtracts from the GDP. Thus, even if a nation's people work very hard to produce products for exports, but still import more than they export, the nation's GDP will be negatively impacted. This is one of the reasons trade deficits are frequently a political target. Because the balance of trade can be either positive or negative, we can rewrite the equation, showing the components of E, using X for Exports and M for Imports:

$$\boxed{\text{GDP} = C + I + (X - M) + G} \tag{15.3.155}$$



The practitioner mus obviously never that all these fours variables are associates with an estimation error that must be taken into account in any micro or macroeconomics model (for example Switzerland say that the error is only about $\pm 0.5\%$... but this statement should be check by a private independent company as some areas in the country say they have an error of $\pm 2.5\%$).

15.3.4 Supply and Demand Theory

The theory of supply and demand as presented below requires a major revision because highly incomplete. Therefore the ideas presented below are to this day to be taken lightly and only as a simple introduction to the underlying concepts of prices adjustment of goods.

In our human society where there is a exchange (reference) money and goods, one major problems remains that is the of determining the monetary value of a good (material or immaterial). To determine this, we need at least to know the evolution of supply and demand. This is on what we will focus now by starting with simplistic models and complicating them increasingly!

Remark

In our point of view and based on our consulting experience the determination of a product price belongs more to the field of corporate financial engineering than to Economy or Econometrics. Indeed, determining the product of an insurance or Call option doesn't use at all the same techniques level as determining the price of a manufacturing price.

15.3.4.1 Expected utility theory

Before going trough the lecture of a highly complex model on supply and demand, it is necessary to identify what motivates economic agents in their consumption choices and to model their behaviour based on the fundamental principle of rationality.

The economic agent will be perceived as a unique individual with a choice that he seeks to maximize the satisfaction. His tastes are subjective even though they depend on certain objective characteristics such as age, the level of culture, his fortune, etc. The level of satisfaction will be defined from a utility function that we will see the basic principles and the maximization under constraints.

Several principles based utility of goods and lead to the concept of "marginal utility", a central concept in the theory of the preference of the economic agent. According to Aristotle (being at the origin of the concept of value-utility), the utility of goods derives from the satisfaction of needs. Étienne Bonnot de Condillac states: "the value of things is based on their usage". This idea of value based on utility, fundamental for marginalist economists, opposes therefore to the current theoretical labour-value based on the amount of work, direct and indirect, incorporated in the manufacture of the good (Adam Smith, Karl Marx).

However we should, preferably, consider an important assumption in this model: There is a certain satiation of needs, but it is almost never total.

Thus, for a given good marginal utility of the last unit consumed is lower than that of previous units but not null and always positive. This is the "principle of diminishing marginal utility" on the additional unit consumed. Or in other words this law states that as additional units of a good are consumed, while holding then consumption of all other goods constant, the resulting increments in utility will diminish.

Thus, under the multiple consumption $n \in \mathbb{N}$ of a single good of given nominal value, the total utility U_T (sum of marginal utilities $U_M(n)$) is a curve of the type:

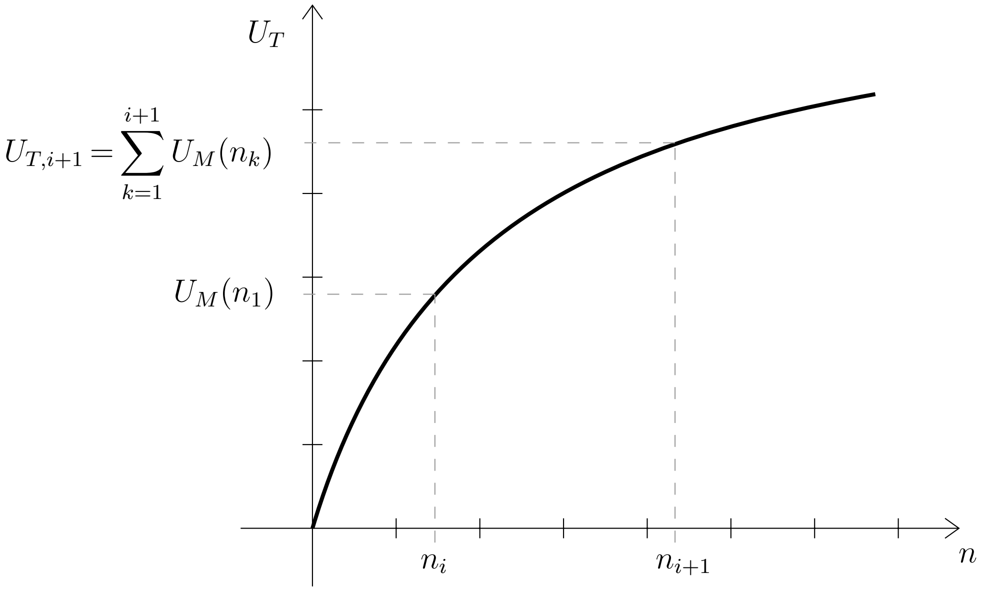


Figure 15.84: **Asymptotic utility**

and therefore the marginal utility is of the type:

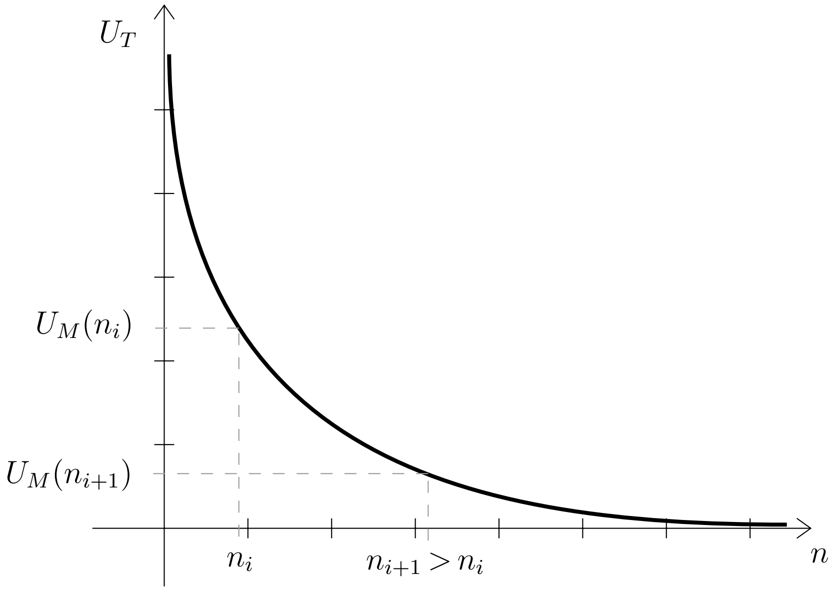

Figure 15.85: **Corresponding decreasing marginal utility**

So, faced with a price for each good, the economic agent compares this price with the marginal utilities that he could successively use from their consumption. He buys them as long as their value exceeds the price (surplus related to their purchase) and ceases to buy as soon as the marginal utility falls below the price of the good. His interest is therefore to buy other products for which there is a positive surplus (marginal utility that is higher to their prices).

This example, relative to one good, should now be extended to a basket of goods to determine the overall utility of this basket.

Consider for this an economic agent i in an economy that has $I \in \mathbb{N}$ goods. It can therefore buy at most I goods. A basket of consumption can therefore corresponds to a vector $\vec{n}_i = (n_1, n_2, \ldots, n_k)$ of goods: where the n_j may represent null quantities purchased by the consumer. The utility $U(\vec{n}_i)$ of this basket will be assumed as additive such that:

$$U(\vec{n}_i) = \sum_j U_{T,j}(n_j) \tag{15.3.156}$$

that is to say the sum of total of utilities relative to the quantities consumed of each good. Let us now consider a basket with two goods, we can without much error hypothesize that these goods can be divided into small fractions x_i as small as we want from other goods/components. So roughly, we no longer work $\mathbb{N}$ but in $\mathbb{N}_+$. Therefore if we consider a basket $\mathbb{R}^2$ of an economic agent, we will assume that it is such that its exact total differential (see section Differential and Integral Calculus page 1466) is zero such that:

$$\mathrm{d}U = \frac{\partial U}{\partial x_1}\mathrm{d}x_1 + \frac{\partial U}{\partial x_2}\mathrm{d}x_2 \tag{15.3.157}$$

The ratio:

$$\text{MRS} = -\frac{\mathrm{d}x_1}{\mathrm{d}x_2} = \frac{\dfrac{\partial U}{\partial x_2}}{\dfrac{\partial U}{\partial x_1}} \tag{15.3.158}$$

is defined as the "marginal rate of substitution" (MRS) between the two elementary goods $1, 2$. That is to say the additional quantity of good 1 we need to provide to the economic agents to accurately compensate for a decrease of one unit of good j under the hypothesis that they are always compensated (fact of the null total exact differential).

The behaviour attributed to the economic agent is to classify all the baskets of possible goods (vectors) using a scale of utility without it necessarily corresponds to a quantified assessment. This classification capability corresponds to the concept of "ordinal utility" (which can - by its name - therefore be ordered...) and to the use of a preference relation, denoted by $\succeq$ (preferred or indifferent to) that satisfies the following trivial properties:

P1. Reflexivity: For every $\vec{n}_1$, For every $\vec{n}_1 \succeq \vec{n}_1$.

P2. Completeness: For every $\vec{n}_1$ and $\vec{n}_1$ either $\vec{n}_1 \succeq \vec{n}_2$ or $\vec{n}_1 \preceq \vec{n}_2$.

P3. Transitivity: $\vec{n}_1 \succeq \vec{n}_2 \wedge \vec{n}_2 \succeq \vec{n}_3 \Leftrightarrow \vec{n}_1 \succeq \vec{n}_3$ (consistency of successive rankings).

P4. Continuity: Let $\vec{n}_1$, $\vec{n}_2$ and $\vec{n}_3$ be such that $\vec{n}_1 \succeq \vec{n}_2 \succeq \vec{n}_3$ then there exists a proportion/fraction $p \in [0,1]$ (that can be assimilated to a probability) such that $\vec{n}_2$ is equally good as $\vec{n}_2 \sim p\vec{n}_1 + (1-p)\vec{n}_3$.

This order relation in the mathematical sense, is used in most of today's presentations of preference theory. This order is complete if it permits to compare two baskets of goods in the set I of goods.

Such a complete order relations permits to define an equivalence relation on the set of goods and a strict order, and to represent preferences from utility functions:

$$\begin{gathered}\vec{n}_1 \succeq \vec{n}_2 \Leftrightarrow U(\vec{n}_1) \geq U(\vec{n}_2)\\ \vec{n}_1 \succ \vec{n}_2 \Leftrightarrow U(\vec{n}_1) > U(\vec{n}_2)\\ \vec{n}_1 \sim \vec{n}_2 \Leftrightarrow U(\vec{n}_1) = U(\vec{n}_2)\\ \vec{n}_1 \sim \vec{n}_2 \sim \vec{n}_3 \Leftrightarrow \forall p \in [0,1]: \quad U(\vec{n}_2) = pU(\vec{n}_1) + (1-p)U(\vec{n}_3)\end{gathered} \tag{15.3.159}$$

If the function U is defined by a number, it does not reflect anymore an assessment of the utility, but since only the possibility to compare the order of the utilities, relatives to baskets with any goods.

The ability to order different baskets of goods of $\mathbb{R}^I$ permits to define surfaces with isolines (see section Functional Analysis page 2857) where the utility is constant, named "indifference curves" or "iso-utility curves".

The following figures give a good representation of these curves in $\mathbb{R}^2$ (basket of two type of goods) and their main properties that will help us latter to better understand the indifference curved used to build the Capital Asset Pricing Model (CAPM) for the study of modern portfolio theory (see further below page 7740).

Thus, two baskets such that $\vec{A} \sim \vec{B}$ in $\mathbb{R}^2$ is graphically traduced in a family of curves, where each is constantly decreasing such that:

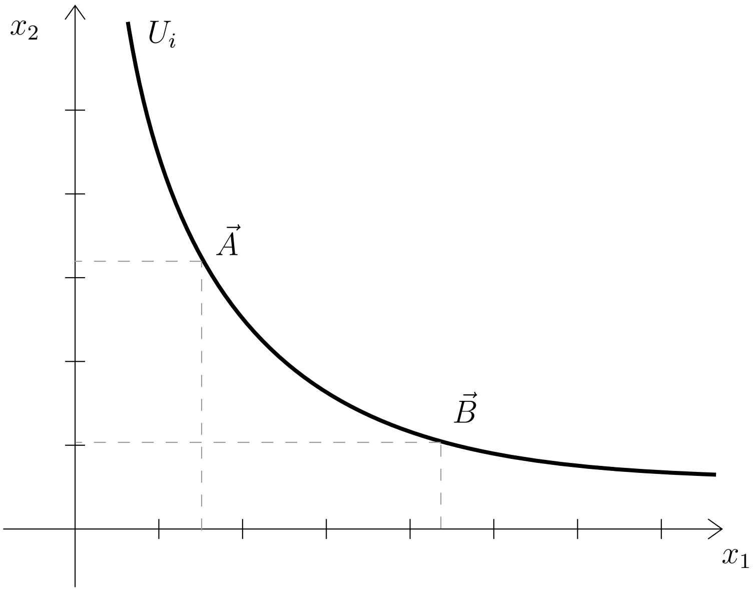

Figure 15.86: **Example of iso-utility (indifference) curve**

Why do not we have straight lines plots or other things? The reason is relatively simple and the following chart explains that trivially. Consider the iso-utility (indifference) curve below that is a projection in the plane of the $U_{\vec{B}}(x_1,x_2): \mathbb{R}^2 \mapsto \mathbb{R}^3$:

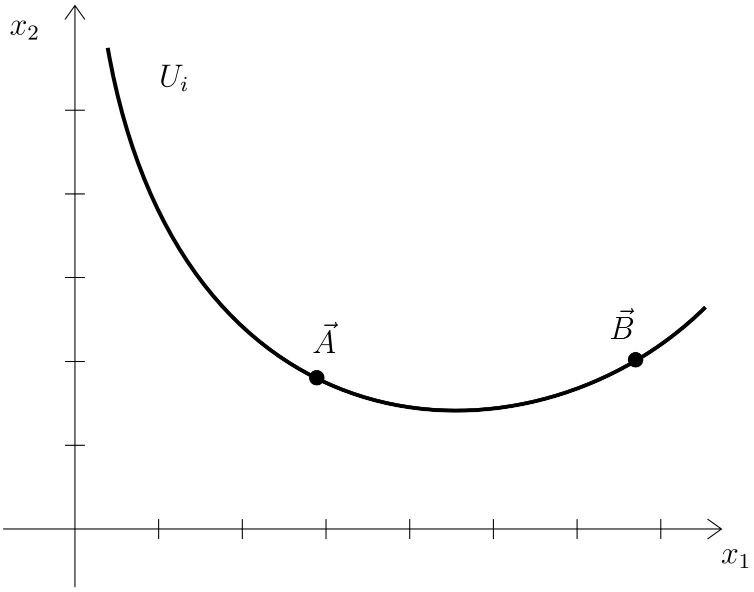

Figure 15.87: **Counter example of iso-utility (indifference) curve**

Above $\vec{B}$ dominates $\vec{A}$ but its basket of goods has more x_1 AND x_2 than $\vec{A}$ and then $U_{\vec{B}}(x_1,x_2)>U_{\vec{A}}(x_1,x_2)$. These two points can therefore not be on the same indifference curve (iso-line) and impose an indifference curve to be decreasing i.e. to be convex!

The assumption that $\vec{A}\sim\vec{B}$ also implies directly that the total exact differential is zero.

The iso-utility curves (indifference curves) can not cut themselves (may not intersect). Even if it is obvious if you did forget that $U_{\vec{B}}(x_1,x_2):\mathbb{R}^2\mapsto\mathbb{R}^3$, consider the two iso-utility curves (indifference curves) below:

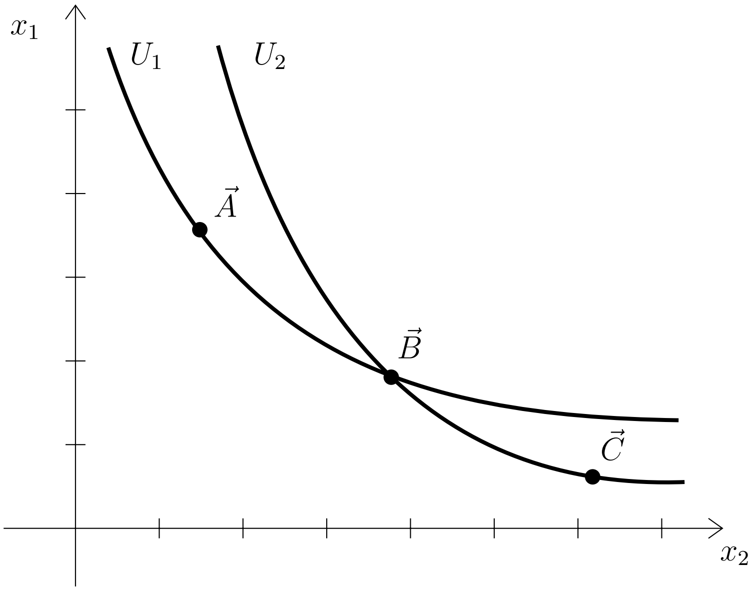

Figure 15.88: **Iso-utility intersection impossibility**

The baskets $\vec{A}$ and $\vec{B}$ are located on the same iso-utility curve U_1 while $\vec{B}$ and $\vec{C}$ are themselves located on the same curve U_2. Thus, we can write $\vec{A}\sim\vec{B}$ and that $\vec{B}\sim\vec{C}$. According the property of transitivity of the utilities, we should then have $\vec{A} \sim \vec{C}$. These two baskets are not equivalent since $\vec{A}$ and $\vec{C}$ are not located on the same curve. Therefore two indifference curves can not intersect.

We are therefore aware that there are special relations between the goods that will change our consumption attitudes. This is especially true for complementary and substitutions goods:

Definitions (#15.3.661):

D1. Two goods are said to be "complementary goods" if the possession of one and the other provides superior satisfaction to the total satisfaction of both goods if taken isolated ("super-additive"). Thus, there is complementarity between skis and a package on the ski lifts, between a car and gasoline. This can be interpreted by the following indifference curve:

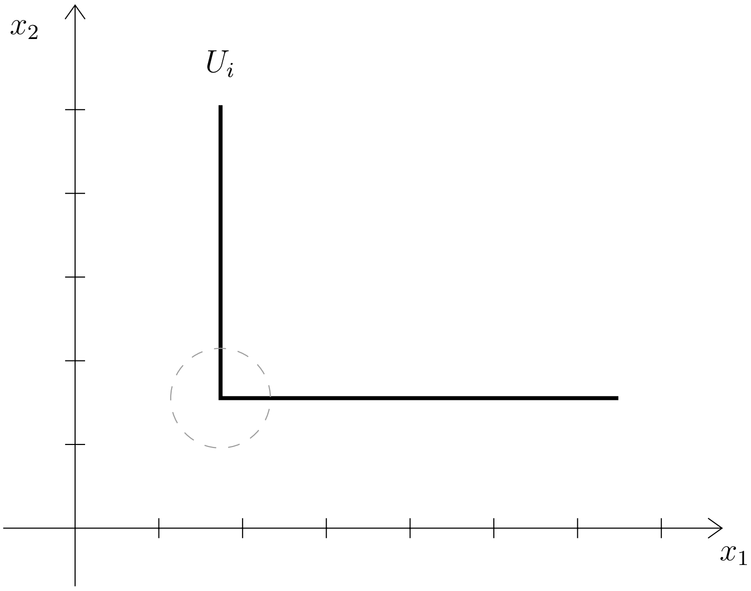

Figure 15.89: **Utility super-additivity visual representation**

Indeed, for the couple $\{\text{car}, \text{petrol}\}$ each curve has respectively a minimum below which we can not go down so that the couple maintains its consumer interest as such (it is not worthwhile to buy a car if the utility of gasoline tends to zero).

D2. Two goods are said to be "substitutable goods" if we can easily replace one by the other, for example in the case of or prices increasing or decreasing. Tea and coffee are substitutable goods because without one, we often defer to the other one. This is even more true for two brands of the same drink (Pepsi® and Coca-Cola®). The mad cow crisis is also a good indicator of the substitutability of meat products, with a postponing consumption on poultry and lamb. This can be interpreted by the following indifference curve:

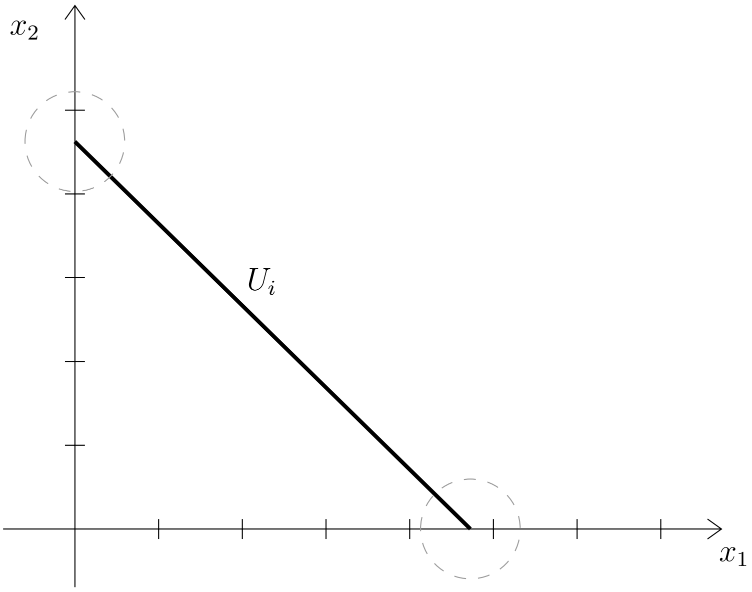

Figure 15.90: **Visual representation of substitutable goods utility**

Indeed, the intersection with the respective axes indicates precisely the total possible substitution of one good by the other in the basket.

✍**Example:**

Consider we want to calculate the MRS along the indifference curve of $U=x_1x_2=100$ (this is a hyperbolic function). We have proved that MRS was given by under a given assumption that:

$$\text{MRS}=-\frac{\mathrm{d}x_1}{\mathrm{d}x_2}=\frac{\dfrac{\partial U}{\partial x_2}}{\dfrac{\partial U}{\partial x_1}}=\frac{\dfrac{\partial x_1x_2}{\partial x_2}}{\dfrac{\partial x_1x_2}{\partial x_1}}=\frac{x_2}{x_1} \tag{15.3.160}$$

Therefore, for the three points A,B,C of respective coordinates:

$$A(5,20);B(10,10);C(20,5) \tag{15.3.161}$$

we found the respective MRS values:

$$\text{MRS}_A=4,\text{MRS}_B=1,\text{MRS}_C=0.25 \tag{15.3.162}$$

These values express the equivalences between the goods 2 and 1 for marginal changes in the quantities of these goods. Thus at point A, to keep the utility level of 100, the consumer is willing to abandon the good 2 for 1 to increase its consumption of good 1 by a factor of 4. At point B the equivalence between the two goods is in a ratio of 1 to 1, etc.

Remark

The concept of indifference curves was developed by Vilfredo Pareto and others in the first part of the 120th century (holocene calendar). The use of this concept has allowed the economic analysis to use this concept of preferences in determining the choice rather than the concept of utility that has the problem of not being able to be measured objectively.

15.3.5 Net gain/loss opposite feedback model

Let us now consider, regardless of the preference theory, a monopoly model with perfect information for a primary need. We denote by $D(t)$ the demand in the market and $O(t)$ the offer. We assume then a infinitely small change in demand depending on the time proportional to the demand (in absence of offer) that is to say the demand follows an exponential law:

$$\frac{\mathrm{d}D}{\mathrm{d}t}=rD(t)\Rightarrow D(t)=c_1^{te}e^{rt} \tag{15.3.163}$$

and for the offer, in the absence of demand (!), is a decreasing exponential law:

$$\frac{\mathrm{d}O}{\mathrm{d}t}=-mO(t)\Rightarrow O(t)=c_2^{te}e^{-mt} \tag{15.3.164}$$

Customers (demand) and suppliers (offers) are interacting. To quantify the contribution between groups, we consider the offer on the assumption that its value or intensity is a function of probability of meeting between the consumer and the supplier and will be proportional to the multiplication of the percentage of supply and demand $O\cdot D$.

The fact of discovering a new product does not have the same effects on both groups (consumers/suppliers). First, of course, each offer acquired by a supplier is a net gain for the second (supplier) and will be assumed as a net loss for the first (consumer). Therefore, if the effect of interactions is assumed as being proportional to $O\cdot D$ the signs of influence of interaction differ by:

$$\begin{aligned}\frac{\mathrm{d}D}{\mathrm{d}t}&=rD-cDO\\ \frac{\mathrm{d}O}{\mathrm{d}t}&=-mO+bDO\end{aligned} \tag{15.3.165}$$

As we can see this model is strongly inspired by the famous "Lotka-Voltera model" (see section Population Dynamics page 7350).

Therefore this model could be used to explain economics crash or the fact that some trends product have a cyclic demand (for sure with periods that need to be determined) or that we can see in supply chain management small periodic fluctuations.

Before going further, let us look to the values for which the derivatives vanish (which will give us in fact the equilibrium point between supply and demand because the two relations can therefore be written as equal):

$$\begin{aligned}r'D'-cD'O'&=0\\ -mO'+bD'O'&=0\end{aligned} \tag{15.3.166}$$

Thus:

$$\begin{aligned}(r'-cO')D'&=0\\ (bD'-m)O'&=0\end{aligned} \tag{15.3.167}$$

A trivial solution is the "solution of inexistence" (also sometimes named "critical solution") given by:

$$D_e' = O_e' = 0 \tag{15.3.168}$$

Otherwise, we also have as a possible solution:

$$\begin{aligned} r = CO' \rightarrow O' = \frac{r}{c} \\ bD' = m \rightarrow D' = \frac{m}{b} \end{aligned} \tag{15.3.169}$$

Now we normalize these equations by writing (so they are dimensionless):

$$\begin{aligned} x = \frac{D}{D'} = \frac{b}{m}\frac{1}{D'} := \frac{b}{m}D \rightarrow D = \frac{m}{b}x \\ y = \frac{O}{O'} = \frac{c}{r}\frac{1}{O'} := \frac{c}{r}O \rightarrow O = \frac{r}{c}y \end{aligned} \tag{15.3.170}$$

with this normalization, the model can be rewritten:

$$\begin{aligned} \frac{m}{b}\frac{\mathrm{d}x}{\mathrm{d}t} = \frac{mr}{b}x - \frac{cmr}{xy} \\ \frac{r}{c}\frac{\mathrm{d}y}{\mathrm{d}t} = \frac{bmr}{bc}xy - \frac{mr}{c}y \end{aligned} \tag{15.3.171}$$

By rearranging the coefficients, the system can finally be written (excluding the solution of inexistence):

$$\begin{aligned} \frac{\mathrm{d}x}{\mathrm{d}t} = rx(1-y) \\ \frac{\mathrm{d}y}{\mathrm{d}t} = my(x-1) \end{aligned} \tag{15.3.172}$$

for which derivatives vanish at the point $(1,1)$, which can be assimilated to the "Say equilibrium".

The discreet plot of this system of equations (in which we recognize a logistic term as seen in the section of Populations Dynamics) gives us with $m = r = b = c = 1$ and initial conditions $(x_0, y_0) = (4,1)$:

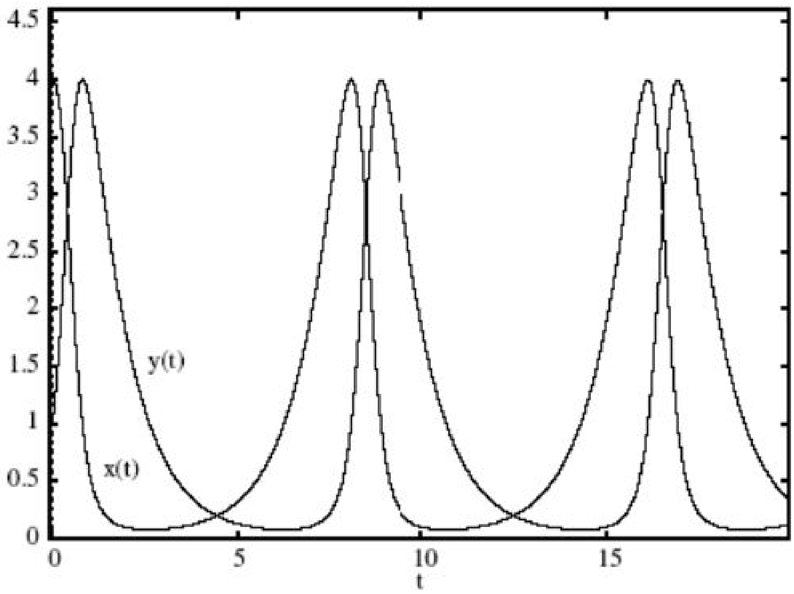

Figure 15.91: **Cycle of offer and demand**

We see as the real market seems show to us, the cycles of supply/demand (some outdated products become fashion again) for which, using statistics, we must determine the initial conditions in order to know the period of time. We note also on that figure that offers is always a little behind demand in this model (which is not always true because we know that many times that offer created demands). Unfortunately this model does not have a damping or multiplier factor suggesting a potential for improvement.

The previous figure represent the variables x and y as a function of time. However, what can be interesting for a scientist (or an economist) is the representation of y in terms of x and vice versa. Thus, we obtain for the same initial conditions m, r, b, c and for the various initial values of (x_0, y_0) (the Offer is in ordinate and the Demand on the abscissa):

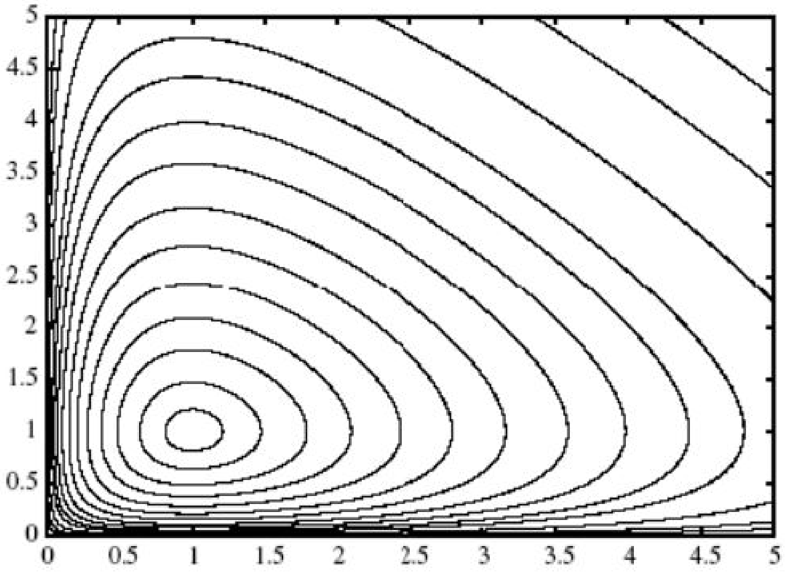

Figure 15.92: **Representation in phase space offer/demand cycle**

The above figure is very interesting to interpret when you follow a path in the counter-clockwise direction.

Thus we see (in the phase space representation) that for fixed initial conditions, the system is periodic and has trivially an equilibrium point at:

$$(x,y)=(1,1) \tag{15.3.173}$$

that correspond to the points where:

$$\frac{\mathrm{d}x}{\mathrm{d}t}=\frac{\mathrm{d}y}{\mathrm{d}t}=0 \tag{15.3.174}$$

Finally, we have two pairs of equilibrium points (that is almost trivial, looking at the system of equations):

$$(x_1^e,y_1^e)=(0,0) \qquad (x_2^e,y_2^e)=(1,1) \tag{15.3.175}$$

The question that will naturally arise is the "real" direction of rotation (representation) of the phase plane. Thus, representing the directions using a vector field, we get the representation which is effectively counter-clockwise:

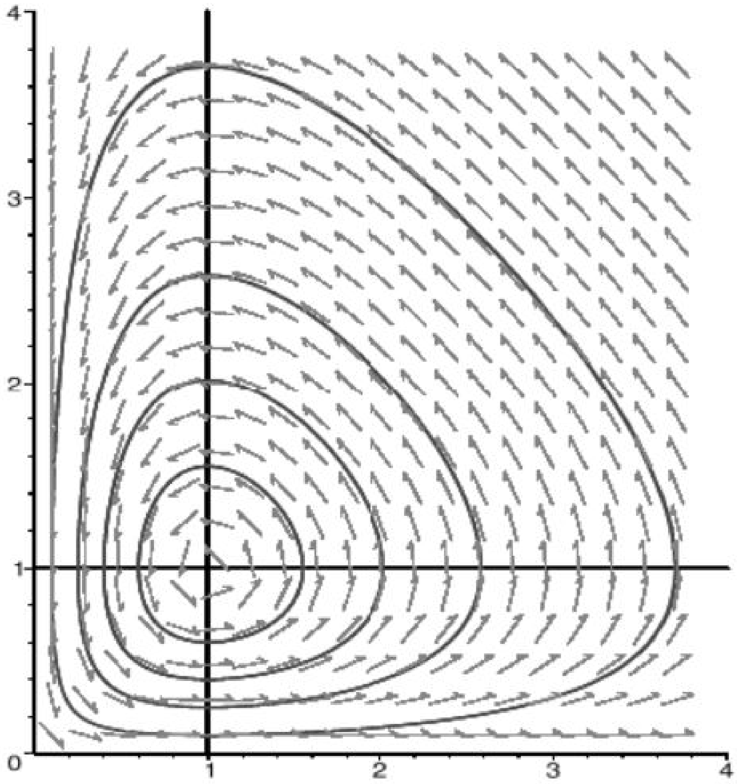

Figure 15.93: Rotation direction offer/demand phase space

To know in which direction we are going in the phase space at a given time, it suffices to know the derivative $\mathrm{d}y/\mathrm{d}x$ (or vice versa $\mathrm{d}x/\mathrm{d}y$). Therefore we have:

$$\frac{\mathrm{d}y}{\mathrm{d}x}=\frac{\mathrm{d}y}{\mathrm{d}t}\frac{\mathrm{d}t}{\mathrm{d}x}=\frac{\mathrm{d}y}{\mathrm{d}t}\left(\frac{\mathrm{d}x}{\mathrm{d}t}\right)^{-1}=\frac{my(x-1)}{rx(1-y)} \tag{15.3.176}$$

That said, we see well on the phase diagram with vector field as vectors that it comes a time in the cycle of this model where the offer is very high for low demand. So the mathematical model (theoretical) clearly explains what can be a priori counter-intuitive to many humans (offer creates the demands).

However, we can (must) ask ourselves the question of what happens after a small perturbation around the equilibrium point (which is of utmost importance in economy).

So we have the following Lotka-Volterra system in equilibrium:

$$\begin{aligned}\frac{\mathrm{d}x}{\mathrm{d}t}&=rx(1-y)\\ \frac{\mathrm{d}y}{\mathrm{d}t}&=my(x-1)\end{aligned} \tag{15.3.177}$$

By putting an infinitely small perturbation, it is will be written:

$$\begin{aligned}\frac{\mathrm{d}x}{\mathrm{d}t}&=r(x+x^*)(1-(y+y^*))\\ \frac{\mathrm{d}y}{\mathrm{d}t}&=m(y+y^*)((x+x^*)-1)\end{aligned} \tag{15.3.178}$$

Neglecting the quadratic xy terms, we obtain:

$$\begin{aligned}\frac{\mathrm{d}x}{\mathrm{d}t}&\cong r\left[(1-y^*)x+(1-y-y^*)x^*\right]\\ \frac{\mathrm{d}y}{\mathrm{d}t}&\cong -m\left[(1-x^*)y+(1-x-x^*)y^*\right]\end{aligned} \tag{15.3.179}$$

1. We focus first on the study near the point of extinction $(0,0)$, this is why we can neglect the quadratic terms xy but the expression remain too complicated. So, always considering we are near the point of extinction $(0,0)$, we consider a bit unfairly but cleverly (otherwise we still could not solve the problem analytically) the following approximations:

$$\begin{aligned}\frac{\mathrm{d}x}{\mathrm{d}t}&\cong r\left[x-\underbrace{y^*x}_{=0}+x^*-\underbrace{yx^*}_{=0}-\underbrace{y^*x^*}_{=0}\right]\underset{x\gg x^*}{\cong} r(x+x^*)\cong rx\\ \frac{\mathrm{d}y}{\mathrm{d}t}&\cong -m\left[y-\underbrace{x^*y}_{=0}+y^*-\underbrace{xy^*}_{=0}-\underbrace{x^*y^*}_{=0}\right]\cong -m(y+y^*)\underset{y\gg y^*}{\cong} -my\end{aligned} \tag{15.3.180}$$

   Therefore:

$$\begin{aligned}\frac{\mathrm{d}x}{\mathrm{d}t}&\cong rx=rx(t)\\ \frac{\mathrm{d}y}{\mathrm{d}t}&\cong -my=-my(t)\end{aligned} \tag{15.3.181}$$

This shows us for the system in equilibrium, close to the inexistence point, the offer (supply) decreases exponentially (power law) as demand increases exponentially:

$$\begin{aligned} x(t) &= c_1^{te} e^{rt} \\ y(t) &= c_2^{te} e^{-mt} \end{aligned} \qquad (15.3.182)$$

This makes economic sense: when there is little offer (respectively demand), the demand (respectively offer) is growing when as far as demand increases, the offer grows and converge increasingly near to the demand (nature...).

Remark

In the literature we find sometimes the "$-$" sign in the top or bottom in the previous equations. In reality, the position of the "$-$" sign is not important because it is just the starting choice in the system dynamics.

2. Close to the equilibrium point $(1,1)$ we start from:

$$\begin{aligned} \frac{\mathrm{d}x}{\mathrm{d}t} &= rx(1-y) \\ \frac{\mathrm{d}y}{\mathrm{d}t} &= my(x-1) \end{aligned} \qquad (15.3.183)$$

And we put $x := 1+x, y := 1+y$ where x, y are now small perturbations near the point $(1,1)$. Therefore we have:

$$\begin{aligned} \frac{\mathrm{d}x}{\mathrm{d}t} &= r(1+x)(1-(1+y)) = -r(1+x)y \cong -ry \\ \frac{\mathrm{d}y}{\mathrm{d}t} &= m(1+y)((x+1)-1) = m(1+y)x \cong mx \end{aligned} \qquad (15.3.184)$$

(hop! we change the position of the "-" sign on purpose to show that this is only a starting choice !!!):

$$\begin{aligned} \frac{\mathrm{d}x}{\mathrm{d}t} &\cong -ry \\ \frac{\mathrm{d}y}{\mathrm{d}t} &\cong mx \end{aligned} \qquad (15.3.185)$$

To solve this system, let us differentiate the first equation once again:

$$\frac{\mathrm{d}^2x}{\mathrm{d}t^2} \cong -r\frac{\mathrm{d}y}{\mathrm{d}t} \qquad (15.3.186)$$

and by injecting in it $\mathrm{d}y/\mathrm{d}t$:

$$\frac{\mathrm{d}^2x}{\mathrm{d}t^2} \cong -rmx \qquad (15.3.187)$$

So we get a small second order differential equation (see section Differential and Integral Calculus page 1610). Whose typical simple solution is:

$$x = x_0 e^{-\lambda t} \tag{15.3.188}$$

By injecting this solution into the differential equation, we obtain after simplification of exponentials a simple polynomial of the second degree (see section Calculus page 1368):

$$\lambda^2 x_0 + rmx_0 = 0 \tag{15.3.189}$$

Whose solution is trivial:

$$\lambda_{1,2} = \pm \mathrm{i}\sqrt{rm} \tag{15.3.190}$$

Thus, the general solution of the differential equation is the linear combination of the two special solutions we get:

$$x(t) = x_0 \left(e^{+\mathrm{i}\sqrt{rm}} + e^{-\mathrm{i}\sqrt{rm}} \right) \tag{15.3.191}$$

But we therefore have:

$$\frac{\mathrm{d}x}{\mathrm{d}t} \cong -ry \Leftrightarrow y(t) = -\frac{1}{r}\frac{\mathrm{d}x}{\mathrm{d}t} \tag{15.3.192}$$

Therefore, knowing $x(t)$ we obtain easily:

$$x(t) = -x_0 \sqrt{\frac{m}{r}} \left(\mathrm{i}e^{+\mathrm{i}\sqrt{rm}} - \mathrm{i}e^{-\mathrm{i}\sqrt{rm}} \right) \tag{15.3.193}$$

Now let us use the Euler formula (see section Numbers page 251):

$$e^{\mathrm{i}x} = \cos(x) + \mathrm{i}\sin(x) \tag{15.3.194}$$

Thus we have:

$$x(t) = x_0 \left[\cos\left(-\sqrt{rm}t\right) + \mathrm{i}\sin\left(-\sqrt{rm}t\right) + \cos\left(\sqrt{rm}t\right) + \mathrm{i}\sin\left(\sqrt{rm}t\right) \right] \tag{15.3.195}$$

and as (see section Trigonometry page 2514) $\cos(x) = \cos(-x), -\sin(x) = \sin(-x)$ then we have:

$$x(t) = 2x_0 \cos(\sqrt{rm}t) \tag{15.3.196}$$

and similarly, we obtain:

$$\begin{aligned} y(t) &= -x_0 \sqrt{\frac{m}{r}}\mathrm{i} \left[-\left(\cos\left(-\sqrt{rm}t\right) + \mathrm{i}\sin\left(-\sqrt{rm}t\right)\right) + \cos\left(\sqrt{rm}t\right) + \mathrm{i}\sin\left(\sqrt{rm}t\right) \right] \\ &= -x_0 \sqrt{\frac{m}{r}}\mathrm{i} \left[-\left(\cos\left(\sqrt{rm}t\right) - \mathrm{i}\sin\left(\sqrt{rm}t\right)\right) + \cos\left(\sqrt{rm}t\right) + \mathrm{i}\sin\left(\sqrt{rm}t\right) \right] \\ &= -x_0 \sqrt{\frac{m}{r}}\mathrm{i} \left[-\cos\left(\sqrt{rm}t\right) + \mathrm{i}\sin\left(\sqrt{rm}t\right) + \cos\left(\sqrt{rm}t\right) + \mathrm{i}\sin\left(\sqrt{rm}t\right) \right] \\ &= -x_0 \sqrt{\frac{m}{r}}\mathrm{i}2\mathrm{i}\sin\left(\sqrt{rm}t\right) = 2x_0\sqrt{\frac{m}{r}}\sin\left(\sqrt{rm}t\right) \end{aligned} \tag{15.3.197}$$

Thus, around the equilibrium point $(1, 1)$ with sufficiently small perturbations to validate linearisation the system oscillate as ellipses (or circles) whose axes are defined by the two equations above.

We can get the graphs above with Maple™ 4.00b (this is a nice example of application of this software):

```
>restart:  with(plots):  with(DEtools):
>rate_eqn1:= diff(h(t),t)=(0.1)*h-(0.005)*h*(1/60)*u;
rate_eqn2:=diff(u(t),t)=(0.00004)*h*u-(0.04)*u;vars:= [h(t), u(t)];
>init1:=[h(0)=2000,u(0)=600]; init2:=[h(0)=2000,u(0)=1200];

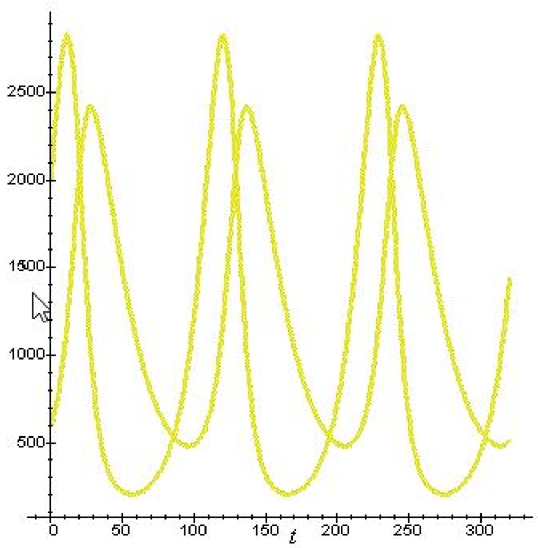

Figure 15.94: **Lotka-Volterra offer/demand model periodic plot in Maple™ 4.00b**

```
>DEplot(rate_eqn1, rate_eqn2, vars, t= 0 ..  160, init1, init2, init3,
stepsize=0.5, scene=[h,u], title='Demande vs.  60 * Offer for t = 0 ..
160', arrows=slim);
```

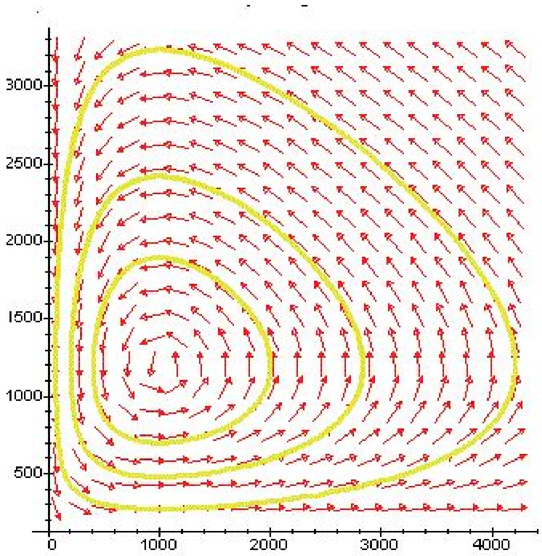

Figure 15.95: **Lotka-Volterra offer/demand phase space model plot in Maple™ 4.00b**

This model, however is imperfect because it takes into account only a disgruntled monopoly with net loss and perfect information. The fact of considering the population constant is not too bothersome but strictly speaking we should add a logistic term in the initial equations. There is still work to do...

15.3.6 Capitalization and Actuarial

Definition (#15.3.662): The "capitalization" is the field of financial mathematics which calculates future values based on present values, while the "actuarial calculation" consist to determine how much should be loaned to get a given amount fixed in advance (the opposite of capitalization).

In a dynamic market, economic agents can lend or borrow capital in return for which they receive or respectively pay a periodic interest. This interest is justified by the risk-taking that takes the creditor (the lender's of capital) in case of non-repayment of all or a share of the initial capital that must repay the debtor (the one who must repay the borrowed capital). Alternatively, in the point of view of economic market, loans allow some economic agents to set up goods by betting on the fact that either they will create the offer or that the offer will come by itself but wishing be ahead of the concurrence.

Remark

When credit is contracted with an economic agent that is non solvable financial analysts speak about "NINJA" loan for "No Income, No Job and no Assets".

When a capital is lent (or borrowed, it depends from the point of view...) in order to increase market dynamics (the amount of goods in circulation on a given duration) then we talk of "financial asset", this to make clear that capital participates in the activities of the economy.

Definitions (#15.3.663):

D1. We name "yield of a loaned financial asset" the relative progress ratio given by:

$$r_f\% = \frac{A_{t+\Delta t} - A_t}{A_t} \cdot 100 \tag{15.3.198}$$

D2. We name "arithmetic return on investment" the relative progress ratio:

$$\text{ROI}^{\text{Arith.}} = \frac{V_f - V_i}{V_i} \tag{15.3.199}$$

where V_i is the initial value of the investment and V_f its final value.

It follows from this latter definition that if an investment has reported 5% the first year and carried a net loss of 2% the second year, the "arithmetic return on investment" is then:

$$\overline{\text{ROI}}^{\text{Arith.}} = \frac{1}{n}\sum_{k=1}^{n} \text{ROI}_k^{\text{Arith.}} = \frac{\text{ROI}_1^{\text{Arith.}} + \text{ROI}_2^{\text{Arith.}}}{2} = \frac{5\% + (-2\%)}{2} = 1.50\% \tag{15.3.200}$$

But it is wrong to use the arithmetic average for this type of situation because the final sum obtained after two years would be mathematically:

$$V_n^f = V_0 \prod_{k=1}^{n} (1 + \text{ROI}^{\text{Arith.}}) \tag{15.3.201}$$

which then gives the previous example:

$$V_2^f = V_0(1+5\%)(1+(-2\%)) \tag{15.3.202}$$

So the real average return is by definition the "geometric return on investment" as:

$$V_2^f = V_0(1+5\%)(1+(-2\%)) = V_0(1+\text{ROI}^{\text{Geom.}}) \tag{15.3.203}$$

that is to say, it is simply a geometric mean (see section Statistics page 565) . It comes then:

$$\text{ROI}^{\text{Geom.}} = (1+5\%)(1+(-2\%)) - 1 = 2.90\% \tag{15.3.204}$$

which is obviously much different from the ROI arithmetic average obtained above!

Remark

We say of an asset that it has a "risk-free return" or "risk-free rate of return" if its future value (respectively it's corresponding rate) is perfectly known.

Given an asset that can have the future optimistic return $r_{f,1}$ with probability p_1 and the pessimistic value $r_{f,2}$ with a probability p_2 or other values r_{fn} with probabilities p_n then expected mean of return is obviously given by:

$$\text{E}(r_f) = \sum_{i=1}^{n} r_{fi}p_i \tag{15.3.205}$$

that the monetary sum is of the type active/passive, the types of applicable yields can be identical or variable. There exists, however, classic cases that are well known and non-stochastic. For their study, let us define some variables:

- C_0 represents the initial capital or more technically the "actual value" (AV) or "present value" (PV).
- C_n represents the final capital or "capitalized value" (CV) or "future value" (FV) after n time periods.
- $t\%$ is the rate most technically named "effective rate".
- I_n represents the "interest" obtained after n periods (horizon) by the current value

Let us add also the relation:

$$f_c = 1 + t\% \tag{15.3.206}$$

named "capitalization factor".

Definition (#15.3.664): We define the "interest" as the remuneration of a capital (the amount of money) loaned or invested for a given time. The interest can be paid at once or periodically if the duration of the loan or investment is for a long time. The interest may be payable in advance (praenumerando) or at the end of the period (postnumerando). The interest is based on the duration of the loan (or investment), of the borrowed (or paid) capital that we also name the "principal" and also from the "rate" of interest charged. The period over which the interest is calculated is in general the year, but it can be shorter: semester, quarter, month, day, hour, minute, seconds, etc.

Remark

In a text, the interest rate is normally expressed in percentage % but in financial calculations, it is customary to calculate or write it in decimal form.

The reader should also be aware the in the finance industry, we use many times the "basis points" (BPS) as common unit of measure for interest rates and other percentages. One basis point is equal to $1/100$th of 1%, or 0.01% (0.0001), and is used to denote the percentage change in a financial instrument. The relation between percentage changes and basis points can be summarized as follows: 1% change $=$ 100 basis points, and $0.01\% = 1$ basis point.

Basis Points	**Percentage Terms**
1	0.01%
10	0.1%
50	0.5%
100	1%
1000	10%
$10,000$	100%

Table 15.35: **Basis points (BPS) and percentage equivalence**

15.3.6.1 Dates Intervals

In determining the amount of interest of a loan (or investment), it is first necessary to know the duration of the latter or the dates defining the periods of payment of an obligation, i.e. the "settlement date".

The calculation of dates and durations is the first step to learn in actuarial mathematics. If some software used in the calculation of the period the calendar with the civil year (365 days according to the Gregorian calendar), others are based on the commercial year (360 days), which was the case of most European banks (it is to their advantage financially to make the choice of this latter...) before the arrival of the calendar for the Eurozone.

Remarks

R1. In financial markets, there is as far as we know only one single convention for determining a date range to calculate a duration: the first day (departure date) is included in the period. The last day (end date or settlement date) is excluded from the period. Thus the period from 15 to 25 June has 10 days.

R2. In the context of this textbook, who wish to have the more rigorous possible approach on treated topics, we will not dwell on the aberrant German, European or American 30/360, methods (we can then do every country on the planet then... and refer to the calculations of dates functions of a spreadsheet software like Microsoft® Excel®...) to focus only on 365 days method (the exact base system) that is, and remains, the most natural counting system to use as it includes the months with 28, 29, 30 or 31 days.

R3. Note that in regard to savings accounts, banks are based on a system of "fortnight" (two weeks/half a month), and they therefore estimate that there are 24 fortnights a year.

We must therefore in this system of the exact basis know how to calculate the number of days between two dates D_1, D_2 given by the calculation $D_2 - D_1$ each such date being encrypted in standardized format $yyyy - mm - dd$ (year-month-day compliant with ISO ISO 8601) or under non-standardized $d.m.y$ format (day.month.year).

Definitions (#15.3.665):

D1. The Gregorian Calendar is defined as having 12 months.

D2. The months:

$$\text{january}(1), \text{march}(3), \text{may}(5), \text{july}(7), \text{august}(8), \text{october}(10), \text{december}(12) \quad (15.3.207)$$

are 31-day months and the months of:

$$\text{april}(4), \text{june}(6), \text{september}(10), \text{november}(11) \quad (15.3.208)$$

have 30 days.

D3. February is a special case to correct the fact that the civil year calendar of 365 days does not correspond quite the orbital period of the Earth around the Sun (actually a G2V-type star, aka yellow dwarf) that is about 365.25 days... Thus, all the years that are multiples of 4 or 400 are leap years (February has 29 days instead of 28) but the years that are divisible by 100 are not leap years.

✍**Examples:**

E1. 11992, 11996, 12004, 12008 are leap (holocene) years.

E2. The years 11900, 12100, 12200, 12300 are not leap (holocene) years (because divisible by 100).

E3. The years 11600, 12000, 12400, 12800 are leap (holocene) years because even if they are divisible by 100, they are multiples of 400.

These definitions and examples being given, imagine now date given following the above rules. The number of days since year 1 is therefore (as seen in the section of Numerical Methods $[x]$ will be the integer part of x):

$$\boxed{D(d,m,y) = 365(y-1) + \left[\frac{y-1}{4}\right] - \left[\frac{y-1}{100}\right] + \left[\frac{y-1}{400}\right] + 31(m-1) + d} \quad (15.3.209)$$

This relation is logically deduced as follows for the dates where $m \leq 2$ (that is to say only for the first two months of the year including the problematic of February):

1. We have $365(y-1)$ because given a the number of calendar days since the year 1 is 365 times the number of years y has decreased by one unit as the current year is not over.
2. The same remark applies for months with $31(m-1)$: considering months of 31 days, the current month is not taken into account (this is why we have $m-1$). The correction for the months with 28 or 30 days is taken into account in the case where $m>2$ that we will see later below.
3. Logically, we add d (which contains all the information as to know whether the year y is leap year or not) to the sum of the previous two terms.
4. The terms:
$$\left[\frac{y-1}{4}\right]-\left[\frac{y-1}{100}\right]+\left[\frac{y-1}{400}\right]$$
give the number of 29th February between year 1 and taking into account all leap years that occur all the multiples of 4 and 400 years except for years that are multiples of 100.

If $m>2$, we must use the following relation:

$$\boxed{D(d.m.y)=365(y-1)+\left[\frac{y}{4}\right]-\left[\frac{y}{100}\right]+\left[\frac{y}{400}\right]+31(m-1)+d-[0.42M+2+0.5]} \tag{15.3.210}$$

This relation is deducted in the same way as the previous one except that certain terms in the numerator are not reduced by one unit because having $m>2$, it is necessary, for these terms, to consider the current year in the calculation.

The last term $[2+0.5+0.42M]$ is here to fix the fact that every month does not have 31 days (at least for the Gregorian calendar...). To get it, we build the following table (the third column gives the offset in days compared to the case where all the months have 31 days):

Month	Month number n	Offset Δ
march	3	3
april	4	4
may	5	4
june	6	5
july	7	5
august	8	5
september	9	6
october	10	6
november	11	7
december	12	7

Table 15.36: **Monthly offset Δ in days**

A simple linear regression (see section Numerical Methods page 6324) gives:

$$\Delta(n)=0.4242n+2.018 \tag{15.3.211}$$

By taking the integer value and verifying that the selected function is correct, we finally get (taking an accuracy of two decimal places):

Month	Month number n	Offset Δ	$\Delta(n)$	Offset $[\Delta(n)]$
march	3	3	3.26	3
april	4	4	3.68	4
may	5	4	4.1	4
june	6	5	4.52	5
july	7	5	4.94	5
august	8	5	5.36	5
september	9	6	5.78	6
october	10	6	6.2	6
november	11	7	6.62	7
december	12	7	7.04	7

Table 15.37: **Comparison of the regression function with the target**

15.3.6.2 Rates Equivalence

Let us now briefly focus on rates calculation before directly addressing the various calculations of interests types.

Definition (#15.3.666): The "proportional rate $t_p\%$" is bringing to a same capital, during the same period, the same "simple interest" (see the definition of the simple interest further below), and given by the relation:

$$\boxed{t_p\%=\frac{t\%}{n}} \tag{15.3.212}$$

If the proportional rate is calculated on the basis of a year, then we speak of "annualized yield rate"; if calculated on the basis of a month, then we speak of "monthly-rate of return".

✍**Example:**

Calculate the monthly proportional rate $t_p\%$ (i.e.: the monthly rate of return) of an annual rate $t\%$ of 12%:

$$t_p\%=\frac{t\%}{n}=\frac{12\%}{12\,\text{months}}=1\% \tag{15.3.213}$$

Definition (#15.3.667): The "equivalent rate $t_e\%$" is bringing to a same capital, during the same period, the same "compound interest" (see definition of compound interest below), and given by the relation:

$$\begin{aligned}&(1+t_e\%)^m=(1+t\%)^n\\ &\Rightarrow(1+t_e\%)=\sqrt[m]{(1+t\%)^n}=(1+t\%)^{\frac{n}{m}}\\ &\Rightarrow t_e\%=(1+t\%)^{\frac{n}{m}}-1\end{aligned} \tag{15.3.214}$$

and vice versa:

$$\boxed{t\% = (1 + t_e\%)^{\frac{m}{n}} - 1} \tag{15.3.215}$$

✍**Example:**

Monthly equivalent rate $t_e\%$ to an annual rate of 12% (result truncated at ten-thousandth):

$$t_e\% = (1 + 12\%)^{\frac{1}{12}} - 1 \cong 0.9488\% \tag{15.3.216}$$

the reverse procedure would therefore be to calculate the annualized rate and then we see that a monthly rate of 1% annualized would be not exactly 12%!!

15.3.6.3 Simple Interest

Definition (#15.3.668): The "simple interest" is defined by the relation (see above for the definition of notations):

$$I_n = C_0 t\% n \tag{15.3.217}$$

implying a capitalization (final value):

$$\boxed{C_n = C_0 + I_n = C_0(1 + nt\%)} \tag{15.3.218}$$

It is simply the interest that is calculated each period on the sole basis of the capital loaned or borrowed originally.

From the latter we get obviously the also following famous relation:

$$C_0 = \frac{C_n}{1 + nt\%} \tag{15.3.219}$$

And another one that is famous is to determine I_n if we don't know C_0. To get this we do a little bit of elementary algebra:

$$I_n = C_n - C_0 = C_n - \frac{C_n}{1 + nt\%} = C_n\left(1 - \frac{1}{1 + nt\%}\right) = C_n\frac{nt\%}{1 + nt\%} \tag{15.3.220}$$

In the field of real estate investments, with $n = 1$ we have the interest rate:

$$t\% = \frac{I_n}{C_o} \tag{15.3.221}$$

that is named quite obviously "capitalization rate" or simply "cap-rate", and I_n that is abbreviated NOI for "net operating income" (the NOI of a rental property is its rent minus the expenses paid for its maintenance like property management, property taxes, insurance, etc.).

Remarks

R1. It is very easy from the knowledge of three of the four parameters of the above relation to find the fourth one. As this is a simple equation of the first degree, we will not dwell on this kind of elementary algebra exercise.

R2. A specificity of the simple interest is to be proportional to the duration of the investment. If interest e.g. over a year is 12%, the "equivalent rate $t_e\%$" of an identical placement for 12 months will be 1% per month. This property is not true for compound interest as we will see afterwards.

R3. For savings accounts, we have already mentioned that some financial institutions use as fifteen time period (24 periods in the year consisting of fictive 30-day months). So to calculate the annual interest at each fortnight, they take the lowest balance on the account during the fortnight and calculate simple interest on a reported rate of 24 fortnights a year and defer the result obtained in annual closure of the account at the end of the year (they are not crazy...).

Moreover, if more simple interests investments are made simultaneously for different periods and at different rates, we may calculate the average T of all of these investments.

If we note C_t the investment number k, I_k the interest rate of investment number k, n_k the duration (number of periods) of the investment and N the number of investments, we obtain the following weighted arithmetic mean (see section Statistics page 548) as follows:

$$T=\frac{C_1I_1n_1+C_2I_2n_2+\ldots+C_NI_Nn_N}{C_1n_1+C_2n_2+\ldots+C_Nn_N}=\frac{\displaystyle\sum_{k=1}^{N}C_kI_kn_k}{\displaystyle\sum_{k=1}^{N}C_kn_k} \tag{15.3.222}$$

✍**Example:**

We seek the average annual rate of three placements $\{1000.\text{-}; 90 \text{ days}; 3\%\}$, $\{2000.\text{-}; 120 \text{ days}; 4\%\}$, $\{3000.\text{-}; 170 \text{ days}; 5\%\}$. Then we have:

$$T=\frac{1000\cdot 3\%\dfrac{90}{360}+2000\cdot 4\%\dfrac{120}{360}+3000\cdot 5\%\dfrac{170}{360}}{1000\dfrac{90}{360}+2000\dfrac{120}{360}+3000\dfrac{170}{360}}=0.045=4.5\% \tag{15.3.223}$$

15.3.6.3.1 Discounts

Still regarding to the simple interest, we can come back to a concept we talked about at the beginning of this section: the discount. This concept is used both in the traditional trade as in the financial markets for Treasury bills (see further below).

Let us recall that the discount is a rebating granted to a buyer by a seller in order to induce him to pay quickly before n units (periods) of time (that is the number of units n that matters!). A buyer should in principle take advantage of this discount (which can be seen as a credit). Otherwise, it is as if the purchaser implicitly borrowed from a bank for a given period (n units).

Historically, the discount is the withholding that does a banker on a promise of payment that has a merchant (promise signed by a buyer for a certain date), that the banker pays before maturity (thus as an advance).

Let us see this:

Let us note C_0 the present value discount included, C_n the amount without discount named "nominal value", n the duration relative to the time scale of the discount rate, $t\%$ the discount rate and I the implicit simple equivalent interest in case of renunciation of the discount.

We now have the following trivial relations:

$$C_0 = C_n - t\%C_n = C_n - I = C_n(1-t\%) \tag{15.3.224}$$

And nothing prevents us from writing that the amount without discount can be obtained by simple interest of the form:

$$C_n = C_0(1+nI) \tag{15.3.225}$$

from the value with discount. The simple implicit interest on the present value being then trivially:

$$I = \frac{C_n - C_0}{nC_0} \tag{15.3.226}$$

Therefore, it comes by substitution:

$$I = \frac{C_n - C_0}{nC_0} = \frac{C_n - C_n(1-t\%)}{nC_n(1-t\%)} = \frac{1-(1-t\%)}{n(1-t\%)} = \frac{t\%}{n(1-t\%)} \tag{15.3.227}$$

We notice then that it is sufficient to know the discount rate $t\%$ granted (often annualized...) and the renunciation period n to determine the simple equivalent rate of the granted credit.

If the rate $t\%$ communicated from the start is not the rate corresponding to the entire duration of n (as is the case above) but the rate of the corresponding time unit, then we have the following relation:

$$I = \frac{t\%}{n(1-t\%)} = \frac{nt'\%}{n(1-nt'\%)} = \frac{t'\%}{(1-nt'\%)} \tag{15.3.228}$$

✍**Example:**

Let us calculate the implicit simple rate i of a discount of 1% to 10 days or net at 30 days:

$$I=\frac{0.01}{20(1-0.01)}\cong 0.0505\% \qquad (15.3.229)$$

Thus, the discount if it is not considered, can be seen as being a credit to of 0.0505% daily during 20 days on the sum with discount! This corresponds on a month of 30 days to a simple interest rate of 1.515%.

This calculation method is named "commercial discount" because the calculations are based on the nominal value and not of the current value. However, historically, the calculations were rather similar to the following:

✍**Example:**

On March 19, a banker discount of $t\%=6\%$ (annualized) a buyer contract to a trader of $240,000$.- payable on May 31 (so there are 73 calendar days between the two dates). The discount value is then (on an annual basis of 360 days):

$$\text{Discount}=240,000\cdot\frac{6\%}{360}\cdot 73=2,920.\text{-} \qquad (15.3.230)$$

So the present value of the contract will be $237,080$. The simple daily implicit rate will be given by:

$$C_n=C_0(1+ni)=(C_n-C_nnt\%)(1+ni)\Rightarrow i=\frac{\dfrac{1}{1-nt\%}-1}{n}=\frac{t\%}{1-nt\%} \qquad (15.3.231)$$

Therefore:

$$I=\frac{t\%}{1-nt\%}=\frac{\dfrac{6\%}{360}}{1-\dfrac{6\%}{360}-1}=0.0169\% \qquad (15.3.232)$$

Let's see a last example involving a Treasury bill:

✍**Example:**

A dealer purchase a US Treasury bill with 40 day to maturity at a quote discount rate of 5.5%. The face value is $100,000$.-, we then get for the settlement value:

$$\text{settlement value}=100,000\left(1-5.5\%\frac{40}{360}\right)=99,389.\text{-} \qquad (15.3.233)$$

If necessary here is a summary of some concepts (if it may be useful to the reader):

Treasury Bills	Treasury Bonds	Treasury Notes
	Maturities	
Up to 1 year	20 and 30 years	2 to 10 years
	Investment Term	
Short-term	Long-term	Intermediate-term
	Yield and Risk	
Lowest yield, Least risk	Highest yield, Greatest risk	Balanced yield and risk
	Liquidity	
Highly liquid	Highly liquid	Highly liquid
	Pricing Mechanism	
Sold at discount, No coupon payments	Sold at par, Discount or premium, Make semi-annual interest payments	Sold at par, Discount, or premium, Make semi-annual interest payments

Table 15.38: **Treasury Bills vs Treasury Bonds vs Treasury Notes**

15.3.6.4 Compound Interest

Definition (#15.3.669): The "compound interest" is defined by the relation:

$$I_n = C_0 f_c^n - C_0 = C_0(f_c - 1) \tag{15.3.234}$$

and implies that the final value is given by:

$$\boxed{C_n = C_0 f_c^n = C_0(1+t\%)^n} \tag{15.3.235}$$

We say that the interest rate is "compound" when at the end of each period the interest is added to capital for the calculation of the next period. This relation obviously implies that there is no withdrawal or deposit in all periods.

We also deduce the following trivial relations (see section Calculus page 1350 and Functional Analysis page 2284):

$$C_0 = \frac{C_n}{(1+t\%)^n} \qquad n = \frac{\ln\left(\dfrac{C_n}{C_0}\right)}{\ln(1+t\%)} \qquad t\% = \sqrt[n]{\frac{C_n}{C_0}} - 1 \tag{15.3.236}$$

where the first relation gives the initial value if the final value is known and that there is no withdrawal or deposit during all periods.

Remark

The equivalent function in Microsoft Office Excel 11.8346 are respectively to find C_n, C_0, n, i the function `FV()`, `PV()`, `NPER()`, `RATE()` where the abbreviation `NPER` means "Number of PERiodic payments".

In the context of cumulative interest (compounds), two important concepts are the "present value" (PV) and "future value" (FV) of an acquired a capital.

By answering the question: «*What capital C_n do we get after some time today placing an amount C_0 in a savings account?*», we make a research of future value of capital. We speak then of "capitalization process".

By cons, if we ask, «*What capital C_0 should we place today on a savings account to get after some time a capital C_n?*», we make a research of present value of a capital. We speak then about "discount operation" (that is characteristic of "actuarial calculations").

Definition (#15.3.670): We name the f_c the "capitalization factor" and f_e the "discount factor" defined by the relations:

$$f_c = 1 + t\% \qquad f_e = \frac{1}{1+t\%} \tag{15.3.237}$$

also sometimes denoted by DF.

This brings us also to have:

$$f_c = f_e^{-1} \tag{15.3.238}$$

Starting from the compound capitalization relation give above but with the condensed notation we get:

$$C_n = C_0 f_c^n \tag{15.3.239}$$

The initial capital (present value) can be therefore expressed with the discount factor:

$$C_0 = \frac{C_n}{f_c^n} = C_n f_e^n \tag{15.3.240}$$

This then makes very simple the calculation of the actualization or capitalization as it is to multiply the final or initial capital by the discount factor or capitalization factor to the n-th power. So as we already know we talk about calculate the "future value" (FV) or "present value" (PV) when we invest a certain amount for a certain time at a certain rate and we speak of "present value" when we calculate what should be the initial value investing to get a given amount after a given time at a given rate.

Let us now recall the relation that we have obtained in our initial presentation of equivalent rates:

$$t_e\% = (1+t\%)^{\frac{n}{m}} - 1 \tag{15.3.241}$$

Often in order to simplify the calculations, the person seeking the equivalent rate will simply ask (normalized) $n = 1$. This led him to write:

$$t_e\% = (1+t\%)^{\frac{1}{m}} - 1 \qquad t\% = (1+t_e\%)^m - 1 \tag{15.3.242}$$

Then comes a small trick that use credit analysts in their sales processes that are the concepts of "effective rate" (already seen above!) and "nominal rate". The nominal rate is always lower than the actual rate, it allows the issuer of the debt to show a lower rate than what it actually is (incidentally this practice is prohibited by law in some countries!).

✍**Example:**

Suppose that the conditions for a loan are as follows: annual interest $t_n = 12\%$ (nominal rate written in small in the contract or in the add) payable by monthly increments of $t_e\% = t_n\%/12 = 1\%$. A careful individual realizes that paying 1% monthly interest in a compound system does not give an annual interest of 12% but:

$$t\% = (1+t_p\%)^n - 1 = \left(1+\frac{t_p\%}{p}\right)^p - 1 = \left(1+\frac{t_p\%}{12}\right)^{12} - 1 \cong 12.682\% \tag{15.3.243}$$

which is the effective rate $t_e\%$. In this special case $t_e\%$ is often named "effective annual rate" (EAR) and $t_p\%$ is named "annual percentage rate" (APR)!

Remark

Warning! Never forget that the nominal rate $t_n\%$ includes the rate of inflation $t_i\%$. So the "real rate" $t_r\%$ is equal in reality to:

$$(1+t_n\%) = (1+t_i\%)(1+t_r\%) \tag{15.3.244}$$

For example, if the nominal interest rate for one-year money is 10% with annual compounding and the assumed rate of inflation over the period is 5%, then the real interest rate can be calculated as follows:

$$t_r\% = \frac{1.10}{1.05} - 1 = 4.76\%$$

Now, if more investments are made simultaneously for different durations and at different rates, we may calculate the average compound rate T of all of these investments.

If we denote by C_t the investment number t, $f_{c,t}$ the capitalization factor of investment umber t, n_t the duration of investment number t, k the number of investments and finally T the average compound rate of all investments we can with the help of algebra rule until fourth degree (see section Calculus) or using numerical method (taking the solver or target tool of Microsoft® Excel® for example), solve the following equation:

$$C_1 f_{c,1}^{n_1} + C_2 f_{c,2}^{n_2} + \ldots + C_k f_{c,k}^{n_k} = C_1(1+T)^{n_1} + C_2(1+T)^{n_2} + \ldots + C_k(1+T)^{n_k} \tag{15.3.245}$$

If we make a change of variables $x = 1+T$ we then solve the unknown equation in x (all other terms are normally known in the problem statement):

$$C_1 x^{n_1} + C_2 x^{n_2} + \ldots + C_k x^{n_k} - C_1 f_{c,1}^{n_1} + C_2 f_{c,2}^{n_2} + \ldots + C_k f_{c,k}^{n_k} = 0 \tag{15.3.246}$$

15.3.6.5 Continuous Interest

Let us recall that the compound interest is defined by (with a different common notation for f_c):

$$C_n = C_0 r^n = C_0 (1 + t_n\%)^n \tag{15.3.247}$$

For n periods on a given time basis. Now consider an equivalent rate slitted in smaller periods p such that:

$$C_n = C_0 \left(1 + \left[\left(1 + \frac{t_n\%}{p}\right)^p - 1\right]\right)^n \tag{15.3.248}$$

We can now ask ourselves what would happen to the rate $t_n\%$ if interest was paid not monthly, not daily, but continuously, in an instantaneous way (or almost instantaneous). We write therefore (see section Functional Analysis page 2289):

$$\lim_{p \to +\infty} \left(1 + \frac{t_n\%}{p}\right)^p - 1 = e^{t_n\%} - 1 \tag{15.3.249}$$

Thus, in case of continuous capitalization, the function of capitalization can be finally written:

$$C_n = \lim_{p \to +\infty} C_0 \left(1 + \left[\left(1 + \frac{t_n\%}{p}\right)^p - 1\right]\right)^n = C_0 \left(1 + \left[e^{t_n\%} - 1\right]\right)^n = C_0 \left(e^{t_n\%}\right)^n = C_0 e^{n t_n\%} \tag{15.3.250}$$

And as:

$$\frac{C_n}{C_0} = (1 + t\%)^n \cong e^{n t_n\%} \Rightarrow \frac{C_1}{C_0} = 1 + t\% \cong e^{t_n\%} \tag{15.3.251}$$

We then have (relatively important relation in finance markets) the "logarithmic returns" or just "log-returns":

$$\boxed{t_n\% = \ln\left(\frac{C_n}{C_0}\right) \cong \ln(1 + t\%)} \tag{15.3.252}$$

Therefore the logarithmic return is defined as the Napierian logarithm of the ratio of two values distant in time by a very small interval.

In practice we can use this approximation for large sums of money if the rate is relatively low (under 10%) and that the number of investment period not exceed the ten...

A useful property and widely used in trading of the continuous interest is that it is "time consistent". To see what it is, consider the following three values of any portfolio of equity invested:

Capital	Value	Simple return rate	Logarithmic return rate
C_{n-2}	10.00.-	-	-
C_{n-1}	14.00.-	$=(14-10)/10 = 40\%$	$=\ln\left(\dfrac{14}{10}\right) \cong 33.65\%$
C_n	9.00.-	$=(9-14)/14 = -35.71\%$	$=\ln\left(\dfrac{9}{14}\right) \cong -44.18\%$
Sum:		$=4.29\%$	$=-10.54\%$
Comparison:		$=(9-10)/10 = 10\%$	$=\ln\left(\dfrac{9}{10}\right) \cong 10.54\%$

Table 15.39: Comparison between exact rate and approximated continuous

So as we can see, unlike the simple interest rate, the continuous rate of return is time-consistent because we can sum the different rates for the total variation (this is a very important property used a lot in financial market softwares and especially for performance back-testing!). This result simply comes from the following property:

$$C_n=\left(C_{n-2}e^{t_1\%}\right)e^{t_2\%}=C_{n-2}e^{t_1\%}e^{t_2\%}=C_{n-2}e^{t_1\%+t_2\%}\Rightarrow\ln\left(\frac{C_n}{C_{n-2}}\right)=t_1\%+t_2\% \quad (15.3.253)$$

Or more generally and traditionally:

$$\ln\left(\frac{C_n}{C_0}\right)=t_n\%-t_0\% \quad (15.3.254)$$

Compounding logarithmic returns over small intervals characterized by time points 1, 2, 3 and up to T, each equal interval results in the compounded return from 0 to T. The compounded continuous return collapses into a simple formula:

$$t_n\%=\ln\left(\frac{C_T}{C_0}\right)=\ln\left[\frac{C_1}{C_0}\frac{C_2}{C_1}\frac{C_3}{C_2}\ldots\frac{C_T}{C_{T-1}}\right] \quad (15.3.255)$$

The logarithmic return over several sub-periods is the sum of intermediate logarithmic returns because the logarithm of a product is the sum of logarithms:

$$t_n\%=\ln\left(\frac{C_n}{C_0}\right)=\ln\left(\frac{C_1}{C_0}\right)+\ln\left(\frac{C_2}{C_1}\right)+\ln\left(\frac{C_3}{C_2}\right)+\ldots+\ln\left(\frac{C_T}{C_{T-1}}\right) \quad (15.3.256)$$

Therefore:

$$t_n\%=\ln\left(\frac{C_T}{C_0}\right)=\sum_{i=0}^{T-1}\ln\left(\frac{C_{i+1}}{C_i}\right) \quad (15.3.257)$$

That's why you can find in many financial computer code the following expression:

$$\frac{C_T}{C_0}=e^{\sum_{i=0}^{T-1}\ln\left(\frac{C_{i+1}}{C_i}\right)} \quad (15.3.258)$$

To prior-previous relation can be compared with the traditional discrete compound interest:

$$t_n\%=\frac{C_T}{C_0}=\prod_{i=0}^{T-1}(1+t\%) \quad (15.3.259)$$

Or if we denote the return by the letter R we also found the later relation in the following form:

$$R^{\ln}_{\text{long-period}}=\sum R^{\ln}_{\text{short-period}} \quad (15.3.260)$$

For a log annual return, we could apply the following relation:

$$\boxed{R^{\ln}_{\text{annual}}=\sum R^{\ln}_{\text{monthly}}=\sum R^{\ln}_{\text{daily}}=\ldots} \quad (15.3.261)$$

15.3.7 Progressive interest (annuities)

Definition (#15.3.671): A "pension" or "annuity" is a series of periodic payments at regular time intervals and for a period fixed in advance with compound Interest (typical of the second or third pillar in Switzerland).

Then it is enough to apply the relation (see above proof) $C_0 = C_n f_e^n$ to each annuity term paid if we wish to know the present value of the annuity.

By cons, if we wish to obtain the final value of an annuity, we will apply to each term the following relation (see just earlier above for the proof):

$$C_n = C_0 f_c^n \tag{15.3.262}$$

Definition (#15.3.672): If the annuity is payable at the period end, it is named "postnumerando annuity". By cons, if payable a the beginning of period, it is named "praenumerando annuity".

Remarks

R1. Annuities that are always paid are named "certain annuities" and when the duration is predetermined, we speak of "temporary annuities".

R2. Annuities based on the life of an individual are named "life annuities".

Since the terms are often assumed to be constant, we have the habit of basing the calculations on the value of a currency unit (1$). Thus, we note (the adopted notation is that we find in the literature and as they are not very practical, they are original and pretty to look at ...):

- $a_{\overline{n}|}$ the present value of an annuity of a monetary unit payable postnumerando (at deadline) for a duration of n periods
- $\ddot{a}_{\overline{n}|}$ the present value of an annuity of a monetary unit payable praenumerando (in advance) for a duration of n periods
- $s_{\overline{n}|}$ the future value of an annuity of a monetary unit payable postnumerando (at deadline) for a duration of n periods
- $\ddot{s}_{\overline{n}|}$ the future value of an annuity of a monetary unit payable praenumerando (in advance) for a duration of n periods

The relations that determine these values make use of the properties of geometric series and their partial sum (see section Sequences and Series page 1656 and page 1664).

15.3.7.1 Postnumerando annuities

At constant term, to calculate the final value of an annuity at maturity/postnumerando, we can therefore only work on the capitalization factor multiplied by the final annuity amount.

✍**Example:**

We want to calculate the final value of a postnumerando annuity of $3,500$.- paid during 10 periods and calculated with the periodic effective interest rate of 6%.

Payments held on dates $1,2$, and 10. The payment $C_0=3,500$.- of date 1 has for acquired value on the date 10: $C_0(1+t\%)^9$. Similarly, the payment at date 2 earns interest for 8 years. Its value gained at date 10 is therefore : $C_0(1+t\%)^8$, etc. Finally, at the end, the payment at date 10 (which we have just put in the bank) has the value C_0. The acquired value of the 10 payments is therefore, setting $f_c=1+t\%$ (we will prove the simplifications right after):

$$\begin{aligned}C_0(f_c^9+f_c^8+\ldots+f_c^1+f_c^0)=C_0(f_c^9+f_c^8+\ldots+f_c^1+1)=C_0\frac{1-f_c^{10}}{1-f_c}=C_0\frac{f_c^{10}-1}{f_c-1}\\=C_0\frac{f_c^{10}-1}{t\%}=46,132.80.\text{-}\end{aligned} \tag{15.3.263}$$

In Microsoft® Excel® 14.0.7106 we simply write:

```
=3500*FV(6%,10,-1,0,0)=46,132.80.-
```

Therefore the postnumerando annuity is a payment with constant terms and at constant rates over a number of given periods leading to a simple geometric sequence.

Let us recall (again!) that:

$$C_n=C_0f_c^n \tag{15.3.264}$$

For the postnumerando annuity with constant terms, we then have the general form:

$$C_n=C_0f_c^0+C_0f_c^1+C_0f_c^2+\ldots+C_0f_c^{n-1} \tag{15.3.265}$$

Which is written:

$$C_n=C_0(f_c^0+f_c^1+f_c^2+\ldots+f_c^{n-1})=C_0(1+f_c^1+f_c^2+\ldots+f_c^{n-1})=C_0s_{\overline{n|}} \tag{15.3.266}$$

Therefore:

$$s_{\overline{n|}}=\sum_{t=0}^{n-1}f_c^t \tag{15.3.267}$$

In fact, we have a geometric series of reason q (see section Sequences and Series page 1656). Since then:

$$\begin{aligned}S_n&=a_0+a_1+\ldots+a_{n-1}\\-qS_n&=qa_0+qa_1+\ldots+qa_{n-1}=a_1+a_2+\ldots+a_n\\\hline S_n-qS_n&=a_0-a_n\Rightarrow S_n=\frac{a_0-a_n}{1-q}=a_0\frac{1-q^n}{1-q}\end{aligned} \tag{15.3.268}$$

Therefore:

$$s_{\overline{n}|}=\sum_{t=0}^{n-1} f_c^t = f_c^0\frac{1-f_c^n}{1-f_c}=1\frac{1-f_c^n}{1-f_c}=\frac{f_c^n-1}{f_c-1} \tag{15.3.269}$$

Finally:

$$\boxed{s_{\overline{n}|}=\frac{f_c^n-1}{t\%}} \tag{15.3.270}$$

✍**Example:**

So we have for your example ten periods (and therefore ten terms with $n=10$):

$$C_{10}=3,500s_{\overline{n}|}=3,500\frac{f_c^n-1}{t\%}=3,500\frac{1.06^{10}-1}{0.06}=46,132.60.\text{-} \tag{15.3.271}$$

This capital corresponds then to the sum gained after ten periods.

The method of calculating the "present value of an annuity at maturity/postnumerando" works on the same principle but in reverse according to the relation proved above:

$$C_0=C_nf_e^n \tag{15.3.272}$$

So if the terms (amounts paid) are constant we can write:

$$C_0=C_n(f_e^1+f_e^2+\ldots+f_e^n)=C_na_{\overline{n}|} \tag{15.3.273}$$

Therefore:

$$a_{\overline{n}|}=\sum_{t=1}^{n} f_e^t \tag{15.3.274}$$

Or:

$$\begin{array}{r}
S_n=a_0+a_1+\ldots+a_n\\
-qS_n=qa_0+qa_1+\ldots+qa_n=a_2+a_3+\ldots+a_{n+1}\\
\hline
S_n-qS_n=a_0-a_{n+1}\Rightarrow S_n=\dfrac{a_1-a_{n+1}}{1-q}=a_1\dfrac{1-q^n}{1-q}
\end{array} \tag{15.3.275}$$

Therefore:

$$a_{\overline{n}|}=\sum_{t=1}^{n} f_e^t=f_e^1\frac{1-f_e^n}{1-f_e}=f_e\frac{1-f_e^n}{1-\dfrac{1}{f_c}}=\frac{1}{f_c}\frac{1-f_e^n}{\dfrac{f_c-1}{f_c}}=\frac{1-f_e^n}{f_c-1}=\frac{1-f_e^n}{t\%} \tag{15.3.276}$$

Finally:

$$\boxed{a_{\overline{n}|}=\frac{1-f_e^n}{t\%}} \tag{15.3.277}$$

Remark

The value $C_0 = C_n a_{\overline{n}|}$ correspond therefore to the amount we would need to put on a savings account at the rate of $t\%$to be able to make a constant periodic removal C_n during n periods and thereby settle the account.

✍**Example:**

Let us calculate the present value of a postnumerando annuity of $3,500$.- paid during 10 years at the rate of 6% interest:

$$C_0 = C_n\left(\frac{1-\left(\dfrac{1}{1+t\%}\right)^n}{t\%}\right) = 3,500\left(\frac{1-\left(\dfrac{1}{1+6\%}\right)^{10}}{6\%}\right) = 25,760.30.\text{-} \qquad (15.3.278)$$

Or in Microsoft® Excel® 14.0.1706:

```
=3500*PV(6%,10,-1,0)=25,760.30.-
```

We also have the following relations between actual and final postnumerando rents:

$$\boxed{\left.\begin{aligned} a_{\overline{n}|} &= \frac{1-f_e^n}{t\%} \\ s_{\overline{n}|} &= \frac{f_c^n-1}{t\%} \end{aligned}\right\} \Rightarrow a_{\overline{n}|} = f_e^n s_{\overline{n}|}} \qquad (15.3.279)$$

We also have the following chain rule operations:

$$\begin{aligned} a_{\overline{n+k}|} &= a_{\overline{n}|} + f_e^n a_{\overline{k}|} = f_e^k a_{\overline{n}|} + a_{\overline{k}|} \\ s_{\overline{n+k}|} &= s_{\overline{n}|} + f_c^n s_{\overline{k}|} = f_c^k s_{\overline{n}|} + s_{\overline{k}|} \end{aligned} \qquad (15.3.280)$$

Remark

It is clear that since known $a_{\overline{n}|}$, f_e^n, $t\%$ that $n = \dfrac{\ln(1-t\% a_{\overline{n}|})}{\ln(f_e)}$ and so on for all other types of annuity.

15.3.7.2 Praenumerando annuities

The method of calculating the "present value of an annuity in advance/praenumerando" works on the same principle as the last one still using the relation $C_0 = C_n f_e^n$, but this time the terms of the geometric sequence change since the payment is done in advance:

$$C_0 = C_n\left(f_e^0 + f_e^1 + f_e^2 + \ldots + f_e^{n-1}\right) = C_n \ddot{a}_{\overline{n}|} \qquad (15.3.281)$$

Therefore:

$$\ddot{a}_{\overline{n}|}=\sum_{t=0}^{n} f_e^t \tag{15.3.282}$$

But:

$$\begin{array}{r}
S_n=a_0+a_1+\ldots+a_{n-1}\\
-qS_n=qa_0+qa_1+\ldots+qa_{n-1}=a_1+a_2+\ldots+a_n\\
\hline
S_n-qS_n=a_0-a_n\Rightarrow S_n=\dfrac{a_0-a_n}{1-q}=a_0\dfrac{1-q^n}{1-q}
\end{array} \tag{15.3.283}$$

Therefore:

$$\ddot{a}_{\overline{n}|}=\sum_{t=0}^{n-1} f^t=f_e^0\frac{1-f_e^n}{1-f_e}=1\frac{1-f_e^n}{1-\dfrac{1}{f_c}}=\frac{1-f_e^n}{\dfrac{f_c-1}{f_c}} \tag{15.3.284}$$

Finally:

$$\boxed{\ddot{a}_{\overline{n}|}=\frac{1-f_e^n}{t\% f_e}} \tag{15.3.285}$$

Remark

For the same number of periods and the same interest rate, we obviously have $\ddot{a}_{\overline{n}|}\geq a_{\overline{n}|}$ as $\ddot{a}_{\overline{n}|}=f_e a_{\overline{n}|}$.

✍**Example:**

Let us calculate the present value of a praenumerando annuity of $3,500$.- paid during 10 years at the rate of 6% interest:

$$C_0=C_n\left(\frac{1-\left(\dfrac{1}{1+t\%}\right)^n}{t\%\left(\dfrac{1}{1+t\%}\right)}\right)=3,500\left(\frac{1-\left(\dfrac{1}{1+6\%}\right)^{10}}{6\%\left(\dfrac{1}{1+6\%}\right)}\right)=27,305.92.\text{-} \tag{15.3.286}$$

Or in Microsoft® Excel® 14.0.1706:

```
=3500*PV(6%,10,-1,0,1)=27,305.92.-
```

The method of calculating the "final value of a rent in advance/praenumerando" works on the same principle as the last one using the relation $C_n=C_0 f_c^n$ but this time the terms of the geometric sequence change since the payment is done in advance:

$$C_n=C_0\left(f_c^1+f_c^2+\ldots+f_c^n\right)=C_0\ddot{s}_{\overline{n}|} \tag{15.3.287}$$

Therefore:

$$\ddot{s}_{\overline{n}|}=\sum_{t=1}^{n} f_c^t \tag{15.3.288}$$

As we have proved in the section Sequences and Series (page 1679) during our study of geometric series that:

$$S_n = u_0 \frac{(1-q^{n+1})}{(1-q)} \tag{15.3.289}$$

Therefore:

$$\ddot{s}_{\overline{n}|} = \sum_{t=1}^{n} f_c^t = f_c^1 \frac{1-f_c^n}{1-f_c} = \frac{f_c^n - 1}{\dfrac{f_c - 1}{f_c}} = \frac{f_c^n - 1}{\dfrac{t\%}{1-t\%}} \tag{15.3.290}$$

finally noting $d = \dfrac{t\%}{1-t\%}$ we have:

$$\boxed{\ddot{s}_{\overline{n}|} = \frac{f_c^n - 1}{d}} \tag{15.3.291}$$

Remarks

R1. With the same notation we have also the present value of the praenumerando annuity that is written $\ddot{a}_{\overline{n}|} = \dfrac{1-f_e^n}{d}$.

R2. For the same number of periods and the same interest rate, we obviously have $\ddot{s}_{\overline{n}|} \geq s_{\overline{n}|}$ as $\ddot{s}_{\overline{n}|} = f_c s_{\overline{n}|}$.

✍**Example:**

Let us calculate the final value of a praenumerando annuity of $3,500$.- paid during 10 years at the rate of 6% interest:

$$C_0 = C_n \left(\frac{1+t\%)^n - 1}{t\% \left(\dfrac{1}{1+t\%} \right)} \right) = 3,500 \left(\frac{(1+6\%)^{10} - 1}{6\% \left(\dfrac{1}{1+6\%} \right)} \right) = 25,760.30.\text{-} \tag{15.3.292}$$

Or in Microsoft® Excel® 14.0.1706:

```
=3500*FV(6%,10,-1,0,1)=48,900.75.-
```

15.3.8 Rounding

Rounding a numerical value means replacing it by another value that is approximately equal but has a shorter, simpler, or more explicit representation. Rounding is often done to obtain a value that is easier to report and communicate than the original. Rounding can also be important to avoid misleadingly precise reporting of a computed number, measurement or estimate; for example, a quantity that was computed as $123,456$ but is known to be accurate only to within a few hundred units is better stated as "about $123,500$".

On the other hand, rounding of exact numbers will introduce some round-off error in the reported result. Rounding is almost unavoidable when reporting many computations — especially when dividing two numbers in integer or fixed-point arithmetic; when computing mathematical functions such as square roots, logarithms, and sines; or when using a floating point representation with a fixed number of significant digits. In a sequence of calculations, these rounding errors generally accumulate, and in certain ill-conditioned cases they may make the result meaningless.

To round a number x to the nearest multiple of $1/n$ the relation to be used is as follows:

$$f(x,n)=\frac{\mathrm{E}[nx+0.5]}{n} \tag{15.3.293}$$

The proof is almost intuitive. Just imagine the real axis and cut it into $1/n$ small intervals. Then given x, the number of these intervals will be given by:

$$\frac{x}{1/n}=nx \tag{15.3.294}$$

Finally, to know the number strictly less than the desired multiple, we take the integer value of the last relation and multiply it by $1/n$ such that:

$$f_{\text{inf}}(x,n)=\lfloor x\rfloor=\mathrm{E}[nx]\frac{1}{n}=\frac{\mathrm{E}[nx]}{n} \tag{15.3.295}$$

Notice that the famous "round down" function above, formally named "floor function" is alos sometimes defined as a function $\lfloor x\rfloor:\mathbb{R}\rightarrow\mathbb{Z}$ with the following formula:

$$\lfloor x\rfloor:=\max\{k\in\mathbb{Z}\,|\,k\leq x\} \tag{15.3.296}$$

If, however, we wish to have the number rounded to the nearest multiple, then we see with a linear regression that it is necessary to add 0.5 as:

$$\boxed{f(x,n)=\frac{\mathrm{E}[nx+0.5]}{n}} \tag{15.3.297}$$

To round to the upper multiple we add one such that:

$$f_{\text{sup}}(x,n)=\lceil x\rceil=\frac{\mathrm{E}[nx+1]}{n} \tag{15.3.298}$$

OK... this seems simple but there's a lot more to rounding than might at first meet the eye...:

- Round-Toward-Nearest
- Round-Half-Up (Arithmetic Rounding)
- Round-Half-Down
- Round-Half-Even (Banker's Rounding)
- Round-Half-Odd
- Round-Ceiling (Positive Infinity)
- Round-Floor (Negative Infinity)
- Round-Toward-Zero
- Round-Away From-Zero
- Round-Up

- Round-Down
- Truncation (Chopping)
- Round-Alternate
- Round-Random (Stochastic Rounding)
- Sign-Magnitude Binary Values
- Rounding Signed Binary Values

For business training purpose, among this list, let us just introduce the "Banker's rounding":

If values are always rounded in the same direction (for example, if $+5.5$ rounds up to $+6$ and $+6.5$ rounds up to $+7$, as is the case with the "Round-Half-Up" algorithm presented earlier), the result can be a bias that grows as more and more rounding operations are performed. One solution toward minimizing this bias is to sometimes round up and sometimes round down.

In the case of the round-half-even algorithm (which is often referred to as "Bankers Rounding" because it is commonly used in financial calculations), "half-way" values are rounded toward the nearest even number. Thus, $+5.5$ will round up to $+6$ and $+6.5$ will round down to $+6$.

This algorithm is, by definition, symmetric for positive and negative values, so both -5.5 and -6.5 will round to the nearest even value, which is -6.

In the case of data sets that feature a relatively large number of "half-way" values (financial records often provide a good example of this), the round-half-even algorithm performs significantly better than the Round-Half-Up scheme in terms of total bias (it is for this reason that the use of round-half-even is a legal requirement for many financial calculations around the world!).

As surprising as it can be, a spreadsheet software like Microsoft® Excel® seems to not implement by default a simple function to do such a rounding... (when we know that this a legal requirement).

Remark

It turns out that IBM SAS implements round to the nearest number, and, if equidistant, round away from zero (RA0) with the functions `round()` and `put()`. That is the values of $-2.5, -1.5, 1.5, 2.5$ are rounded to $-3, -2, 2, 3$. In the `R` software however, the `base::round()` function uses the IEEE 754 standard, differing from RA0 only for the equidistant case. `R` rounds to even (R2E) and $-2.5, 2.5$ will round to -2 and 2, respectively.

15.3.9 Loans Amortization/Repayments

Individuals and companies often use loans (credit) as a financial way to find money. Here we will define the main types of loans encountered in practice and the mathematical relations that characterize them.

Definitions (#15.3.673):

D1. In finance, a "loan" is a debt provided by an entity (organization or individual) to another entity at an interest rate, and evidenced by a note which specifies, among other things, the principal amount, interest rate, and date of repayment. A loan entails the reallocation of the subject asset(s) for a period of time, between the lender and the borrower.

D2. We name "indivis loan", a loan with only one lender, usually a financial institution.

D3. As for equity management (see further below) a "guarantor" is the party exposed to the loan risk, but he don not present credit risk itself. We thus avoid the problem of two-sided credit risk.

Remark

When talking in financial terms, a loan is usually followed by an interest on the amount unlike a credit, which might or might not be followed by an interest. As they seems not to be a consensus on the difference between loan and credit some people say that credit grants them the ability to borrow, while a loan is actually the act of borrowing. If a bank gives me a 500.- line of credit, I can, at some date in the future when I want to, borrow money from them. If a bank gives me a 500.- loan, I take possession of the money today.

In a loan, the borrower initially receives or borrows an amount of money, named as we already know the "principal", from the lender, and is obligated to pay back or repay an equal amount of money to the lender at a later time.

The major variables in a mortgage calculation include loan principal, balance, periodic compound interest rate, number of payments per year, total number of payments and the regular payment amount. More complex calculators can take into account other costs associated with a mortgage, such as local and state taxes, and insurance.

When purchasing a new home, most buyers choose to finance a portion of the purchase price via the use of a mortgage. Prior to the wide availability of mortgage calculators, those wishing to understand the financial implications of changes to the five main variables in a mortgage transaction were forced to use compound interest rate tables. These tables generally required a working understanding of compound interest mathematics for proper use. In contrast, mortgage calculators make answers to questions regarding the impact of changes in mortgage variables available to everyone.

Mortgage calculators can be used to answer such questions as:

If one borrows $250,000$.- at a 7% annual interest rate and pays the loan back over thirty years, with $3,000$.- annual property tax payment, $1,500$.- annual property insurance cost and 0.5%

annual private mortgage insurance payment, what will the monthly payment be? The answer is $2,142.42$.-.

Mainly we consider two type of loans:

D1. A "secured loan" is a loan in which the borrower pledges some asset (e.g. a car or property) as collateral.

D2. An "unsecured loan" is monetary loan that is not secured against the borrower's assets. These may be available from financial institutions under many different guises or marketing packages (credit card, peer-to-peer landing, etc.).

The main points of interest on loans are:

- Know the state of the debt at any time
- Know the amount repayable in each period
- Know the interest due each period

Definition (#15.3.674): We name "annuities", payments made in the context of the clearance of a loan. An annuity includes a part of refund R also named "financial depreciation" and part I of interest according to the relation:

$$\begin{gathered}\text{Annuity}=\text{Refund}+\text{Interest}\\ A=R+I\end{gathered}\tag{15.3.299}$$

The decomposition of the annuity in a depreciation part and interest is an important concept not only in finance but also in accounting. Indeed, the part of financial amortization corresponds to a debt repayment at the difference of the interest that is a financial burden.

We will study here three types of loans:

1. Loan with fixed maturity
2. Loans with constant repayments
3. Loans with constant annuities (the most practised)

Remarks

R1. We consider here periodic loans. The transition from one temporal period to another and the calculation of an equivalent rate will be based on relation already proved before.

R2. Stable monthly annuities are named obviously "monthly payments".

15.3.9.1 Fixed-Term Loan

Definition (#15.3.675): We speak about "fixed-term loan" or "in fine loan" when at each period the annuity includes only the part of interest! The last period the annuity includes interest and all (!) the repayment of the loan.

Remark

This model of amortization is particularly used in bonds that we will study later.

The following relations make possible to establish any element of the "amortization table".

Thus, the status of debt (loan) C on n years is at the beginning of the year k is always:

$$C_k = C \quad \forall k < n \in \mathbb{N}^* \tag{15.3.300}$$

The payment (amortization) R_k performed at the en of the year k is equal to the accumulated depreciation S_k at the end of the year k and as it is only made last year n such that:

$$R_k = S_k = \begin{cases} 0 \text{ if } k < n \\ C \text{ if } k = n \end{cases} \tag{15.3.301}$$

The paid I_k will be constant throughout the loan term according to an interest rate $t\%$ on borrowed capital C as (simple interest):

$$I = I_k = t\% C_k = t\% C \quad \forall k \tag{15.3.302}$$

The annuity becomes therefore:

$$A_k = R_k + I_k \tag{15.3.303}$$

✍**Example:**

Let us see the amortization table of a loan of $1,000$.- at 10% year repaid at maturity after 4 years. The corresponding amortization table will be:

Period k	**Debt** C_k	**Amort.** R_k	**Cumulated Amort.** S_k	**Interest** I_k	**Annuity** A_k
1	$1,000$	0	0	100	100
2	$1,000$	0	0	100	100
3	$1,000$	0	0	100	100
4	1.000	$1,000$	$1,000$	100	$1,100$

Table 15.40: **Fixed-Term loan amortization table**

The cost of credit is the sum of interest that is 400.-.

15.3.9.2 Loan with constant amortization

Definition (#15.3.676): We speak of a "constant amortization loan" when the annual amount repaid (amortization) is constant, that is to say identical from year to year (intuitive case).

The following relation make possible to establish any element of this amortization table (no more details are needed because it is very trivial):

$$\begin{aligned}C_K &= C-k\frac{C}{n}+\frac{C}{n}=\frac{C}{n}(1+n-k)\\ R_k &= R=\frac{C}{n}\\ S_k &= k\frac{C}{n}\\ I_k &= t\%C_k\\ A_k &= R_k+I_k=R+I_k\end{aligned} \tag{15.3.304}$$

✍**Example:**

A loan of $1,000$.- at 10% per year is reimbursed by constant amortization in 4 years. The corresponding amortization table will be:

Period k	**Debt** C_k	**Amort.** R_k	**Cumulated Amort.** S_k	**Interest** I_k	**Annuity** A_k
1	1000	250	250	100	350
2	750	250	500	75	325
3	500	250	750	50	300
4	250	250	$1,000$	25	275

Table 15.41: **Constant amortization loan table**

The cost of credit is the sum of interest that is 250.-. So we pay less than with the previous system.

15.3.9.3 Loan with constant annuity

This is the most common case (the definition is in the title itself). It is used by most small credit and leasing institutions. The borrower knows in advance the amount he will have to pay each year. In other words, it is as if it were a capital C that must be settle each period by a constant withdrawal A: which consists to determine the present value of a postnumerando annuity such that:

$$C=Aa_{\overline{n}|} \tag{15.3.305}$$

The following relations are then used to establish any element of the amortization table:

$$A=A_k=\frac{C}{a_{\overline{n}|}} \tag{15.3.306}$$

and because $C=Aa_{\overline{n}|}$, then:

$$C_k=Aa_{\overline{n-k+1}|} \tag{15.3.307}$$

therefore, when $k=1$, we have in accordance with what we expect $C_1=Aa_{\overline{n}|}$.

And therefore the amortization is equal to:

$$R_k=A_k-I_k=A-I_k=A-t\%C_k \tag{15.3.308}$$

The cumulated depreciation is a little less obvious to find with common sense, let us take for the proof a depreciation A with a rate $t\%$ on n periods. Then we have by definition:

$$S_k=\sum_{i=1}^{k}R_i \tag{15.3.309}$$

with $k=2$ and $n=3$ we get:

$$\begin{aligned}R_1&=A-t\%C_1\\ R_2&=A-t\%C_2\end{aligned} \tag{15.3.310}$$

Therefore:

$$\begin{aligned}S_2&=2A-t\%(C_1+C_2)=2A-t\%(Aa_{\overline{3}|}+Aa_{\overline{2}|})=A\left[2-t\%(a_{\overline{3}|}+a_{\overline{2}|})\right]\\ &=A\left[2-t\%(f_e^1+f_e^2+f_e^3+f_e^1+f_e^2)\right]=A\left[2-t\%(2f_e^1+2f_e^2+f_e^3)\right]\\ &=A\left[2-t\%(2\frac{1}{(1+t\%)^1}+2\frac{1}{(1+t\%)^2}+\frac{1}{(1+t\%)^3})\right]=A\left[2-t\%\left(\frac{2(1+t\%)^2+2(1+t\%)+1}{(1+t\%)^3}\right)\right]\\ &=A\frac{1}{(1+t\%)^3}\left[2(1+t\%)^3-t\%(2(1+t\%)^2+2(1+t\%)+1)\right]\\ &=A\frac{1}{(1+t\%)^3}\left[2(1+3t\%+3t\%^2+t\%^3)-t\%(5+6t\%+2t\%^2)\right]\\ &=A\frac{1}{(1+t\%)^3}\left[2+t\%\right]=Af_e^3\left[\frac{t\%}{t\%}2+t\%\right]=Af_e^3\left[\frac{2t\%+t\%^2}{t\%}\right]\\ &=Af_e^3\left[\frac{1+2t\%+t\%^2-1}{t\%}\right]=Af_e^3\left[\frac{(1+t\%)^2-1}{t\%}\right]=Af_e^3s_{\overline{2}|}\end{aligned} \tag{15.3.311}$$

Therefore:

$$S_k=Af_e^n s_{\overline{k}|} \tag{15.3.312}$$

and also:

$$I_k=t\%C_k \tag{15.3.313}$$

✍**Example:**

A loan of $1,000$.- at 10% per year is reimbursed by constant annuity in 4 years. The corresponding amortization table is:

Period k	**Debt** C_k	**Amort.** R_k	**Cumulated Amort.** S_k	**Interest** I_k	**Annuity** A_k
1	1000	215	215	100	315
2	785	237	452	78	325
3	548	261	713	55	325
4	287	287	$1,000$	29	325

Table 15.42: **Constant annuity loan table**

The cost of credit is the sum of interest that is 262.-. This result could be obtained by $nA-C$.

Remark

Financial institutions add different charges to credit as filing fees, insurance costs, guarantee fees, etc. Adding these fees has the effect of increasing the interest rate whose final real value (all inclusive) is named "global effective rate" (GER). Because each financial institution made its small recipes or that each country imposes a particular calculation method (the obligation to communicate the GER and the associated methodology is specified in many countries by legislation to ensure that consumers are not deceived) we did not want to develop the subject in this textbook. However, the reader interested may refer to Econometrics exercises available on the associated website of this textbook where he will be able to find a concrete special case example!

15.3.9.3.1 Equivalent Monthly Installment (EMI)

The "Equivalent Monthly Instalment" (EMI) is the same thing as the loan with constant annuity but just based on a different word used by professional of actuarial science.

The EMI is however well known because the main idea is to have a unique simple formula to get the cost of the credit in one shot. That means the value of 262.- of the previous example given in the table above (remember that this value is rounded as 261.88.-).

Let's say, an amount P is borrowed on which interest is payable at the rate of i per installment period. This amount is to be paid back along with interest in n equal installments.

Let these installments be $I_1, I_2, I_3, \ldots, I_n$ respectively. Since they are all equal, we can say:

$$I_1 = I_2 = I_3 = \cdots = I_n = I \tag{15.3.314}$$

Each installment comprises some part of the principal P that is paid back, the rest is interest on the amount that was outstanding for that installment period. Let the part of the principal that is paid back with $I_1, I_2, I_3, \ldots, I_n$ respectively be $P_1, P_2, P_3, \ldots, P_n$. These principal payments must add up to the original amount P that was borrowed:

$$P_1 + P_2 + P_3 + \cdots + P_n = P \tag{15.3.315}$$

Now let's talk about interest. Don't forget that the idea is that the interest payable in this regard is $P \cdot i$ which will be paid along with a given P_1 to give the I_1 to pay, i.e. $I_1 = P_1 + P \times i$. At the end of the second installment period, only the amount $P - P_1$ will have been outstanding for the same period. Therefore, only $[P - P_1] \cdot i$ is payable as interest for the second installment period which will be paid along with P_2 when I_2 is paid. Similarly, at the end of the third installment period, interest will be paid only on $[P - (P_1 + P_2)]$ for one installment period along with P_3 when I_3 is paid.

Making the above argument for all installments, we get:

$$\begin{gathered}
I_1 = P_1 + P \cdot i \\
I_2 = P_2 + [P - P_1] \cdot i \\
I_3 = P_3 + [P - (P_1 + P_2)] \cdot i \\
\vdots \\
I_n = P_n + [P - (P_1 + P_2 + \cdots + P_{n-1})] \cdot i
\end{gathered} \tag{15.3.316}$$

If we add up the above equations, we get:

$$\begin{gathered}
I_1 + I_2 + I_3 + \cdots + I_n = [P_1 + P \cdot i] + [P_2 + [P - P_1] \cdot i] + [P_3 + [P - (P_1 + P_2)] \cdot i] \\
+ \cdots + [P_n + [P - (P_1 + P_2 + \cdots + P_{n-1})] \cdot i] \\
I_1 + I_2 + I_3 + \cdots + I_n = [P_1 + P_2 + P_3 + \cdots + P_n] + P \cdot i + [P - P_1] \cdot i \\
+ [P - (P_1 + P_2)] \cdot i + \cdots + [P - (P_1 + P_2 + \cdots + P_n)] \cdot i \\
I_1 + I_2 + I_3 + \cdots + I_n = [P_1 + P_2 + P_3 + \cdots + P_n] + P \cdot i + P \cdot i - P_1 \cdot i + P \cdot i \\
- (P_1 + P_2) \cdot i + \cdots + P \cdot i - (P_1 + P_2 + \cdots + P_n) \cdot i \\
I_1 + I_2 + I_3 + \cdots + I_n = [P_1 + P_2 + P_3 + \cdots + P_n] + n \cdot P \cdot i \\
- [P_1 + (P_1 + P_2) + \cdots + (P_1 + P_2 + \cdots + P_{n-1})] \cdot i
\end{gathered} \tag{15.3.317}$$

Remember that $I_1 = I_2 = I_3 = \cdots = I_n = I$ and $P_1 + P_2 + P_3 + \cdots + P_n = P$:

$$n \cdot I = P + n \cdot P \cdot i - [P_1 + (P_1 + P_2) + \cdots + (P_1 + P_2 + \cdots + P_{n-1})] \cdot i \tag{15.3.318}$$

Now, let j be a natural number such that $j \in [2, n-1]$. Then I_j and I_{j+1} can be written as follows:

$$\begin{gathered}
I_j = P_j + \left[P - \sum_{k=1}^{j-1} P_k \right] \cdot i \\
I_{j+1} = P_{j+1} + \left[P - \sum_{k=1}^{j} P_k \right] \cdot i
\end{gathered} \tag{15.3.319}$$

Consider $I_{j+1}-I_j$:

$$\begin{aligned}
I_{j+1}-I_j &= P_{j+1}+\left[P-\sum_{k=1}^{j}P_k\right]\cdot i-\left(P_j+\left[P-\sum_{k=1}^{j-1}P_k\right]\cdot i\right)\\
&= P_{j+1}+P\cdot i-\sum_{k=1}^{j}P_k\cdot i-P_j-\left[P-\sum_{k=1}^{j-1}P_k\right]\cdot i\\
&= P_{j+1}+\cancel{P\cdot i}-\sum_{k=1}^{j}P_k\cdot i-P_j-\cancel{P\cdot i}+\sum_{k=1}^{j-1}P_k\cdot i\\
&= P_{j+1}-\left(\sum_{k=1}^{j-1}P_k\cdot i+P_j\cdot i\right)-P_j+\sum_{k=1}^{j-1}P_k\cdot i\\
&= P_{j+1}-\cancel{\sum_{k=1}^{j-1}P_k}\cdot i-P_j\cdot i-P_j+\cancel{\sum_{k=1}^{j-1}P_k}\cdot i P_k\cdot i\\
&= P_{j+1}-P_j\cdot i-P_j
\end{aligned} \tag{15.3.320}$$

From $I_1=I_2=I_3=\cdots=I_n=I$ we then obviously have $I_j=I_{j+1}=I$. Therefore the last equality :

$$I_{j+1}-I_j=P_{j+1}-P_j\cdot i-P_j \tag{15.3.321}$$

Can be simplified to:

$$0=P_{j+1}-P_j\cdot i-P_j \tag{15.3.322}$$

And rearranged into (with $j\in[2,n-1]$):

$$P_{j+1}=P_j\cdot(i+1) \tag{15.3.323}$$

Again, since $I_1=I_2=I$:

$$\begin{aligned}
\cancel{I_2}-\cancel{I_1}&=P_2-P_1\cdot i-P_1\\
0&=P_2-P_1\cdot i-P_1\\
P_2&=P_1\cdot(i+1)
\end{aligned} \tag{15.3.324}$$

If we expand out $P_{j+1}=P_j\cdot(i+1); j\in[2,n-1]$ and add $P_2=P_1\cdot(i+1)$ to the resulting set of equations, we get:

$$\begin{aligned}
P_1&=P_1\\
P_2&=P_1\cdot(i+1)\\
P_3&=P_2\cdot(i+1)\\
&\vdots\\
P_j&=P_{j-1}\cdot(i+1)\\
&\vdots\\
P_{n-1}&=P_{n-2}\cdot(i+1)\\
P_n&=P_{n-1}\cdot(i+1)
\end{aligned} \tag{15.3.325}$$

Multiplying the above equations gives us:

$$\begin{aligned}
P_1\cdot P_2\cdot P_3\cdot\ldots\cdot P_{n-1}\cdot P_n &= P_1\cdot[P_1\cdot(i+1)]\cdot[P_2\cdot(i+1)]\cdot\ldots\\
&\cdot[P_{n-2}\cdot(i+1)]\cdot[P_{n-1}\cdot(i+1)]\\
\cancel{P_1}\cdot\cancel{P_2}\cdot\cancel{P_3}\cdot\ldots\cdot\cancel{P_{n-1}}\cdot P_n &= P_1\cdot\left[\cancel{P_1}\cdot(i+1)\right]\cdot\left[\cancel{P_2}\cdot(i+1)\right]\cdot\ldots\\
&\cdot[\cancel{P_{n-2}}\cdot(i+1)]\cdot[\cancel{P_{n-1}}\cdot(i+1)]\\
P_n &= P_1\cdot[(i+1)\cdot(i+1)\cdot\ldots\cdot(n-1)\text{ times }]\\
P_n &= P_1\cdot(i+1)^{n-1}
\end{aligned} \tag{15.3.326}$$

Now we would like to have an expression for $\sum_{k=1}^{j} P_k; j\in[1,n]$. The same set of equations that helped us figure the last relation will be useful in this regard:

$$\begin{aligned}
\sum_{k=1}^{j} P_k &= P_1+P_2+P_3+\ldots+P_j\\
\sum_{k=1}^{j} P_k &= P_1+P_1\cdot(i+1)+P_2\cdot(i+1)+\cdots+P_{j-1}\cdot(i+1)\\
\sum_{k=1}^{j} P_k &= P_1+[P_1+P_2+\cdots+P_{j-1}]\cdot(i+1)\\
\sum_{k=1}^{j} P_k &= P_1+[P_1+P_2+\cdots+P_{j-1}+P_j-P_j]\cdot(i+1)\\
\sum_{k=1}^{j} P_k &= P_1+\left[\sum_{k=1}^{j} P_k-P_j\right]\cdot(i+1)\\
\sum_{k=1}^{j} P_k &= P_1+\left(\sum_{k=1}^{j} P_k\right)\cdot(i+1)-P_j\cdot(i+1)\\
\cancel{\sum_{k=1}^{j} P_k} &= P_1+i\cdot\sum_{k=1}^{j} P_k+\cancel{\sum_{k=1}^{j} P_k}-P_j\cdot(i+1)\\
0 &= P_1+i\cdot\sum_{k=1}^{j} P_k-P_j\cdot(i+1)
\end{aligned} \tag{15.3.327}$$

Hence after rearranging:

$$\sum_{k=1}^{j} P_k=\frac{P_j\cdot(i+1)-P_1}{i}; j\in[1,n] \tag{15.3.328}$$

We get the following relation by using the relation above:

$$\begin{aligned} P_1 &= \frac{P_1\cdot(i+1)-P_1}{i} \\ P_1+P_2 &= \frac{P_2\cdot(i+1)-P_1}{i} \\ P_1+P_2+P_3 &= \frac{P_3\cdot(i+1)-P_1}{i} \\ &\vdots \\ P_1+P_2+P_3+\cdots+P_{n-1} &= \frac{P_{n-1}\cdot(i+1)-P_1}{i} \end{aligned} \tag{15.3.329}$$

Let us add these up to get the following:

$$\begin{gathered} P_1+(P_1+P_2)+(P_1+P_2+P_3)+\cdots+(P_1+P_2+P_3+\cdots+P_{n-1}) \\ = \frac{P_1\cdot(i+1)-P_1}{i}+\frac{P_2\cdot(i+1)-P_1}{i}+\frac{P_3\cdot(i+1)-P_1}{i}+\cdots \\ +\frac{P_{n-1}\cdot(i+1)-P_1}{i} \\ P_1+(P_1+P_2)+(P_1+P_2+P_3)+\cdots+(P_1+P_2+P_3+\cdots+P_{n-1}) \\ = \frac{(P_1\cdot(i+1)-P_1)+(P_2\cdot(i+1)-P_1)+(P_3\cdot(i+1)-P_1)+\cdots+(P_{n-1}\cdot(i+1)-P_1)}{i} \\ P_1+(P_1+P_2)+(P_1+P_2+P_3)+\cdots+(P_1+P_2+P_3+\cdots+P_{n-1}) \\ = \frac{(P_1+P_2+P_3+\cdots+P_{n-1})\cdot(i+1)-P_1\cdot(n-1)}{i} \\ P_1+(P_1+P_2)+(P_1+P_2+P_3)+\cdots+(P_1+P_2+P_3+\cdots+P_{n-1}) \\ = \frac{(P_1+P_2+P_3+\cdots+P_{n-1}+P_n-P_n)\cdot(i+1)-P_1\cdot(n-1)}{i} \end{gathered} \tag{15.3.330}$$

Let us substitute the value of $P_1+P_2+P_3+\cdots+P_{n-1}+P_n=P$ into the last relation above. Then we get:

$$\begin{gathered} P_1+(P_1+P_2)+(P_1+P_2+P_3)+\cdots+(P_1+P_2+P_3+\cdots+P_{n-1}) \\ = \frac{(P-P_n)\cdot(i+1)-P_1\cdot(n-1)}{i} \end{gathered} \tag{15.3.331}$$

Let us substitute into this relation the values of:

$$P_n = P_1\cdot(i+1)^{n-1} \tag{15.3.332}$$

derived earlier above. Then we get:

$$\begin{gathered} P_1+(P_1+P_2)+(P_1+P_2+P_3)+\cdots+(P_1+P_2+P_3+\cdots+P_{n-1}) \\ = \frac{(P-P_1\cdot(i+1)^{n-1})\cdot(i+1)-P_1\cdot(n-1)}{i} \\ P_1+(P_1+P_2)+(P_1+P_2+P_3)+\cdots+(P_1+P_2+P_3+\cdots+P_{n-1}) \\ = \frac{P\cdot(i+1)-P_1\cdot(i+1)^n-P_1\cdot(n-1)}{i} \\ P_1+(P_1+P_2)+(P_1+P_2+P_3)+\cdots+(P_1+P_2+P_3+\cdots+P_{n-1}) \\ = \frac{P\cdot(i+1)-P_1\cdot((i+1)^n+(n-1))}{i} \end{gathered} \tag{15.3.333}$$

Let us now substitute the value of $P_1+(P_1+P_2)+(P_1+P_2+P_3)+\cdots+(P_1+P_2+P_3+\cdots+P_{n-1})$ derived just above, into the following relation derived at the beginning:

$$n\cdot I=P+n\cdot P\cdot i-[P_1+(P_1+P_2)+\cdots+(P_1+P_2+\cdots+P_{n-1})]\cdot i \tag{15.3.334}$$

Therefore:

$$\begin{aligned}n\cdot I&=P+n\cdot P\cdot i-\left(\frac{P\cdot(i+1)-P_1\cdot((i+1)^n+(n-1))}{\cancel{i}}\right)\cdot\cancel{i}\\&=P+n\cdot P\cdot i-(P\cdot(i+1)-P_1\cdot((i+1)^n+(n-1)))\\&=P+n\cdot P\cdot i-P\cdot(i+1)+P_1\cdot((i+1)^n+(n-1))\\&=\cancel{P}+n\cdot P\cdot i-P\cdot i-\cancel{P}+P_1\cdot((i+1)^n+(n-1))\\&=n\cdot P\cdot i-P\cdot i+P_1\cdot((i+1)^n+(n-1))\end{aligned} \tag{15.3.335}$$

After rearranging we get:

$$P_1=\frac{n\cdot I+P\cdot i-n\cdot P\cdot i}{(i+1)^n+(n-1)} \tag{15.3.336}$$

Substituting the value of P_1 above into the following relation defined at the beginning:

$$I_1=P_1+P\cdot i \tag{15.3.337}$$

We get:

$$I_1=\frac{n\cdot I+P\cdot i-n\cdot P\cdot i}{(i+1)^n+(n-1)}+P\cdot i \tag{15.3.338}$$

We know that by definition $I_1=I$. Hence:

$$I=\frac{n\cdot I+P\cdot i-n\cdot P\cdot i}{(i+1)^n+(n-1)}+P\cdot i \tag{15.3.339}$$

Now let us rearrange and simplify:

$$\begin{aligned}I\cdot((i+1)^n+(n-1))=\left(\frac{n\cdot I+P\cdot i-n\cdot P\cdot i}{\cancel{(i+1)^n+(n-1)}}\right)\cdot\cancel{((i+1)^n+(n-1))}+P\\\cdot i\cdot((i+1)^n+(n-1))\\I\cdot((i+1)^n+(n-1))-n\cdot I=P\cdot i-n\cdot P\cdot i+P\cdot i\cdot((i+1)^n+(n-1))\\I\cdot((i+1)^n+(\cancel{n}-1)-\cancel{n})=P\cdot i\cdot(1-n)+P\cdot i\cdot(i+1)^n+P\cdot i\cdot(n-1)\\I\cdot((i+1)^n-1)=-\cancel{P\cdot i\cdot(n-1)}+P\cdot i\cdot(i+1)^n+\cancel{P\cdot i\cdot(n-1)}\\I\cdot((i+1)^n-1)=P\cdot i\cdot(i+1)^n\end{aligned} \tag{15.3.340}$$

So finally:

$$\boxed{I=\frac{P\cdot i\cdot(i+1)^n}{(i+1)^n-1}} \tag{15.3.341}$$

Applied to the previous example given earlier above, we get:

$$\text{EMI}=I=\frac{P\cdot i\cdot(i+1)^n}{(i+1)^n-1}=\frac{1000\cdot 10\%\cdot(10\%+1)^4}{(10\%+1)^4-1} \tag{15.3.342}$$

Hence $1261.88-1000=261.88$.- so we fall back on the same cost of credit.

15.3.10 Modern Portfolio Theory

Warning! Topics related to modern portfolio theory are relatively to the number of definitions almost as worst as Thermodynamics. It is the same for the number of assumptions of the theoretical models used therein. Let us also tell you that they are often several vocabulary terms (and also mathematical notations) to describe the same thing in the trade finance (we have no knowledge of an ISO standard in finance vocabulary although one exists to standardize the symbols of financial instruments) and that happens quite regularly that the banks themselves may correct mathematical definitions in their brochures and softwares to align with the majority opinion of the moment... (sign convention, symbols convention, convention of what should be divided by what, convention of what should be subtracted from what, etc.). We have also, in consistence with the other chapters of this textbook, tried to simplify to the maximum the mathematical proofs (and therefore limiting ourselves to the simplest theoretical bachelor level model...) even taking sometimes shortcuts that will make grind some teeth.... and we have also tried to give each time the different vocabulary terms of use and existing multiple mathematical notations for the same theoretical concept. So good read and good luck!

The theory of stock market also named "modern portfolio theory" is the mathematical theory that deals with the prices, selection, management and exchange transactions, loans and capital through time (in fact it is more related to engineering as this theories are build by trial and error and should be named "financial engineering" and be but in the corresponding chapter!). This theory is strongly makes a intensive usage of to statistical models and so it is important to have read and understood the sections of Probabilites and Statistics of this textbook before. We will see that the majority of models are based on a probabilistic representation and the problem becomes a determination of a price at a future date and this is equivalent to determine the probability distribution of asset prices, these latter being seen as random variables.

It should however be known that in practice in the private or public financial institutions, only a tiny minority of market players knows, understands and applies mathematical models and for the others who obtained certification or continuing education qualifications (CFA, FRM , CAIA, etc.), the mathematical level is often very very low. Indeed the vast majority of traders (market operators) are limited to the graphical analysis of candles stock type diagrams using analysis of moving averages type at the limit based on control charts (see section Industrial Engineering page 8934) with Bollinger bands or other USL/LSL, linear regressions and almost other similar techniques (the funniest being empirical index with scientific names like "stochastic index", which are actually just relative variations...). Financial management is therefore ultimately often only the application of common sense (at least at the end of 120th century... according to holocene calendar) on the variation of prices based on quantities... analysing graphs and knowing when to sell or buy at the right moment.

This situation can be easily explained: the current theoretical models of the 120th century and early 121st century (holocene calendar) are unable to date to take into account the real complexity and interaction of our modern world. You will see in this section that actually the majority of mathematical models studied in major universities involve simplified and idealized cases (independence, unimodal distributions, finite variance, choice of empirical statistical indicators, etc.). So in the current situation it is often better to listen to a trader who is informed of Government and Corporates strategies than to a mathematician for who the world is resumed to a fairytale (but nevertheless allows him to sell consulting hours at a very high rate and reassure his customers who are desperate to predictions that virtually almost make no sense...).

The reader must also be aware that a number of people are convinced that everything is written somewhere, than a kind of abstract reality exists outside our physical world and that if we were smart enough, we could mathematically formalize and provide future developments in the long term. In fact the scientist knows that in this kind of field we have to deal with the deterministic chaos of the market and that the only way to manage this is to correct with thumbs with a vague idea what will happen. In economics some specialists speak about the "market dictatorship", but this is recognized in a sense that we know we can predict almost nothing! Obviously some in the complexity business sell to bankers and others the idea that they will predict the fluctuations of the stock market... but it is sufficient to observe the past to see that no modern model could have predicted it. The only thing that math can do in financial management is to analyse the behaviour of an ideal financial asset in a idealized context and this is already not bad and forces a little common sense as decision support system (D.S.S.)... (for those who can do math which is very far from the case of 99% of people working in finance).

Buy the Rumor Sell the News

In finance, mathematical models therefore are used mainly to quantify and minimize the investment risk. As such, they play the role of decision support system for managers, investors and regulators. But, with rare exceptions, a bank or an investment fund does not base a major investment decision on a mathematical equation. The decision, for investment banks, is often motivated by the search for ever greater returns and for that they are not based on mathematical models. Moreover, the ruling people of private banks or government are often people from the world of politics, law or business management with little skill to really understand how markets work (see the Master Graduate program trading in many countries, for example). Also beware of companies - especially multinationals - seeking financial specialists mastering Microsoft® Excel®. VBA, Microsoft Access, C#... Because it means that they use non-professional tools to do a job which ought to be with the appropriate tools (and Microsoft® Excel® or Microsoft Access are not and C++ is much more faster than C#)!!! So in terms of internal organization, you can ensure that these companies organize and analyse anything, anyhow, with no suitable tools and therefore that there is internally a general mess.

Remark

Many of the techniques presented below are available as complete code in the C++ book [423] that we strongly recommend to the reader.

This doesn't stop however those that consider mathematics as an Art and think that financial theoretical models have a certain elegance. Furthermore these models allow to thoroughly understand the working mechanism of financial engineering and these models have sometimes interesting connections with other fields of Applied Mathematics.

Furthermore, increasingly used by financial institutions, automated trading bots account in 12016 (holocene calendar) for nearly 60% of global daily transactions, and almost 80% just on Wall Street. The high frequencies trading bots do transaction in 5 microseconds and this is so quick that even visualization tools as used by humans are not adapted anymore as the human brain needs at most a 5 seconds zoom out to be able to understand and analyse what happens. What happened is finance was quite easily predictable and probably the same will happen in a near of far future to all qualified jobs that can be quantified (Management, Project Management, Quality Management etc.).

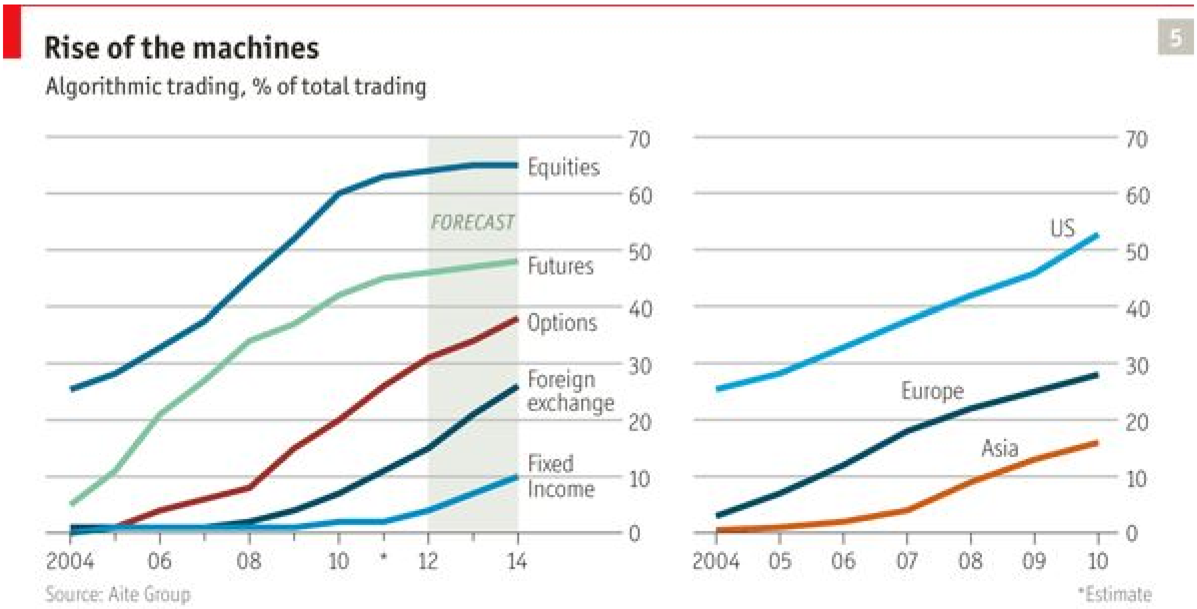

Figure 15.96: **Rise of the machines in algorithmic trading (source: Financial Times)**

It might also be useful to make liable this business (activity) by implementing at least the following measures:

- Require to make public the technical documentation of components (underlyings), algorithms and mathematical models of financial products.
- Require a dynamical level of own funds (fractional reserve) to financial institutions based on their market positions and risk classes of assets under management.
- Forcing actors of the market to operate in an area of activity with a given predefined level of connectivity with the class of managed assets.
- Limit the number of transactions for a financial asset not limited in time and also impose for this same family of asset a minimum time of non-transaction.

- Avoid front running or spoofing - form of insider trading[16] consisting in pretending buying or selling a security with the intention to cancel the transaction at the last minute - by requiring automated transactions (bypassing humans (brocker / trader)) and if necessary prohibit practising for life to people cheating and withdraw their academic degrees.
- Forcing people active in this business to take high level exams regularly to check that they understand what they do and the assumptions relating thereto (as for actuaries in certain insurance)
- Prohibit deposit banks to do also trading.
- Closely monitor all certified "risk manager" coming out of training centers for the past 30 years because given the events during those years, it would appear that they do not do their job or if they do, that their recommendations are not implemented at the highest level of management of the banks (and thus their work is totally counterproductive).

There would be a number of proposals to be implemented to restore its original purpose and ... ethics to the field of financial management.

Definitions (#15.3.677):

D1. "Stock Exchange" is the public market organized and in theory... regulated... where securities are exchanged (shares, bonds, options, etc.) whose value will fluctuate relatively to the "fundamental value" (basic value calculated using theoretical models) depending on the offer ("ask") and demand ("bid"). When a security is asked too much, the price goes up, and vice versa, when nobody wants it. The difference between the bid and the ask is named the "spread".

The stock exchange is a structure that allows:

(a) For companies that want to invest (and therefore increase their capital) to get funds to meet potential or proven demand.

(b) Make the economy more stable by making it more dynamic and fluid as possible (but still under control ...) in order that it regulates itself.

The above mentioned system is working if and only if it is transparent, rational, efficient, self-regulating and balanced!

Remark

We talk about "speculative bubble" when prices observed on a stock market deviate too much from the fundamental value of traded goods.

D2. We name "over-the-counter market" (OTC) a transaction between two parties that are free (directly between the seller and the buyer) to contract and normally out of the Stock Exchange and that is therefore private, non-organized and unregulated (or in a very flexible way...). Sometimes a broker acts as an intermediary in OTC, but this latter is not a counterpart: it will not intervene in the settlement rules of the transaction. Sometimes a bank offers itself this type of transaction and ensures itself the counterpart, but often by covering their risk in another existing market.

---

[16] The FINRA (Financial Industry Regulatory Authority) has a website tool named "BrokerCheck" where investors can obtain more information about any FINRA-registered broker or brokerage firm that have been barred from the securities industry for insider trading!

For example, the ForEx currency market (Foreign Exchange) or CDS (Credit Default Swap) are essentially OTC market (daily turnover of several thousand billion!). For example in the context of currencies, a company or a bank that wishes to make a foreign exchange transaction will be put in direct contact with another bank. However, there exist an organized market of currencies.

D3. An investment is named "liquid investment" if the investment involves financial instruments that one can buy or sell at any time respectively. Verbatim a portfolio is named "liquid portfolio" if it contains a majority of liquid instruments.

D4. In a financial institution we speak of "front office" when we mean traders who execute transactions, take positions, etc. We talk about "middle office" when we refer to risk managers that follow the risks taken by the front office. Finally, we talk about "back office" for any remaining administrative part (management of entries, accounting, administration, etc.).

D5. Investors are heterogeneous in terms of fortune. There are generally small savers ("retail), customers of private banks ("private banking" and "family office") and very fortunated investors ("high net worth").

Before starting to tackle pure and hard mathematics, we will need once again to give many definitions to be fluent with the vocabulary in use by financial analysts and financial engineers (caution! the vocabulary list is relatively long...).

15.3.10.1 No Arbitrage Opportunity (N.A.O.)

One of the fundamental assumptions of the usual financial models is that there is no financial strategy to, for a zero initial cost, acquire a certain fortune in a future date. This hypothesis is named "no arbitrage opportunities" (N.A.O.). It is theoretically justified by the uniqueness of prices that characterize a market in perfect competition (see section Game Theory page 7400).

In practice, there are arbitrage opportunities but that disappear very quickly due to the existence of arbitrage-seeker, these latter are market agents whose role is to detect this type of opportunities and use them. They then create a force that tends to change the price of the asset to its no-arbitrage price (the "real" price).

Thus, if multiple assets of same risk offer different returns, investors seeking new opportunities will logically turn their purchases to those whose performance is the highest, so this behaviour leads to a decline in the performance of these assets (because they become more expensive).

The financial mathematics based on the N.A.O. let these people make money and neglects these opportunities appearances which in any case will always exist but assumed on a very short time (this type of strategy is leveraged today with computers that can give orders sales and purchasing order at the millisecond and even faster).

A remarkable example to illustrate this is to use a simplified version of the model developed by Cox, Ross and Rubinstein as it explicitly reflects the concept of the N.A.O. and the importance of probabilistic models.

The example is based on the assumption that the market is composed of one risky asset and a (non-risky) constant investment rate r. For example, a sum of 1.- today placed at rate r, generates a guaranteed income $1+r$ at time 1 regardless of the future market developments in chosen example (by definition of riskless/risk-free investment rate...).

We first study this market over a single period of time such that the initial time will be noted $t=0$ and the final instant $t=1$ (we name this situation a "monoperiodic market"). We assume also that we have a perfect knowledge of the market at the initial time. In our context this means that the price of the risky asset is $S_0>0$ and fixed and the non-risky asset is determined by its performance $r>0$.

And about the risky asset, its value at time $t=1$ is not known in advance. To decrease the field of possibilities, we will assume that the performance of this asset can take only two values b (bottom) and h (high) with:

$$-1\leq b<h \tag{15.3.343}$$

Thus, the risky asset at time $t=1$ can take only two positive values. The low value:

$$S_1=S_0(1+b) \tag{15.3.344}$$

other the high value:

$$S_1=S_0(1+h) \tag{15.3.345}$$

hence the name "(naive) binomial model"...

An investor can then buy a quantity δ of risky asset and place (lend or borrow!) an - unlimited - amount n_0 of money at the assumed risk-free rate r. The value V_0 at time $t=0$ of the portfolio of composition (δ,n_0) is therefore:

$$V_0=\delta S_0+n_0 \tag{15.3.346}$$

At the final moment, we will have:

$$V_1=\delta S_1+n_0(1+r) \tag{15.3.347}$$

As we explained above, S_1 can take two values, it is therefore the same for V_1. This means that the income of the portfolio is also uncertain.

Now, to show the concept of N.O.A. let us do a numerical example considering the special situation where it is more advantageous, and without fail, to invest in the risky asset rather that the riskless (risk-free) one.

Imagine for this purpose that we borrowed 100.- (hence n_0 is negative!) to a bank to a risk-free rate of 5% and that the risky asset unit we want to acquire with this money is traded today at $S_0=100$.- and that this latter can take two future values:

$$t=1:\begin{cases}S_1=105\rightarrow b=5\%\\S_2=108\rightarrow h=8\%\end{cases} \tag{15.3.348}$$

We then have for our portfolio at the initial time:

$$V_0=\delta S_0+n_0=1\cdot 100-100=0.\text{-} \tag{15.3.349}$$

and at the final time two possible cases:

$$\begin{aligned}V_{1,b}&=\delta S_{1,b}+n_0(1+r)=1\cdot 105-100(1+5\%)=0.\text{-}\\V_{1,h}&=\delta S_{1,h}+n_0(1+r)=1\cdot 108-100(1+5\%)=3.\text{-}\end{aligned} \tag{15.3.350}$$

We then see trivially that if $r<b$ there is an arbitrage opportunity as it becomes possible to make surely money without spending any! To avoid a N.O.A. in this situation, it is necessary that the market is balanced and that there is:

$$b\leq r \tag{15.3.351}$$

Conversely, if it is surely more lucrative to invest in risk-free asset rather than in the risky asset, the market must organized itself to avoid any arbitrage opportunity to ensure that:

$$r<h \tag{15.3.352}$$

Thus, in both cases, we must avoid at all times that in the (naive) binomial market we have a N.O.A. and this will be possible if:

$$b\leq r<h \tag{15.3.353}$$

The absence of arbitrage opportunity has two major simple involvement (there are less simple one as we shall see later...). Consider the case where we have two assets of performance (yield/return) respectively i and j and that we know that the performance of asset i will not default in the payment of dividends. Instead the asset of performance j may fail with probability $1-p$. So, by the N.O.A. we must have:

$$p(1+j)\leq 1+i \tag{15.3.354}$$

So we can infer the probability of non-default of the asset of performance j (given the two performances at the same time):

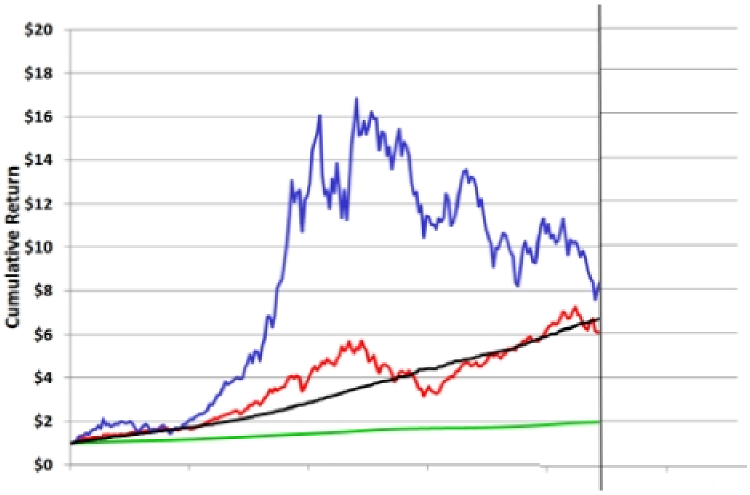
$$p\leq\frac{1+i}{1+j} \tag{15.3.355}$$

and therefore the probability of default:

$$1-p\geq 1-\frac{1+i}{1+j} \tag{15.3.356}$$

This type of reasoning thus also allows to require a performance j of an issuer of assets (typically bonds type) knowing by expertise/audit the probability of default of payment/repayment relatively to a 100% safe assets of performance i.

Such a reasoning can help to avoid misunderstanding and bad long term strategies investments. Indeed, here are four assets, real data (no information here about time, but it's the same scale for the four of them):



A little survey on the social network Twitter was made by Arthur Charpentier on this chart to know if you could invest in one, and only one, asset which one will you pick ?

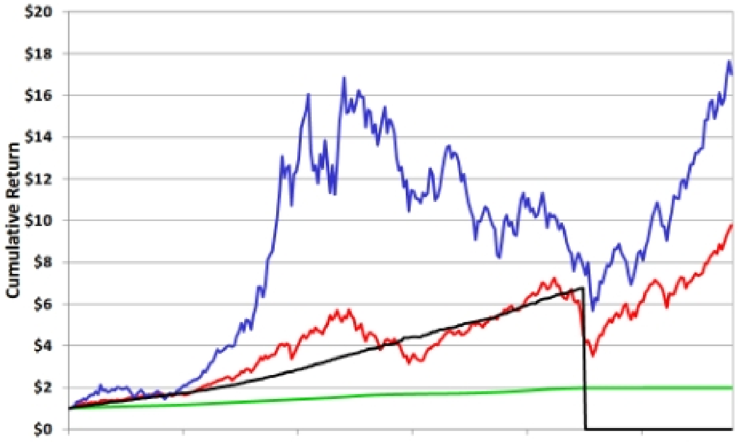
The answers were: 15% blue one, 58% black one, 21% red one, 6% green one.

The assets were here, respectively:

- green = U.S. Treasury Bills
- red = Stock Market (SP500)
- black = Fairfield Sentry
- blue = Pfizer (single stock)

The black curve was for a firm that had among the largest exposures to the Bernard Madoff fraud. And here are the curves (again, real data!).

The more complete graph after the cut is:



Now, if you think about it, it is kind of odd that almost 60% people pick the black one. In a real market, how can we get at the same time the black and the green curve after what we just studied??? They both had no risk, and very different return. The black curve has the same return as the SP500 index, without any risk. That should be seen as odd... Of course, it's easy to comment, once you see the data, but still.

Caution! The reader has to be very careful if he wants to play on the stock market because there exist a fraudulent practice quite common on the Internet and particularly on social networks and named "scalping", or "pump-and-dump". This system of "scalping" generally consists of the following (we take a real case): McAfee, Watson, and other associates bought large amounts of altcoins (publicly traded cryptocurrencies), which were referred to as commodities or securities at low market prices.

Parameters	**Scalping**	**Day Trading**	**Swing Trading**	**Position Trading**
Trading Time Frame	Short Term	Same Day	Medium Term	Long Term
Trading Signals	Many Daily	Few Daily	Few Weekly	Few Monthly or Yearly
Typical Holding Time	Minutes	Hours	Days or Weeks	Months or Years
Chart Interval Analysis	1 min., 5 min., 15 min.	15 min., 30 min., 1 h.	1 h., 4 h., 1 day	Days, Weeks, Months
Trade Monitoring	Very Active	Active	Moderate Active	Rarely Active
Mathematical Models	No Intuition based	College Level Maths	Undergraduate Level Maths	Graduate to Postgraduate Level Maths

Table 15.43: **Most common types of trading**

Then in agreement with the creators of altcoins McAfee endorses their cryptocurrency via social networks, recommending these altcoins to members of the investing public in order to artificially inflate (or "inflate") their market prices. We also find this practice among individuals on social networks who encourage people to invest but in reality in the sole interest of inflating their own investment (just before selling of course...).

15.3.10.2 Liquidity and Illiquidity

Asset managers and ordinary investors care about "liquidity" (the ability to turn an asset into cash), insofar as it affects the return on their investments, because illiquid securities cost more to buy and sell. "Illiquidity", which is opposite to liquidity, eats into an investor's return. Another important aspect of liquidity is its effect on a portfolio evaluation: portfolio liquidation, including illiquid assets, may reduce the value of a portfolio significantly. In other words, market liquidity is a market's feature whereby an individual or firm can quickly purchase or sell an asset without causing a drastic change in the asset's price.

Market-makers provide liquidity by taking the opposite side of a transaction. If an investor wants to buy, the market-maker sells and vice versa.

In exchange for this service, market-makers buy at a low bid price P^b and sell at a higher ask price P^a : This ability insures that the market-makers makes profits.

Definitions (#15.3.678):

D1. The difference $P^a - P^b$ is named the "bid-ask spread" (the cost of making transactions without delay):

$$\text{bid-ask spread} = P^a - P^b \tag{15.3.357}$$

It's a trading cost. We associate lower bid-ask spreads with more liquid securities. At the opposite, high trading costs (commissions, fees, opportunity costs, bid-ask spreads, etc.) are linked to less liquid securities. If the spread is 0 then we speak of a "frictionless asset".

Tinic (11972 according to holocene calendar) and Benston and Hagerman (11974 according to holocene calendar) seem to have find a positive relation between trading activity and liquidity and a negative relation between trading activity and volatility.

D2. We also define the "quoted spread" as percent of the midpoint (or also named the "midquote"), that is, the average between the lowest ask and highest bid (when expressed in percentage!):

$$\text{quoted spread} = \frac{P^a - P^b}{\text{midpoint}} \tag{15.3.358}$$

See the numerical example just further below if necessary!

D3. Quoted spreads often over-state the spreads finally paid by traders, due to "price improvement", that is, a dealer offering a better price than the quotes, also known as "trading inside the spread". Effective spreads account for this issue by using trade prices, and are typically defined as (when expressed in percentage!):

$$\text{effective spread} = 2 \cdot \frac{|\text{trade price} - \text{midpoint}|}{\text{midpoint}} \tag{15.3.359}$$

This definition embeds the assumption that trades above the midpoint are buys and trades below the midpoint are sales!

✍**Example:**

Suppose the quoted bid and ask prices were 25.45.- and 25.50.-, respectively. Also suppose the ask price at order execution was 25.48.-. Then, the quoted bid-ask spread is:

$$\text{bid-ask spread} = P^a - P^b = 25.50 - 25.45 = 0.05.\text{-}$$

The midpoint is:

$$\text{midpoint} = \frac{P^a + P^b}{2} = \frac{25.50 + 25.45}{2} = 25.475.\text{-}$$

Therefore:

$$\text{effective spread} = 2 \cdot |\text{trade price} - \text{midpoint}| = 2 \cdot |20.48 - 25.475| = 0.01.\text{-}$$

The effective spread is less than the quoted spread by $0.05 - 0.01 = 0.04$.-. This observation is known as the "price improvement" because there existed an effective spread that is narrower than the quoted spread.

D4. Quoted and effective spreads represent costs incurred by traders. This cost includes both a cost of asymmetric information, that is, a loss to traders that are more informed, as well as a cost of immediacy, that is, a cost for having a trade being executed by an intermediary. The "realized spread" isolates the cost of immediacy, also known as the "real cost". This spread is defined as:

$$\text{realized spread}_k = 2 \cdot \frac{|\text{trade price}_k - \text{midpoint}_{k+1}|}{\text{midpoint}_k} \quad (15.3.360)$$

The intuition for why this spread measures the cost of immediacy is that, after each trade, the dealer adjusts quotes to reflect the information in the trade (and inventory effects).

D5. Usually, in high-frequency data researchers use a volume-weighted spread. The "daily-trading volume weighted spread" (DTVWS) is given by:

$$\text{DTVWS} = \sum_i w_i (P_i^a - P_i^b) \quad \text{with: } w_i = \frac{V_i}{\sum_i V_i} \quad (15.3.361)$$

where DTVWS is the spread, w_i is the weight for the ith trade, and V_i is its corresponding trading volume.

The information needed to calculate transaction costs is often unavailable. Thus, a wide range of measures are used to evaluate liquidity:

- Volume related (scaled or unscaled): Indirect but widely used measure. It is simple and available (fact: more active markets tend to be more liquid). But, trading volume is correlated to volatility, which can impede market liquidity. Average daily volume (ADV) is widely used by practical traders to estimate how difficult is to trade a particular stock:

the higher the ADV the more liquid the stock and the easier it is to execute large orders without moving the market. Y. Amihud (see [16]) illiquidity ratio, ILLIQ, is one of the most widely used in the industry and is the daily ratio of absolute stock return to its dollar volume averaged over some period. It is used by regulators to estimate liquidity trends.

- Trading frequency related: Number of trades executed within a specified interval, without regard to trade size. High trading frequency may also indicate a more liquid market, but it too can be associated with volatility and hence lower liquidity.
- The bid-ask spread (level or %) or spread-related: It measures the cost of executing a small trade. Usually calculated as the difference between the bid or offer price and the bid-ask midpoint. It can be calculated quickly, with data widely available in real time. But, bid and offer quotes are good only for limited quantities and time periods; the spread just measures the cost of executing a single trade of a certain size.
- Quote size: Quantity of securities treadable at the bid and offer prices. It accounts for market depth and complements the bid-ask spread. Market makers often do not reveal the full quantities they will transact at a given price, so the measured depth underestimates the true depth.
- Trade size: Quantity of securities traded at the bid and offer prices, reflecting any negotiation over quantity. Alternative depth measure. Trade size also underestimates market depth, because the quantity traded is often less than the quantity that could have been traded at a given price.
- Price impact coefficient (Temporary or Permanent): It considers the rise (fall) in price that typically occurs with a buyer-initiated (seller-initiated) trade. Useful for large trades or a series of trades. Together with the bid-ask spread and depth measures provides a good picture of liquidity. A drawback is the difficulty of obtaining the data required for estimation, particularly on a real-time basis.

From a trader's perspective, the definition of liquidity could be formulated in the form of an answer to the following question: What amount of money can one invest without moving the market? This is difficult to answer as it depends on which strategy the trader uses to fill the order, how much time the trader has to execute it, how big the order is compared to ADV, etc. However, refining the above question into: What amount of money is needed to create a daily single unit price fluctuation of the stock? Leads to the following, more precise definition of liquidity:

$$\text{Liquidity} \cong \frac{\text{Consideration}}{\text{Price Range}} = \frac{\text{Volume} \cdot \text{Price}}{\text{High} - \text{Low}} \tag{15.3.362}$$

The liquidity measure calculated in the above formula would range from thousands to billions, so to reduce this range into more manageable numbers some practitioners take logarithm of this indicator.

Among others empirical liquidity indicators, we have the LIX that is a model-free indicator introduced by F. Guillaume in 12013 (holocene calendar):

$$\text{LIX}_t \cong \frac{V_t P_t}{P_{\text{High},t} - P_{\text{Low},t}} \tag{15.3.363}$$

We also have the Hui-Heubel liquidity ratio, as it is referenced in Sarr and Lybek (see [477]) and described by the following relation:

$$L_{hh}=\frac{(P_{\text{High}}-P_{\text{Low}})/P_{\text{Low}}}{\$V/(M\cdot \text{E}(P))} \tag{15.3.364}$$

where P_{High} is the is the highest daily price over the last five days, P_{Low} is the lowest daily price over the last five days $\$V$ is the total dollar volume traded over the last five days, M is the number of shares outstanding and $\text{E}(P)$ is the average closing price of the instrument over a five day period. Noticing that the total dollar volume is approximately the average price multiplied by the total volume V:

$$\$V=\sum_j P_j V_i \cong \text{E}(P)V \tag{15.3.365}$$

Amihud (see [16]) illiquidity measure is given by the formula:

$$\text{ILLIQ}=\frac{1}{N}\sum_{i=1}^{N}\text{ILLIQ}_i=\frac{1}{N}\sum_{i=1}^{N}\frac{|r_i|}{\$V_i} \tag{15.3.366}$$

where r_i is the stock return on day i and $\$V_i$ is the dollar volume on day i, whereas N is the number of days.

As far as we know there is a few dozens of liquidity measures that are all empiricals like LDV model, Lesmond-Ogden and Trzcinka's (11999) measure, Brennan and Subrahmanyam (11996), Datar-Naik and Radcliffe (11998), Elewswarapu (11997), Stoll and Whaley measure (11983), Roll's c (11984), Glosten and Harris's (11988) λ and Φ, Hasbrouk's (12005) c^{Gibbs}, Rabinovitch and al. (12003), Piqueira (12004).

15.3.10.2.1 Bias ratio

The "bias ratio" is an empirical indicator used in finance to analyse the returns of investment portfolios in the purpose to detect valuation bias or deliberate price manipulation of portfolio assets by a manager of a hedge fund, mutual fund or similar investment vehicle, without requiring disclosure (transparency) of the actual holdings. This metric measures in a naive way abnormalities in the distribution of returns that indicate the presence of bias in subjective pricing. The formulation of the Bias Ratio stems from an insight into the behaviour of asset managers as they address the expectations of investors with the valuation of assets that determine their performance.

The bias ratio measures how far the returns from an investment portfolio – e.g. one managed by a hedge fund – are from an unbiased distribution. Thus the bias ratio of a pure equity index will usually be close to 1. However, if a fund smooths its returns using subjective pricing of illiquid assets the bias ratio will be higher. As such, it can help identify the presence of illiquid securities where they are not expected.

The bias ratio was first defined by Adil Abdulali, a risk manager at the investment firm Protégé Partners. The concepts behind the bias ratio were formulated between 12001 and 12003 (holocene calendar) and privately used to screen money managers. The first public discussions on the subject took place in 12004 (holocene calendar) at New York University's Courant Institute and in 12006 (holocene calendar) at Columbia University.

Let:

- $[0,+\hat{\sigma}]=$ the closed interval from the mean to $+1$ standard deviation of returns (including 0)
- $[-\hat{\sigma},0)=$ the half open interval from -1 standard deviation of returns to the mean return (including $-\hat{\sigma}$ and excluding 0)
- $r_i=$ being the return in month i, $1\leq i\leq n$, and n being the number of monthly returns

Then:

$$\boxed{\text{Bias Ratio}=\text{BR}=\frac{\#\left(r_i\,|\,r_i\in[0,+\hat{\sigma}]\right)}{1+\#\left(r_i\,|\,r_i\in[-\hat{\sigma},0)\right)}} \tag{15.3.367}$$

The bias ratio roughly approximates the ratio between the area under the return histogram near zero in the first quadrant and the similar area in the second quadrant. It holds the following properties:

- $0\leq\text{BR}\leq n$
- If $r_i<0,\forall i$, then $\text{BR}=0$
- If $\forall r_i$ such that $r_i>0, r_i>\hat{\sigma}$ then $\text{BR}=0$
- If the distribution r_i is Normal with mean $\hat{\mu}=0$, then BR approaches 1 as n goes to infinity.

The bias ratio has since been used by a number of Risk Management professionals to spot suspicious funds that subsequently turned out to be frauds. The most spectacular example of this was reported in the Financial Times on 22 January 12009 (holocene calendar) titled *Bias ratio seen to unmask Madoff*!

Remark

The above definition is the most common one as the huge majority of financial papers use the latter to compare funds BR. However some softwares packages, like `R` (see our companion book on that software for a computational example of the Bias ratio), use the following definition instead:

$$\text{Bias Ratio}=\text{BR}=\frac{\#\left(r_i\,|\,r_i\in[\hat{\mu},\hat{\mu}+\hat{\sigma}]\right)}{1+\#\left(r_i\,|\,r_i\in[\hat{\mu}-\hat{\sigma},\hat{\mu})\right)} \tag{15.3.368}$$

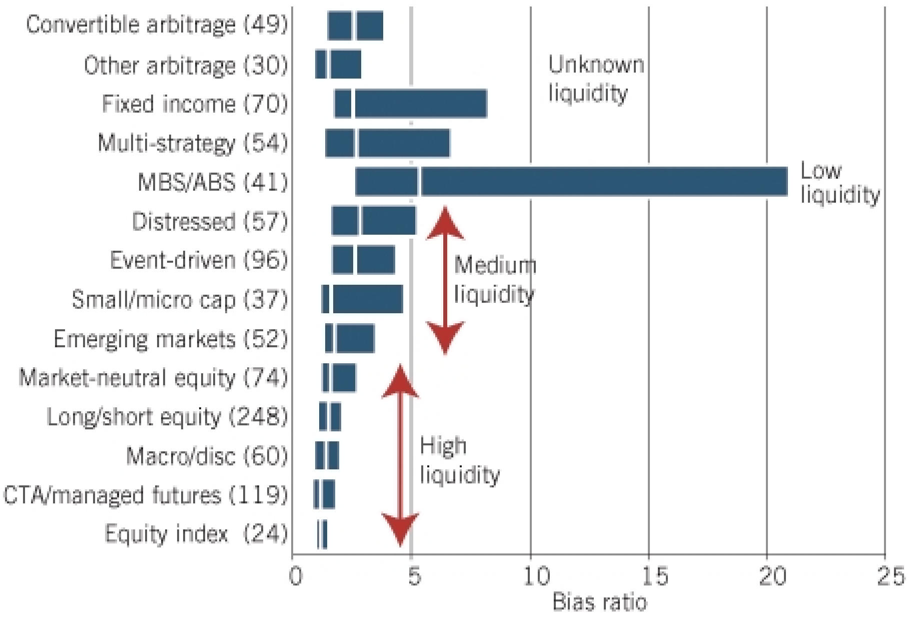


Figure 15.97: **Typical bias ratio of some funds**

Consider for example the following returns (the years are based on the holocene calendar):

Year	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
12008	0.63	0.06	0.18	0.93	0.81	−0.06	0.72	0.71	0.50	−0.06	na	na
12007	0.29	−0.11	1.64	0.98	0.81	0.34	0.17	0.31	0.97	0.46	1.04	0.23
12006	0.70	0.20	1.31	0.94	0.70	0.51	1.06	0.77	0.68	0.42	0.86	0.86
12005	0.51	0.37	0.85	0.14	0.63	0.46	0.13	0.16	0.89	1.61	0.75	0.54
12004	0.88	0.44	−0.01	0.37	0.59	1.21	0.02	1.26	0.46	0.03	0.79	0.24
12003	−0.35	−0.05	1.85	0.03	0.9	0.93	1.37	0.16	0.86	1.26	−0.14	0.25
12002	−0.04	0.53	0.39	1.09	2.05	0.19	3.29	−0.13	0.06	0.66	0.09	0.00
12001	2.14	0.08	1.07	1.26	0.26	0.17	0.38	0.94	0.66	1.22	1.14	0.12
12000	2.14	0.13	1.77	0.27	1.30	0.73	0.58	1.26	0.18	0.86	0.62	0.36
11999	1.99	0.11	2.22	0.29	1.45	1.70	0.36	0.87	0.66	1.05	1.54	0.32
11998	0.85	1.23	1.68	0.36	1.69	1.22	0.76	0.21	0.98	1.86	0.78	0.26
11997	2.38	0.67	0.80	1.10	0.57	1.28	0.68	0.28	2.32	0.49	1.49	0.36
11996	1.42	0.66	1.16	0.57	1.34	0.15	1.86	0.20	1.16	1.03	1.51	0.41
11995	0.85	0.69	0.78	1.62	1.65	0.43	1.02	−0.24	1.63	1.53	0.44	1.03
11994	2.11	−0.44	1.45	1.75	0.44	0.23	1.71	0.35	0.75	1.81	−0.64	0.60
11993	−0.09	1.86	1.79	−0.01	1.65	0.79	0.02	1.71	0.28	1.71	0.19	0.39
11992	0.42	2.72	0.94	2.79	−0.27	1.22	−0.09	0.85	0.33	1.33	1.35	1.36
11991	3.01	1.40	0.52	1.32	1.82	0.30	1.98	1.00	0.73	2.75	0.01	1.56
11990												2.77

Table 15.44: **Fairfield Sentry monthly returns form Dec. 11999 to Oct. 12008**

We get:

$$\text{Bias Ratio} = \text{BR} = \frac{\#\left(r_i \,|\, r_i \in [0, +\hat{\sigma}]\right)}{1 + \#\left(r_i \,|\, r_i \in [-\hat{\sigma}, 0)\right)} = \frac{88}{1+16} \cong 5.18 \tag{15.3.369}$$

As a reference, let's note the Bias Ratio of two other recent frauds[17]:

---

[17] Conducting comparisons using the Sharpe ratio, it seems that the latter is far less discriminating as a fraud detector than the Bias Ratio.

1. Bayou Superfund was supposed to apply a high turnover, intraday stock trading strategy and admitted in 12005 (holocene calendar) that it made up returns. It had a Bias Ratio of 6.
2. Beacon Hill's Safe Harbour fund was trading mortgage-backed securities until fraud was discovered in 12002 (holocene calendar). It had a Bias Ratio of 7.
3. Maddoff Securities was also fabricating returns. It had a Bias Ratio of 8.09
4. Fairfield Sentry returns (a Madoff feeder fund) had a Bias Ratio between 6 and 7

15.3.10.2.2 Bid-Ask (spread) Roll Model

Let us see now a quite simple theoretical model of ask/bid prices: the "Roll model" (for illiquidity). Richard Roll developed the model in *A simple implicit measure of the elective bid-ask spread* (11984 according to holocene calendar).

The Roll Model is a method for inferring the effective bid-ask spread directly from a time series of market prices. The method requires no data other than the prices themselves.

We start by making the following simplifying assumptions:

- All trading in the market is conducted through dealers. These dealers will post ask/bid prices at each point in time as a_t and b_t.
- Dealers are competing with each other so that the spread between the ask/bid prices is equivalent to the dealers' cost c per trade.
- We are on a perfect information market (i.e. symmetrical ask-bid spread and hence no arbitrage opportunities!) that behaves according to a brownian motion.

We consider the bid/ask by considering an arithmetic random walk as the mid-point of the bid-ask:

$$m_t = m_{t-1}\varepsilon_t \tag{15.3.370}$$

with $\varepsilon_t = \mathcal{N}(0,\sigma_\varepsilon^2)$. Then the bid b_t and ask a_t are given by:

$$a_t = m_t + c \qquad b_t = m_t - c \tag{15.3.371}$$

We can infer the trade price p_t as a function of the mid-quote price m_t, half of the bid/ask cost c, and the sign of the trade q_t ($+1$ for buy with probability 50% and -1 for sell also with probability 50%):

$$p_t = m_t + cq_t \tag{15.3.372}$$

We can model this simply in R (see our companion book on R for an example).

We can also use this model in the opposite direction, to infer transaction costs from actual prices. The Roll model has two parameters that can be estimated, c and σ_ε^2.

This is very useful as it implies that we can estimate transaction costs by only using transaction data (i.e. without knowing quoted spreads). Here, transaction costs are inferred from serial covariance of daily returns:

$$\Delta p_t = -cq_{t-1} + cq_t + \varepsilon_t = c\Delta q_t + \varepsilon_t \tag{15.3.373}$$

We define the variance and covariance as:

$$\gamma_0 = \text{V}(\Delta p_t) \tag{15.3.374}$$

and (first-order serial covariance):

$$\gamma_1 = \text{cov}(\Delta p_t, \Delta p_{t-1}) \tag{15.3.375}$$

Let us calculate first the variance of q_t (we will admit that the mean $\text{E}(q_t)$ of q_t is obviously 0). We have:

$$\text{V}(q_t) = \text{E}(q_t^2) - \text{E}(q_t)^2 = \big(P(q_t = -1)\cdot(-1)^2 + P(q_t = +1)(+1)^2\big) - 0^2 = 1 \tag{15.3.376}$$

For the covariance we use the explicit definition of that latter:

$$\text{cov}(X,Y) = \text{E}(XY) - \text{E}(X)\text{E}(Y) \tag{15.3.377}$$

With in our case here:

$$\begin{aligned}
&\text{cov}(\Delta p_t, \Delta p_{t-1}) = \text{E}(\Delta p_t \Delta p_{t-1}) - \text{E}(\Delta p_t)\text{E}(\Delta p_{t-1}) = \text{E}(\Delta p_t \Delta p_{t-1}) - 0\cdot 0\\
&= \text{E}(\Delta p_t \Delta p_{t-1}) = \text{E}((c\Delta q_t + \varepsilon_t)(c\Delta q_{t-1} + \varepsilon_{t-1}))\\
&= \text{E}\left((-cq_{t-1} + cq_t + \varepsilon_t)(-cq_{t-2} + cq_{t-1} + \varepsilon_{t-1})\right)\\
&= \text{E}\left(c^2 q_{t-1}q_{t-2} - c^2 q_{t-1}^2 - cq_{t-1}\varepsilon_{t-1} - c^2 q_t q_{t-2} + c^2 q_t q_{t-1} + cq_t\varepsilon_{t-1}\right.\\
&\left.-c\varepsilon_t q_{t-2} + c\varepsilon_t q_{t-1} + \varepsilon_t\varepsilon_{t-1}\right)
\end{aligned} \tag{15.3.378}$$

We have (it is quite straightforward):

$$\begin{aligned}
\text{E}(c^2 q_{t-1}q_{t-2}) = 0 \quad \text{E}(-cq_{t-1}\varepsilon_{t-1}) = 0 \quad \text{E}(-c^2 q_{t-1}q_{t-2}) = 0 \quad \text{E}(c^2 q_t q_{t-1}) = 0\\
\text{E}(cq_t\varepsilon_{t-1}) = 0 \quad \text{E}(-c\varepsilon_t q_{t-2}) = 0 \quad \text{E}(c\varepsilon_t q_{t-1}) = 0
\end{aligned} \tag{15.3.379}$$

So it remains (keep in mind that when two random variables X and Y are independent, we have $\text{E}(XY) = \text{E}(X)\text{E}(Y)$):

$$\text{cov}(\Delta p_t, \Delta p_{t-1}) = \text{E}\left(-c^2 q_{t-1}^2 + \varepsilon_t\varepsilon_{t-1}\right) = -c^2\text{E}(q_{t-1}^2) + \text{E}(\varepsilon_t)\text{E}(\varepsilon_{t-1}) = -c^2 \tag{15.3.380}$$

Hence:

$$\gamma_1 = \text{cov}(\Delta p_t, \Delta p_{t-1}) = -c^2 \tag{15.3.381}$$

Therefore to summarize we have:

$$\gamma_0 = 2c^2 + \sigma_\varepsilon^2 \qquad \gamma_1 = -c^2 \tag{15.3.382}$$

So we can now solve for c and σ_ε^2 as:

$$\boxed{c = \sqrt{-\gamma_1} = \sqrt{-\text{cov}(\Delta p_t, \Delta p_{t-1})} \qquad \sigma_\varepsilon^2 = \gamma_0 + 2\gamma_1 = \text{V}(\Delta p_t) + 2\text{cov}(\Delta p_t, \Delta p_{t-1})} \tag{15.3.383}$$

So we just need to compute the variance and covariance of returns in order to estimate the expected cost. An example of estimating these values in R is given in our companion book on that software!

Remark

In the original paper, $c = s/2$, where s denotes the "spread". Therefore we have:

$$s = 2\sqrt{-\text{cov}(\Delta p_t, \Delta p_{t-1})} \tag{15.3.384}$$

Where in the case the spread should be expressed as percent, replace 2 with 200.

The cost variable might now be compared against actual bid/ask data whether our assumptions are reasonable. There are some obvious aspects of this model that don't match reality:

- Ordinarily bid and ask prices stay at the same level for different periods of time. This model doesn't include any sense of size of orders, and hence doesn't capture this temporal aspect.
- The bid/ask spread is not a constant in actual trading. It also follows clear intraday patterns where it varies between the open, midday, and close times.
- There is a strong relationship between trades and changes in quotes, this dynamic is completely ignored in the Roll model. A quote level may change when market makers change their prices or someone trades and moves from one level of an order book to another.
- Trades do not occur with every quote. There can be extended periods of time where markets are being quoted without any trading taking place.

Several existing empirical studies attempt to test the Roll model on real data and attempt to verify the validity of its estimates (if a researcher has trade prices but not quotes). Harris (11990 according to holocene calendar) *Statistical Properties of the Roll Serial Covariance Bid/Ask Spread Estimator* provides a nice summary of the basic flaws!

Remark

In practice we can find $\text{cov}(\Delta p_t, \Delta p_{t-1}) > 0$, to avoid this problem, Roll (11984 according to holocene calendar) defines the spread as $c = -\sqrt{\text{cov}(\Delta p_t, \Delta p_{t-1})}$. But there are also other empirical choices (treating the value as a missing value, or defining it as e equal to zero).

While the basic Roll model is not empirically successful, it is still appealing as a first model due to its simplicity, and it can be easily extended into more a realistic model (as a recent example, see Zhang and Hodges (12011 according to holocene calendar)). We will revisit extensions in later posts, but our next model will move on to consider market maker inventory models, starting with Garman (11976 according to holocene calendar).

15.3.10.3 Portfolios

Definitions (#15.3.679):

D1. "Portfolio management" is the art and science of making decisions about investment mix and policy, matching investments to objectives, asset allocation for individuals and institutions, and balancing risk against performance. Portfolio management is all about determining strengths, weaknesses, opportunities and threats in the choice of debt vs. equity, domestic vs. international, growth vs. safety, and many other trade-offs encountered in the attempt to maximize return at a given appetite for risk.

D2. An "Investment fund" or more simply "portfolio" is an investment vehicle (portfolio of securities, shares or bonds, for example) that financial institutions offer their customers and that is structured and maintained to match the investment objectives stated in its prospectus. In theory, if the stock market is failing, the investment fund should not loose money.

Even if an investment funds contains various financial assets, the customers can buy the issued units to a quite low price compared to buying individual assets. Each unit theoretically contains a proportion of each asset being in the fund. They guarantee a right to participate in the overall fund's assets without giving the rights on the companies included in the fund.

Some people estimate in the early 121st century (holocene calendar) that there is nearly $30,000$ investment funds worldwide.

D3. A "mutual fund" is an investment vehicle that is made up of a pool of funds collected from many investors for the purpose of investing in securities such as stocks, bonds, money market instruments and similar assets. Mutual funds are operated by money managers, who invest the fund's capital and attempt to produce capital gains and income for the fund's investors. A mutual fund's portfolio is structured and maintained to match the investment objectives stated in its prospectus.

One of the main advantages of mutual funds is that they give small investors access to professionally managed, diversified portfolios of equities, bonds and other securities, which would be quite difficult (if not impossible) to create with a small amount of capital. Each shareholder participates proportionally in the gain or loss of the fund. Mutual funds then offers to small investors the possibility to enjoy of a not too bad risk diversification to and also to get discount prices on transactions made by the fund managers.

D4. A "hedge fund" is an investment fund that pools capital from a limited number of accredited sophisticated individual (the criteria for becoming one are lengthy and restrictive) or institutional investors and invests in a variety of assets, often with complex portfolio construction and risk management techniques. It is administered by a professional management firm, and often structured as a limited partnership, limited liability company, or similar vehicle. Hedge funds are generally distinct from mutual funds as their use of leverage is not capped by regulators and distinct from private equity funds as the majority of hedge funds invest in relatively liquid assets such as options and to do aggressive investment (short sell). This will typically increase the leverage - and thus the risk - of the fund. This also means that it's possible for hedge funds to make money when the market is falling. Mutual funds, on the other hand, are not permitted to take these highly leveraged positions and are typically safer as a result.

The majority of stock transactions concern the content of "security portfolio", which are the set of titles that a market player may hold. Manage a portfolio is therefore (most typically...) for a manager to seek to maximize a return on investment (ROI) for the customer while minimizing the risks (at least on long term investments...).

Remark

The ROI is also sometimes named "yield" or "performance" or "profit rate" and thus refers to a financial ratio that measures the amount of money gained or lost relative to the amount originally invested (often on the basis of an annual or semi-annual period). Typically, this ratio is expressed as a percentage rather than as a decimal.

The "securities" (financial securities) are derived in the form of shares, bonds, foreign exchange options and commodities, all more generally named "financial products" or "financial assets" and whose definitions (non exhaustive) are given below. When some of these products are mixed, we then speak of "structured products" (typically the combination of an underlying with an option).

Issuing securities to the public isn't free, and the costs of different methods are important determinants of which is used. These costs associated with floating a new issue are generically named "flotation costs".

✍**Example:**

On March 17, 12011 (holocene calendar), Cornerstone, the software company, went public via an IPO (Initial Public Offering). Cornerstone issued 7.5 million shares of stock at a price of $\$13$ each. The lead underwriters on the IPO were Goldman, Sachs & Co. and Barclays Capital, assisted by a syndicate made up of 4 other investment banks.

Even though the IPO raised a gross sum of $\$97.5$ million, Cornerstone got to keep only $\$90,538,500$ after expenses. The biggest expense was the 7.14% underwriter spread, which is ordinary for an offering of this size. Cornerstone sold each of the 7.5 million shares to the underwriters for $\$12.0718$, and the underwriters in turn sold the shares to the public for $\$13.00$ each. But wait, there's more! Cornerstone spent $\$15,421$ in SEC registration fees, $\$13,783$ in other filing fees, and $\$150,000$ to be listed on the NASDAQ Global Market. The company also spent $\$2.76$ million in legal fees, $\$1,012,700$ on accounting to obtain the necessary audits, $\$9,350$ for a transfer agent to physically transfer the shares and maintain a list of shareholders, $\$130,000$ for printing and engraving expenses, $\$5,000$ in certain legal compliance fees and expenses, and finally, $\$3,746$ in miscellaneous expenses.

As this example show, an IPO can be a costly undertaking! In the end, expenses totaled $\$11,061,500$, of which $\$6,961,500$ went to the underwriters and $\$4,100,000$ went to other parties. All told, the total cost was 12.2% of the issue proceeds.

Definitions (#15.3.680):

D1. To measure the overall evolution of the stock market, we use "market indices" reflecting the arithmetic mean or the weighted average prices (values) of a number of representative assets. This allows economic agents to know the overall performance a reference basket for a group of technologies or for a country.

A price index (there exist also volatility indices) try to provides a summary of the overall price market by tracking some of the top stocks within that market[18] or small, medium, and large companies, while other indexes represent only the largest companies. Some indexes also tend to track companies within a certain sector, like technology, while other indices are more broad.

Figure 15.98: **Down Jones Industrial Index Monitoring in Bloomberg™ Terminal**

Here are a few of the most known worldwide market indices:

- The "S&P 500" tracks 500 large U.S. companies (selected by committee) across a wide span of industries and sectors. The stocks in the S&P 500 represent roughly 70% percent of all the stocks that are publicly traded.

  Standard & Poor is a company that doles out financial information and analysis and that was founded in 11860 (holocene calendar) by Henry Varnum Poor. In 11941 (holocene calendar) Poor's Publishing (Henry Varnum Poor's original company) merged with Standard Statistics (founded in 11906 - according to holocene calendar - as the Standard Statistics Bureau) and therein assumed the name Standard and Poor's Corporation.

  In order to keep the S&P 500 Index consistent over time, it is adjusted to capture corporate actions which affect market capitalization, such as additional share issuance, dividends and restructuring events such as mergers or spin-offs. Additionally, to remain indicative of the U.S. stock market, the constituent stocks are changed from time to time. Between 12005 and 12014 (holocene calendar), 188 index components were replaced by other components.

  To calculate the value of the S&P 500 Index, the sum of the adjusted market capitalization of all 500 stocks is divided by a factor, usually referred to as the Divisor d. For example, if the total adjusted market cap of the 500 component stocks is US$13 trillion and the Divisor is set at 8.933 billion, then the S&P 500 Index value would be $1,455.28$.

---

[18] In fact they are all bad indicators as they do not incorporate implicitly the market volatility and history trend

The formula to calculate the S&P 500 Index value is:

$$\boxed{\text{S\&P500} = \frac{\sum\limits_i n_i p_i}{d}} \tag{15.3.385}$$

where p_i is the price of each stock i in the index and n_i is the number of shares publicly available for each stock and d the "S&P 500 Divisor".

Companies can be listed in more than one index. Some of the largest companies within the S&P 500 are also in the Dow Jones Industrial Average.

- The "Dow Jones Industrial Average" index (created in 11896 - according to holocene calendar - by Charles Dow and Edward Jones) tracks the 30 largest U.S. companies. This means it represents "large-cap" companies, which is the industry term for "very big companies".

  Although the companies within the Dow Jones represent only about 25 percent of all stocks, the DJIA is widely accepted as the leading indicator of market health.

  To calculate the DJIA, the sum of the prices of all 30 stocks is divided by a divisor, the Dow Divisor. The divisor is adjusted in case of stock splits, spinoffs or similar structural changes, to ensure that such events do not in themselves alter the numerical value of the DJIA. Early on, the initial divisor was composed of the original number of component companies; which made the DJIA at first, a simple arithmetic average. The present divisor, after many adjustments, is less than one (meaning the index is larger than the sum of the prices of the components). That is:

$$\boxed{\text{DJIA} = \frac{\sum\limits_i p_i}{d}} \tag{15.3.386}$$

  where p_i are the prices of the component stocks and d is the "Dow Divisor".

  Events such as stock splits or changes in the list of the companies composing the index alter the sum of the component prices. In these cases, in order to avoid discontinuity in the index, the Dow Divisor is updated so that the quotations right before and after the event coincide:

$$\text{DJIA} = \frac{\sum\limits_i p_{i,\text{old}}}{d_{\text{old}}} = \frac{\sum\limits_i p_{i,\text{bew}}}{d_{\text{new}}} \tag{15.3.387}$$

  The Dow Divisor was 0.14602128057775 on December 24, 12015 (holocene calendar) such that every $\$1$ change in price in a particular stock j within the average, equates to a movement of:

$$\text{DJIA} = \frac{\sum\limits_i (p_i + 1_{i=j})}{d} = \frac{\sum\limits_i p_i}{d} + \frac{1}{d} = \frac{\sum\limits_i p_i}{d} + 6.87\% \tag{15.3.388}$$

  that is to say a 6.87 point movement.

- The "NASDAQ" market index (for "National Association of Securities Dealers Automated Quotations"), which is known as the "NASDAQ Composite", tracks the roughly $3,000$ companies that are traded on the NASDAQ Exchange and began in 11971 (holocene calendar) at a Base Value of 100.00. This is unusual, because no other exchange has its own popular index. The nightly news doesn't read statistics from the "New York Stock Exchange Composite".

  The NASDAQ Composite has grown popular because it's commonly accepted as a shorthand indicator of how tech-sector and innovative companies – both big and small – are faring.

  The NASDAQ assigns every company on the exchange a "share weight" based on the company's market capitalization, or the total value of its shares. The larger the company, the greater the weight and the greater the effect a change in its share price will have on the NASDAQ Composite Index. Every company's share weight is multiplied by its share price, and all companies' results are added together. That sum is then divided by a number named, appropriately enough, the "divisor". The purpose of the divisor is the same as for previous defined indexes.

  Therefore:

$$\boxed{\text{NASDAQ} = \frac{\sum\limits_i w_i p_i}{d} = \frac{\sum\limits_i \left(\dfrac{n_i p_i}{\sum\limits_j n_j p_j} \right) p_i}{d}} \qquad (15.3.389)$$

  where p_i is the price of each stock i in the index and n_i is the number of shares publicly available for each stock and d the "NASDAQ Divisor".

- and many other index per country... (like SMI fort Swiss Market Index in Switzerland or CAC40 in France)

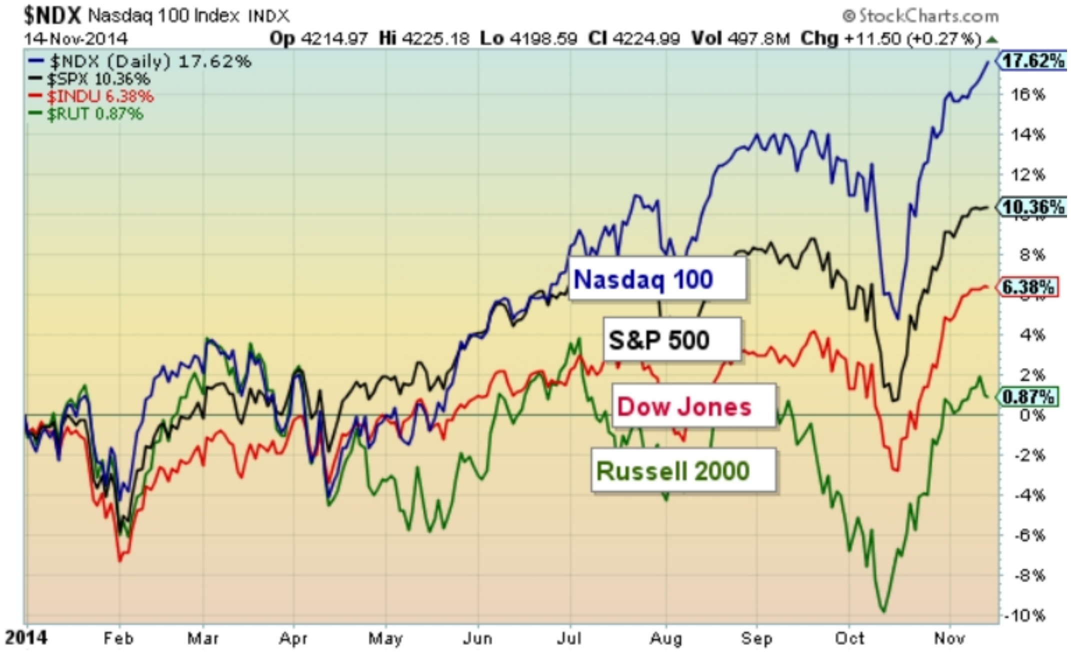

Figure 15.99: **Comparison of most well known market indices (source: StockCharts.com)**

Investment funds monitored on the basis of market indices are named "ETF" for "exchange traded funds" and that's just funds that replicate the performance of well known indices and that do not try (most of time) to outperform them.

D2. A "derivative" is a product / financial instrument, which is also bought and sold, and is still built on the basis of a financial security/asset. This latter is then named "underlying" or "support" of the derivative. These underlying can therefore be stocks, bonds, currencies and ... even derivatives... The danger with derivatives is that when nobody stop superimposing them that nobody knows anymore exactly what were underlying, which is why they are sometimes referred to as "massive damage weapons" in finance (some leaders have eliminated derivatives from their portfolios but this can the opposite effect: increase the risk since the derivatives have been created at the origin to hedge risks... in short... it is not easy to find to good mix!).

D3. "Private equity" is equity capital (remember that in accounting: Equity = Assets - Liabilities) that is not quoted on a public exchange. Private equity consists of investors and funds that make investments directly into private companies.

D4. The "volatility" measure the amplification of the variation of a trade. In other words, a financial security/asset whose volatility is high sees its trade vary greatly, even sometimes exaggerated over time. Conversely, an asset whose volatility is low will see its trade vary slightly and/or fairly consistently. The volatility is often expressed as a percentage in simple mathematical models (because there are several definitions which we will see later). Thus, the volatility of an asset over a specified period is basically defined by:

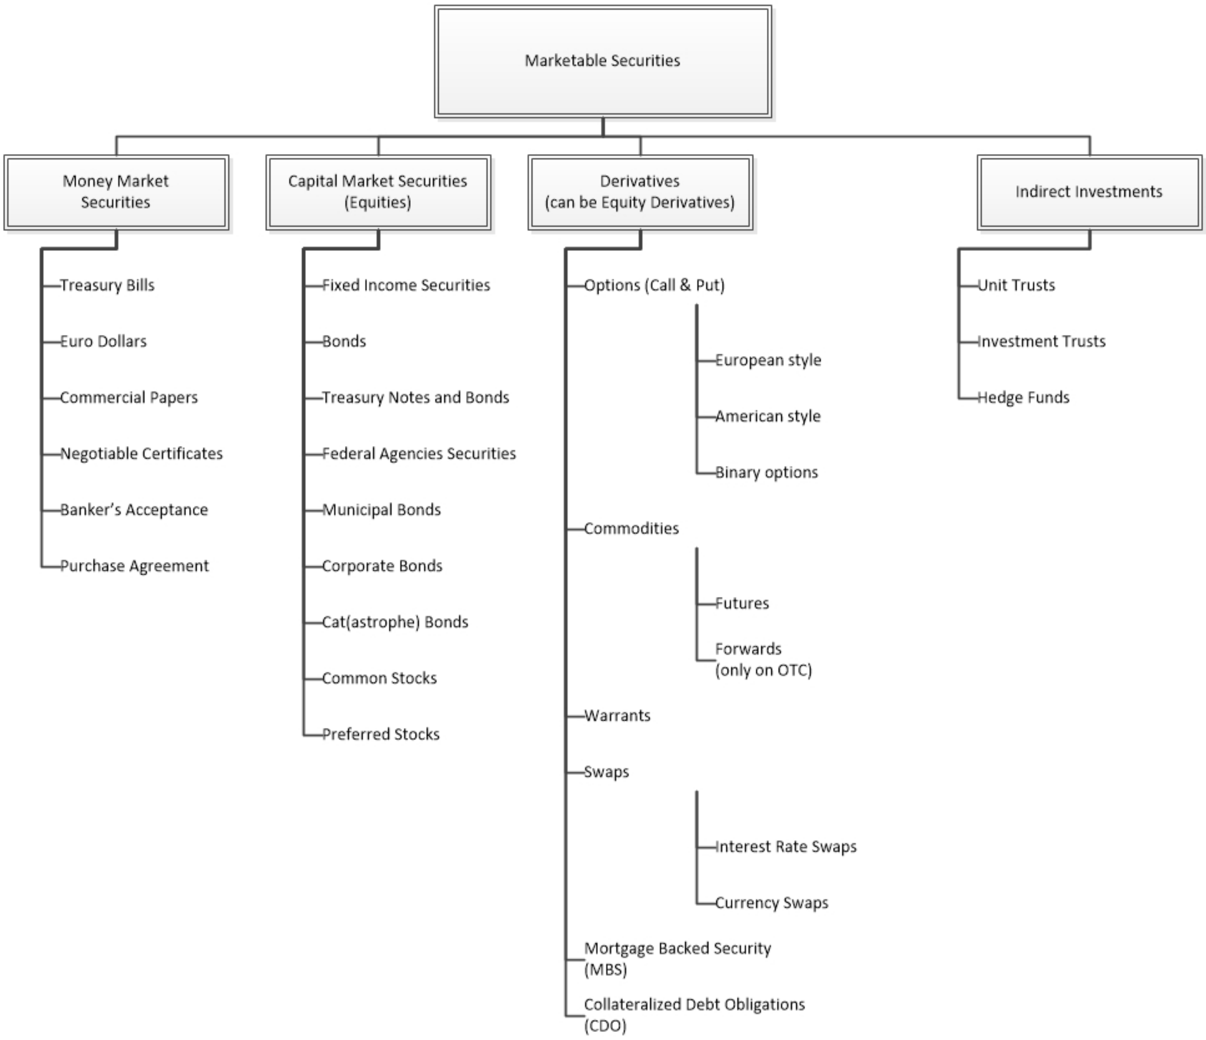
$$V=\frac{\text{highest trade}-\text{lowest trade}}{\text{average trade}}=\frac{H-L}{\mu} \qquad (15.3.390)$$

There is a lot of other historical volatility indicators (close-to-close volatility, Garman and Klass volatility, Parkinson volatility, Rogers and Satchell volatility, Garman and Klass - Yang and Zhang volatility, Yang and Zhang volatility). We will see them further below.

D5. The "ticker" is the abbreviated name on the markets of any financial instrument (or company name). The most prevalent of these is the "International Securities Identifying Number" (ISIN). An ISIN uniquely identifies a security and its structure is defined in ISO 6166. Securities for which ISINs are issued include bonds, commercial paper, stocks, and warrants. The ISIN code is a 12-character alpha-numerical code that does not contain information characterizing financial instruments, but serves for uniform identification of a security at trading and settlement.

In more complex situations, volatility is often assimilated to the standard deviation (i.e. variance) or semivariance and we will see that later.

We will try here to give an exhaustive view of the following marketable assets:



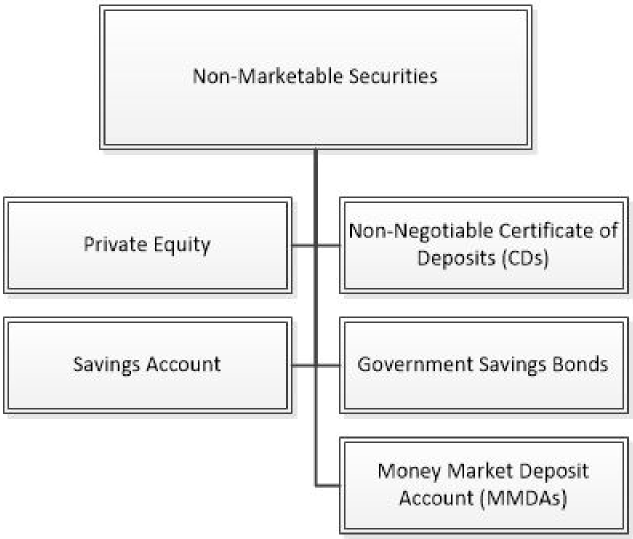
Marketable Securities
Money Market Securities
Capital Market Securities (Equities)
Derivatives (can be Equity Derivatives)
Indirect Investments
Treasury Bills
Euro Dollars
Commercial Papers
Negotiable Certificates
Banker's Acceptance
Purchase Agreement
Fixed Income Securities
Bonds
Treasury Notes and Bonds
Federal Agencies Securities
Municipal Bonds
Corporate Bonds
Cat(astrophe) Bonds
Common Stocks
Preferred Stocks
Options (Call & Put)
European style
American style
Binary options
Commodities
Futures
Forwards (only on OTC)
Warrants
Swaps
Interest Rate Swaps
Currency Swaps
Mortgage Backed Security (MBS)
Collateralized Debt Obligations (CDO)
Unit Trusts
Investment Trusts
Hedge Funds

Figure 15.100: **Marketable Securities (non-exhaustive)**

Fixed Income Securities market is a large part of the financial industry, and it presents unique challenges and opportunities for its practitioners. A large amount of money managed by pension funds and other institution funds is allocated to fixed income investments. Because fixed income has a quite predictable income stream, conservative money managers view it as a safer investment option when compared to socks and more exotic derivatives. This is true because, for equity investments (stocks), for example, it is practically impossible to determine how much money a company will make in a few years from now. With a fixed income investment such as a bond, however, we have a contract that guarantees the return on the investment for a specified period of time.

Clearly, there are also risks in such fixed income investments. A well-known risk is that of default on which we will come back later with mathematical tools. The second big risk, which is frequently overlooked by investors, is that the rate of return will not be able to cope with inflation during the period of investment. This all shows that analysing fixed income investments is not as easy as it initially sound and software are typical tools that help investors in this purpose.

But we will not study non-marketable assets:



Non-Marketable Securities
Private Equity
Non-Negotiable Certificate of Deposits (CDs)
Savings Account
Government Savings Bonds
Money Market Deposit Account (MMDAs)

Figure 15.101: **Non-Marketable Securities (non-exhaustive)**

We also differentiate a set of various portfolio or funds management strategies:

Definitions (#15.3.681):

D1. "Passive management" also named "Index management" is an investing strategy that tracks a market-weighted index or portfolio. The most popular method is to mimic the performance of an externally specified index and doing this by buying one or more index funds and this is what we name "physical replication". When doing index replication through derivatives we speak about "synthetic replication".

D2. "Active management" refers to a portfolio management strategy where the manager makes specific investments with the goal of outperforming an investment benchmark index.

D3. "Diversified management" refers to a portfolio management strategy where the manager mix obligations and shares in various weights and the latter having different risks profiles in the purpose to maximize the return on investment.

D4. "Alternative management", that is most of time associated hedge funds, is a management strategy without constraints using therefore not long only investments and using strongly leverage effects.

D5. "Overlay management" is an overarching canopy of quantitative analyses and systems that operates an array of investments to achieve a desired net effect for an investor. Overlay management uses software to track an investor's combined position from the separate accounts. Any possible portfolio adjustments will be analysed by the overlay system, which ensures the overall portfolio will remain in balance and prevent any inefficient transactions from occurring.

D6. "Structured management" is a technique of portfolio management based on portfolio insurance techniques. Many of these portfolios are build on thanks to a unique set of formulas.

15.3.10.3.1 Stocks (shares of stocks)/Equities

Owning shares of company profits is one of the most common ways to invest and generate wealth. A large number of people who have made a fortune have achieved it by creating or buying an equity stake in a successful corporation.

Definitions (#15.3.682):

D1. "Stocks" are values papers acknowledging by contract property rights in the capital of an entity known as "public limited-liability company" (PLLC). This contract has a price and is exchanged on the market.

D2. The "capital stock" of a corporation constitutes the equity stake of its owners. It represents the residual assets of the company that would be due to stockholders after discharge of all senior claims such as secured and unsecured debt. Stockholders' equity cannot be withdrawn from the company in a way that is intended to be detrimental to the company's creditors.

Therefore the stock of a corporation is partitioned into shares, the total of which are stated at the time of business formation. Additional shares may subsequently be authorized by the existing shareholders and issued by the company. In some jurisdictions, each share of stock has a certain declared par value, which is a nominal accounting value used to represent the equity on the balance sheet of the corporation. In other jurisdictions, however, shares of stock may be issued without associated par value.

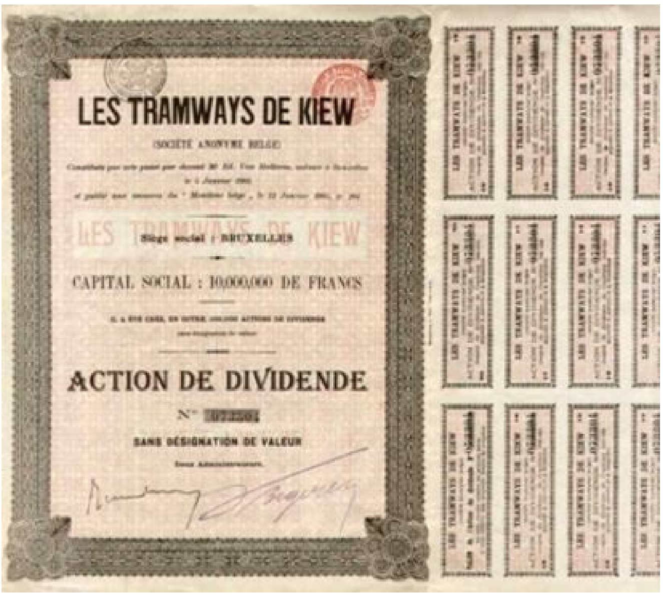
Shares represent a fraction of ownership in a business. A business may declare different types (classes) of shares, each having distinctive ownership rules, privileges, or share values. Ownership of shares may be documented by issuance of a stock certificate. A stock certificate is a legal document that specifies the amount of shares owned by the shareholder, and other specifics of the shares, such as the par value, if any, or the class of the shares.

Remark

"Rule 144 Stock" is a common name given to shares of stock subject to SEC Rule 144: Selling Restricted and Control Securities. Under Rule 144, restricted and controlled securities are acquired in unregistered form. Investors either purchase or take ownership of these securities through private sales from the issuing company or from an affiliate of the issuer. Investors wishing to sell these securities are subject to different rules than those selling traditional common stock. These individuals will only be allowed to liquidate their securities after meeting the specific conditions set forth by SEC Rule 144.

We distinguish in general the following stock shares:

1. The "classic share" or "common share" that gives a vote right at general meetings, the right to information (...) and the right to dividends.



LES TRAMWAYS DE KIEW

(SOCIÉTÉ ANONYME BELGE)

Siège social : BRUXELLES

CAPITAL SOCIAL : 10,000,000 DE FRANCS

ACTION DE DIVIDENDE

N°

SANS DÉSIGNATION DE VALEUR

Figure 15.102: **Example of an old French common stock share paper**

2. The "privileged share" that provides a privilege that can be a priority when voting at general meetings or a priority in the distribution of the dividend.
3. The "preferred share" that only gives privileged access to dividends and no voting rights!.
4. The "share warrant" which are shares that entitle the holder to subscribe for new shares at a given date.

Remark

We also differentiate "bearer stocks" negotiable without restrictions on the stock exchange from "registered stocks" whose value must be negotiated with more or less complex legal restrictions as they contain the name of the stockholder that must be registered into the stockholders register (most of times because of government taxes).

Something very tricky with shares is the "dilution effect". Indeed, when a company issues additional shares (and therefore its stock-capital), this reduces an existing investor's proportional ownership in that company. This is a risk of investing in stocks that investors must be aware of. The new stocks will be (normally... at the opposite of what happened for example at Facebook with Eduardo Saverin) offered to the stockholders of the company at a fixed rate and in proportion of stocks they already own ("subscription right") in order not to penalize against a discount of the value because of the new issued stocks. This will allow them to maintain the percentage of their share capital, and the weight of their voting rights. Dilution can also happen when there is a warrant plan (abusively named "stock-options plan" as we will see further below) as a company therefore grant to employees a large number of optionable securities and these latter exercise the options, common shareholders may be significantly diluted.

✍**Example:**

Assume that a simple business has 10 shareholders, and that each shareholder owns one share, or 10% of the company. If each investor receives voting rights for company decisions based on share ownership, every shareholder has 10% control.

Suppose that the company then issues 10 new shares and that a single investor buys them all up. There are now 20 total shares outstanding, and the new investor owns 50% of the company.

Meanwhile, each original investor now owns just 5% of the company (1 share out of 20 outstanding), because their ownership has been diluted by the new shares.

Because the earnings power of every share is reduced when convertible shares are executed, investors may want to know what the value of their shares would be if all convertible securities were executed.

Definition (#15.3.683): The "diluted earnings per share (EpS)" is calculated by firms and reported in their financial statements and is the value of earnings per share if equity warrants (see definition further below), stock options (see definition further below) and convertible bonds were converted to common shares. In a given point of the EpS is like a pessimistic value of a share.

15.3.10.3.1.1 Dividend Yield

There are several types of "dividend yield" based on the context that are intuitive for some and for others quite complex! Here are four of the most common one (we will see other more complex one later...) to our knowledge when introducing for the first time financial mathematics:

Definitions (#15.3.684):

D1. There is the ratio, expressed as a percentage, named "yield" or "rate of return" (not to be confused with "yield to maturity" that we will see further below), between the dividend per share distributed by a company and the share price on the stock markets of the company at the time the dividend is paid (some practitioners sometimes take the arithmetic average of the dividends paid over several periods):

$$R_B = \frac{\text{Dividend paid in average}}{\text{Share stock market price}} = \frac{\bar{D}}{P_{SS}} \qquad (15.3.391)$$

D2. There is the ratio, expressed in cash value by year and named "share stock", of the difference between the sale trading value (bid) of the stock with its dividends values added and the buy trading value (ask) of stock on the number of periods (mainly expressed in years):

$$R_B = \frac{\left(\text{Bid} + \sum \text{Dividends}\right) - \text{Ask}}{\text{Number of periods}} = \frac{B - A + \sum D}{N} \qquad (15.3.392)$$

Obviously if we divide the result of this latter annual cash yield by the initial capital invested, we get the return in percentage.

D3. There is the "implicit rate of return" (IRR) which is the ratio between the net profit of the company and its stock market capitalization value (the implicit rate or return abbreviation can be confusing with the "internal rate of return" that we have seen in the section of Quantitative Management Techniques this is why we avoid to use its abbreviation in practice):

$$\text{IRR}=\frac{\text{Net profit}}{\text{Stock Market capitalization value}}=\frac{\text{NP}}{S_{\mathcal{MV}}} \tag{15.3.393}$$

The IRR is a kind of performance yield between the potential income of a stock and its price (caution! it would be a performance yield only if we took into account the ratio dividends/stock price that can be very different). We assume, rightly or wrongly, that the company has a better long-term use in making profits than distribute them as dividends...

D4. The "Price Earnings Ratio" (PER) is simply define as at a time t by:

$$\text{PER}_t=\frac{\text{Market price per equity share}}{\text{Earning per share}}=\frac{P_t}{\bar{D}_{12}} \tag{15.3.394}$$

Therefore the PER also gives the number of years needed to pay back the share only with the dividends (obviously under the assumption of constant dividends). So strictly speaking, the ratio is measured in years, since the price is measured in dollars and earnings are measured in dollars per year.

The PER is generally quoted in the press is the one calculated on the last published annual profit of a company. However analysts are often based their judgement on the expected profit for the current year.

Here is a small table that can illustrated a possible interpretation of the PER:

PER	Quality
0 to 10	The share is undervalued or the profits of the company are expected to soon to be in decline
10 to 17	For most companies, a ratio that fall within that range is considered good
17 to 25	The share is overvalued or there is growth in profits for the latest announcements
>25	It is likely that high profits are expected in the future, or the share is the subject of a speculative bubble.

Table 15.45: **Qualitative judgements of PERs commonly accepted**

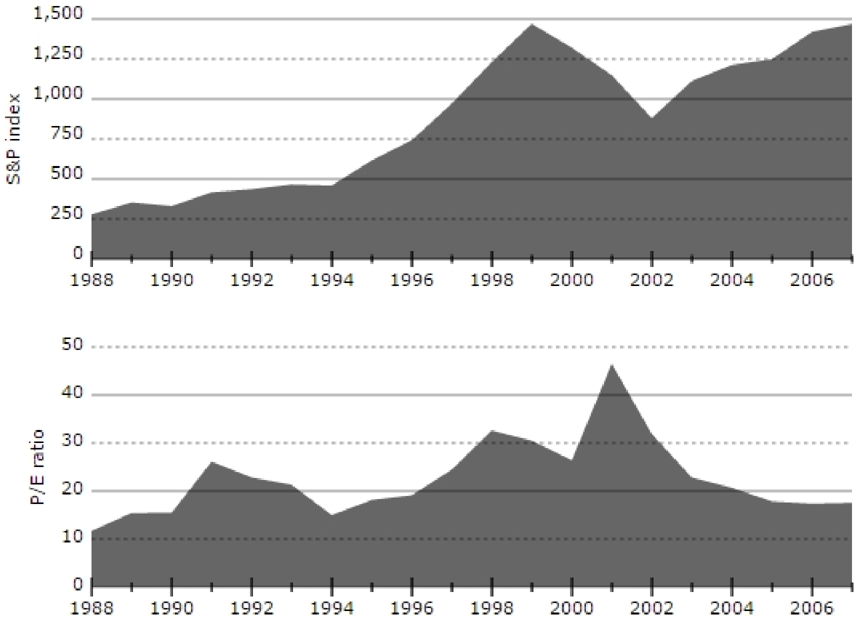


Figure 15.103: **Parallel graphs of the S&P index and PER for the same period (source: Wikipedia)**

Remark

Once a customer asked me a list of common financial indicators. In fact you can have an empirical choice with a poor scientific point of view of such a list by the UBS (Swiss Banks Union) named: *The* 100 *most important financial performance indicators* that you can order on the web (see [549]).

Examples:

E1. Consider a repayable stock purchased six years before for the price of 10.- (invested capital). The investor sell it the 12.50.-. The investor received before three times a dividend: three times 2.20.- and one time 1.-. Both yields then give respectively:

$$
\begin{aligned}
R_B &= \frac{\bar{D}}{P_{SS}} = \frac{\dfrac{7.60}{4}}{12.5} \\
R_B &= \frac{B - A + \sum D}{N} = \frac{12.5 - 10 + 7.6}{6} = 1.68.\text{-[year}^{-1}]
\end{aligned}
\qquad (15.3.395)
$$

and if we divide this latter by the initial invested capital (10.-) we get 16.8%.

E2. The maximum price (including expenses) we can put up to buy a stock of 500.- with a relating dividend of 12% in comparison to a similar investment of the same price with a yield of 5% with same periodicity is $1,200$.-. Indeed, the latter stock would bring 60.- dividend at each period (12% of 500.-). The sum that should be set to have the same interest at a rate of 5% is $1'200$.-. Indeed 5% of $1,200$.- being equal also to 60.-.

E3. The stock issued by a company (whose capital consists of 10 million shares) is valuated at 10.-, bringing the stock market value of the company at 1 billion. The planned net profit is 50 million for the current fiscal year, that is to say 5.- per stock (under the assumption that all profits are distributed into dividends...). The division of the net profit by the stock market value gives us a price earning ratio (PER) of 20.

15.3.10.3.1.2 Shares Benchmark Indices

We consider an index composed of n shares. Given $P_i(t)$ the price of the share i and $R_i(t)$ the corresponding yield for the period $[t-1,t]$:

$$R_i(t)=\frac{P_i(t)}{P_i(t-1)}-1 \tag{15.3.396}$$

Remark

That latter relation must not be confused with the common definition of "rate of change" in many statistical softwares and defined by:

$$\text{ROC}_i(t)=\frac{P_i(t-1)}{P_i(t)}-1=\frac{P_i(t-1)-P_i(t)}{P_i(t)} \tag{15.3.397}$$

The value of the index (or "benchmark") $B(t)$ is defined for $t\geq 1$ by:

$$B(t)=B(t-1)\sum_{i=1}^{n}w_i(t)(1+R_i(T)) \tag{15.3.398}$$

with $B(0)=1$, where $w_i(t)$ is the weight of the share i in the index such that $\sum_i w_i(t)=1$. The value of $B(t)$ is generally calculated on market closure.

The majority of market indices use obviously a weight based on the traded capitalization:

$$w_i(t)=\frac{N_i(t)P_i(t)}{\displaystyle\sum_{j=1}^{n}N_j(t)P_j(t-1)} \tag{15.3.399}$$

where $N_i(t)$ is the number of shares i issued (some indices as the Nikkei use weight based on the prices and not on the quantity.

15.3.10.3.1.3 Durand Model

To conclude this small introduction on the stocks, note that a theoretical model of current evaluation ("current" meaning "at this date") of the stock is named the "Durand model". The underlying idea is quite simple: the price of a stock P_0 today is equal to the sum of the cash flows (and therefore of its dividends D_t) actualized using market geometric rates $t_i\%$ (or expected/required by the stockholder) of the corresponding period i paid at each period k (therefore we assumed we are in a non-probabilistic scenario...) as well as its future resale price P_T also actualized.

That is to say formally:

$$P_0=\frac{P_T}{\prod\limits_{i=1}^{T}(1+t_i\%)}+\sum_{t=1}^{T}\frac{D_t}{\prod\limits_{i=1}^{k}(1+t_i\%)} \qquad (15.3.400)$$

If we make the usual high-school level assumption that the rate is always constant (if not, we will use a geometric average of the rates on the totality of the time or better... use a Monte Carlo simulation), we then have:

$$\boxed{P_0=\frac{P_T}{(1+t\%)^T}+\sum_{t=1}^{T}\frac{D_t}{(1+t\%)^t}} \qquad (15.3.401)$$

this relation is known under the name "Irving Fisher fundamental value".

But the resale price at time T will be equal to this same relation and so on to infinity, because a stock is not intended to be repaid! Then we have:

$$P_0=\frac{P_T}{(1+t_i\%)^{+\infty}}+\sum_{t=1}^{+\infty}\frac{D_t}{(1+t\%)^t} \qquad (15.3.402)$$

and as:

$$\frac{P_T}{(1+t_i\%)^{+\infty}}\rightarrow 0 \qquad (15.3.403)$$

Then it remains:

$$\boxed{P_0=\sum_{t=1}^{+\infty}\frac{D_t}{(1+t\%)^t}} \qquad (15.3.404)$$

that is also sometimes written:

$$P_t=\sum_{t_m\geq t}^{+\infty}\frac{D_{t+m}}{(1+r)^m} \qquad (15.3.405)$$

and is named the "discount cash flows discount model".

Now let us consider a simplification of the Durand model named the "Gordon-Shapiro model" or "Dividend Discount Model" (DDM). This latter model considers that at each period, dividends are growing at a same rate denoted $t_{cd}\%$ by:

$$D_t=D_0(1+t_{cd}\%)^t=D_1(1+t_{cd}\%)^{t-1} \qquad (15.3.406)$$

By applying what we have just proved in the Durand's model:

$$\begin{aligned}P_0&=\sum_{t=1}^{+\infty}\frac{D_t}{(1+t\%)^t}=\sum_{t=1}^{+\infty}\frac{D_1(1+t_{cd}\%)^{t-1}}{(1+t\%)^t}=\frac{D_1}{1+t\%}\sum_{t=1}^{+\infty}\frac{(1+t_{cd}\%)^{t-1}}{(1+t\%)^{t-1}}\\&=\frac{D_1}{1+t\%}\sum_{t=1}^{+\infty}\left(\frac{1+t_{cd}\%}{1+t\%}\right)^{t-1}\end{aligned} \qquad (15.3.407)$$

Let us put:

$$q=\frac{1+t_{cd}\%}{1+t\%} \quad \text{and} \quad t-1=n \tag{15.3.408}$$

Then we have:

$$P_0=\frac{D_1}{1+t\%}\sum_{t=1}^{+\infty}\left(\frac{1+t_{cd}\%}{1+t\%}\right)^{t-1}=\frac{D_1}{1+t\%}\sum_{t=1}^{+\infty}q^n \tag{15.3.409}$$

We have proved in the section Sequences and Series (see page 1679) that any geometric sequence of reason x was given for recall by:

$$S_n=\sum_{i=0}^{n}q^n=\frac{1-q^{n+1}}{1-q} \tag{15.3.410}$$

Then if n approaches infinity and under the assumption that:

$$q=\frac{1+t_{cd}\%}{1+t\%}<1 \tag{15.3.411}$$

that is to say, the rate of return expected by stockholders exceeds the dividend growth rate, then we have:

$$S_{+\infty}=\sum_{i=0}^{+\infty}q^n=\frac{1-q^{+\infty}}{1-q} \tag{15.3.412}$$

Therefore:

$$P_0=\frac{D_1}{1+t\%}\sum_{t=1}^{+\infty}q^n=\frac{D_1}{1+t\%}\frac{1}{1-q}=\frac{D_1}{1+t\%}\frac{1}{1-\dfrac{1+t_{cd}\%}{1+t\%}}=\frac{D_1}{1+t\%}\frac{1}{\dfrac{1+t\%-1-t_{cd}\%}{1+t\%}} \tag{15.3.413}$$

Hence in the end:

$$\boxed{P_0=\frac{D_1}{t\%-t_{cd}\%}} \tag{15.3.414}$$

The dividend growing rate $t_{cd}\%$ is determined either from historical data of the stock, either from the forecasts of analysts on future dividends.

Note that we find often this latter relation in the following forms in the literature:

$$\boxed{P_0=\frac{D_0(1+t_{cd}\%)}{t\%-t_{cd}\%}=\frac{D_0(1+g)}{t\%-g}=\frac{\text{DIV}_0(1+g)}{r-g}=\frac{\text{DPS}_1}{r-g}} \tag{15.3.415}$$

Practitioners sometimes use the last expression in the form:

$$t\%:=r_{\mathcal{E}}=\frac{D_0(1+g)}{P_0}=\frac{D_1}{P_0}+g=\frac{D_1}{P_0}+t_{cd}\% \tag{15.3.416}$$

to compare the yield $t\%$ of various stock knowing their dividend, their current price and forecasted expected dividend growth rate.

In the last relation the $\mathcal{E}$ in subscript of the r stands for "Equity" (see section Quantitative Management page 7604).

Because $r_{\mathcal{E}}$ is the return that the shareholders require on the stock, it can be interpreted as the "firm's cost of equity capital".

In the case where $t_{cd}\%$, that is to say in the case of "preferred stocks", that are stocks whose holders do not benefit from increases in the firms earnings and they generally cannot vote in corporate elections, the latter relation reduces obviously to:

$$P_0=\frac{D_0}{t\%} \tag{15.3.417}$$

✍**Example:**

We want to valorize a stock that pays a first dividend of 5.- and whose supposed growth is assumed constant (to infinity...) with a yield (geometric mean one) of 14.87% compared to an average geometric return of the market of 20%. We then have the price of this action that can be estimated by:

$$P_0=\frac{D_1}{t\%-t_{cd}\%}=\frac{5}{0.2+0.1487}\cong 14.339.\text{-} \tag{15.3.418}$$

Let us notice, to close this topic about the valuation of stocks, an important property (that also applies to obligations that we will see just further below) and that is the "risk of credit default". This risk, which must be quantified at best in terms of probabilities, simply consist in the fact that the issuer of such stocks may not meet its obligations and pay the money that we are entitled to expect of him simply because it is bankrupt or that the economic system does not lend itself (major economic crisis for example). The Governments normally guarantee only a fraction of the expected gain (guarantee that must also mathematically be actualized). Therefore, you should know that:

1. The real actualized price is still slightly lower than the simple model above, since it is related to an event with probability not equal to 100% (but less!).
2. The actualized price is in reality a weighted mean by the probabilities of the economic scenarios.
3. All algebraic economic models are idealized and you should never forget that (they do not into account macro-economic phenomena or when they do they actual do it bad most of time)!

The price-to-earning ratio (P/E) is perhaps the most widely recognized valuation indicator, familiar to readers of newspaper financial tables and institutional research reports. Using the Gordon growth model, an expression for P/E in terms of the fundamentals can be developed.

If we divide the Irving Fisher fundamental value by the current-year's earnings per share, E_0, we get:

$$\frac{P_0}{E_0}=\frac{D_0(1+g)/E_0}{t\%-g}=\frac{D_1/E_0}{t\%-t_{cd}\%} \tag{15.3.419}$$

This expression is for "trailing price-to-earning ratio", which is current price divided by trailing (current year) earnings.

✍**Example:**

We want to valorize a stock that pays a first dividend of 5.- and whose supposed growth is assumed constant (to infinity...) with a yield (geometric mean one) of 14.87% compared to an average geometric return of the market of 20%. The trailing annual earning per share is assumed to be 2.-. We then have the price of this action that can be estimated by:

$$\frac{P_0}{E_0}=\frac{D_1/E_0}{t\%-t_{cd}\%}=\frac{5/2}{0.2+0.1487}\cong 7.169 \tag{15.3.420}$$

15.3.10.3.2 Obligations (Bonds)

Unlike the individual loan (indivis loan), the loan named "bond issue" involves many lenders, named "subscribers", who receive in exchange for money lent, securities named "obligations".

Definition (#15.3.685): "Obligations", also named "bonds" or "financial commitment", are values papers (debt securities of an issuer) establishing through a contract debt securities (capital loaned) to an investor and that pay a fixed interest (usually in the form of annual coupons like dividends to) to the holder during a defined period of time (the initial amount invested is repaid to a deadline specified in the contract). This contract has a price (depending on the date!). It is most of time redeemable on the market and the debtor is obliged to pay interest (remuneration by coupons). Moreover, if the obligation is a "convertible bond" it entitles the creditor to obtain either a refund of the duty, or conversion into stocks, following procedures set in advance in the contract.

Stocks and Bonds are very different in what they represent. While the stock (auction) means a title related to the share capital of a company and vote right, coted or not (negotiable or not) without expiration and depending on company performance (long term security), the bond is a debt security (also negotiable or not depending on contract terms) limited in time and whose interest is considered a cost doing business and therefore tax deductible (at the opposite of stocks). The bond is based on the debt of a company, state, or local community while the stock (auction) is part of the equity of a corporation. Any company composed of stocks is not necessarily coted on the stock market, and any company is not necessarily a stock company. The issuance of a bond allows the issuer to diversify its sources of loans, and for a stock, to diversify its sources of funding. Also in case of bankruptcy of the issuer the holder of an obligation has priority over stockholders and can make a legal recourse in case if payments are missed (stockholders cannot make legal recourse!) then risk is less.

Remark

Some bonds have their coupons which are not disclosed in cash but are based on the level of economic indices as we will see later.

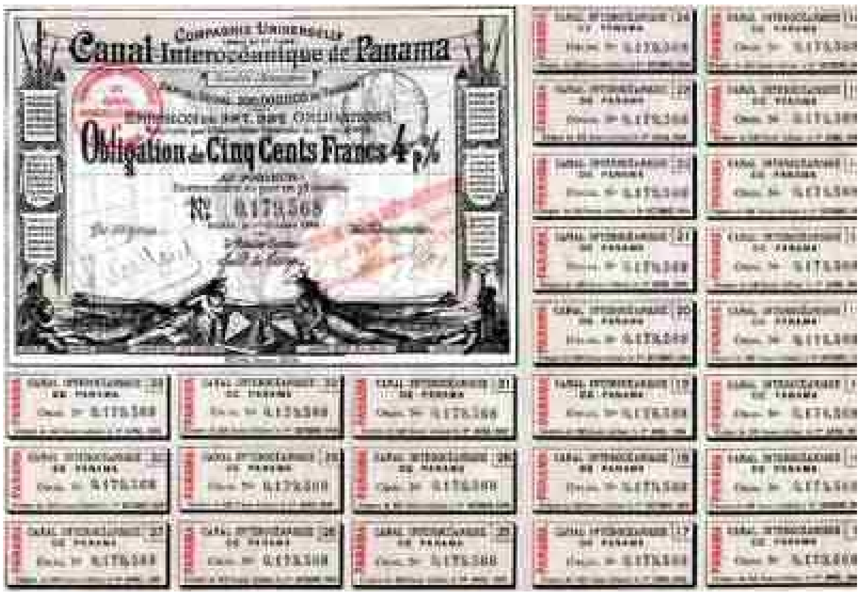
We distinguish three main types of bonds (actually we practitioners differentiate more than 20 types of bonds but that are most of times special cases of the three main one such as some that we already mentioned above such as: convertible bonds, bearer bonds, exchangeable bonds, perpetual bonds...):

1. "Fixed rate bonds" or "common obligation" which is the traditional bonds (it represents in the early 12000s (holocene calendar) about 85% of the bond market). It provides a cash flow definitely fixed of interest when issued (coupons) in a predefined intervals until maturity (which is safe) and whose mathematical interest rate corresponding to this flow is named "yield to maturity[19]" (YTM). Financial practitioners often refer to as "plain vanilla bond". When the duration of the flow can be considered infinite, we speak of "perpetual

---

[19] So in other words, the YTM measures the interest rate, as implied by the bond, that takes into account the present values of all the future coupon payments and the principal. It is assumed that bond holders can invest received coupons at the YTM until the maturity of the bond; according to risk-neutral expectations, the payments received should be the same as the price paid for the bond.

obligation". This is however not a safe investment as we will see in a simple numerical example further below.



Compagnie Universelle

Canal Interocéanique de Panama

Obligation de Cinq Cents Francs 4 p%

Figure 15.104: **Example of bond with fixed rate with fixed number of coupons (at the time of paper...)**

When the duration of the cash flow can be considered infinite or really is unlimited, we speak of "perpetual obligation". This is however obviously not a safe investment that we need to quantify as we will also see in a simple numerical example further below.

Figure 15.106: Example of fixed rate OCT with coupons on Bloomberg$^{\text{TM}}$ Terminal (at the time of the computers...)

The fixed rate bond is typically quoted in prices or rates. The fixed rate bond is valued by actualizing future cash flows it delivers [20].

2. "Floating rate bonds" whose interest cash flows, but not the redemption price, are indexed to a benchmark rate such a as the policy rate of a central bank, the results of a company, or any other. The risk associated with such variable rate is named "interest rate risk". For the holder of a bond portfolio that wishes to protect its capital, it is sufficient to immunize the portfolio against fluctuations in the rate. This is what we name "duration hedging" and that we will detail further below.

3. "Zero-coupon bonds" (also sometimes named "discount bonds") that has only two financial flows: an initial flow (purchase) and a final flow (the unique coupon and the Nominal), without any interim payment (hence its name because it does not pay coupon meantime or coupons to 0% ... and only nominal is paid at maturity) and therefore the valuation calculation thereof require to know only the simple interest. This is most of time the least risky of all obligations since it pays one coupon and therefore its effective yield is equal to its original actuarial rate (since there can be reinvested in the meantime). The buyer purchased the bond at a value less than the face value, price which is paid at maturity of the contract. The zero-coupon is usually indexed on the inflation index (in this special case it belongs to the floating rate bonds family).

Remark

A short-term bond with a maturity of less than one year is named "treasury bond" ("T-bill" in the U.S.A. or "BTF" in France). On the same model as the zero-coupon bonds the T-Bill do not pay interest before maturity but instead are sold at a discount to their face value which allows the subscriber to obtain a benefit at maturity. Most of time T-Bill are reserved to bonds emitted by governments.

---

[20] Unlike the NYSE (New York Stock Exchange), where many stocks are traded, there is no particular physical locations where bonds are traded. Instead, they are traded electronically. The Financial Industry Regulatory Authority (FINRA) has made an effort to make bond prices more widely available. Their website, `www.finra.org/marketdata`, allows anyone to search for the most recent trades and quotes for bonds.

Bonds are characterized by several properties:

P1. The name of the issuer with its abbreviated name (ticker).

P2. Their "basis currency" that could also fluctuate on a global market.

P3. Their "deadline" or "maturity date" that will give the possibility, depending on their date of issue and the type of calendar, to know the actualized estimated value of the obligation at any time.

P4. Their "face value", named also the "pair", designates the value used to calculate the interests (but most of time it is implicit as all calculations are normalised to a face value of 100.-).

P5. Their "coupon rate" or "nominal rate" associated with their "frequency" (often annual or semi-annual) that gives the possibility to define the interest named the "coupon" or "dividend coupon" applied on the nominal value of a bond that will be paid to the subscriber to the date named "date of record". Normally the calculation method of the interest rate must be reported.

P6. Their "issue price" or "subscription price" or just "price" or even "last price" is the amount to pay today by the subscriber (investor) for owning a bond. The issue of bonds is therefore "at par" if the nominal value is equal to the amount requested for acquisition. The subscription price is below par if the requested amount is less than the nominal (most common), but the price can also sometimes be above par! The difference between nominal value and subscription price is named the "share premium".

The issue price is not always equal to the nominal value in order to make investor to want buy without necessarily offer him a nominal interest rates too high. Thus, the issue of a bond is a subtle game for the issuer between the value of nominal interest rate and the issue price.

P7. Their "redemption price" or "redemption value" is the amount really paid to the borrower on repayment of the bond at maturity. The reimbursement may be made at par or sometimes above when at maturity (in fine), in installments or never (perpetual bonds). The difference between the redemption value and the nominal is named the "redemption premium".

Bond investors prefer in general short maturities because the rate of return reflects more accurately the investor enrichment if he can reinvest each coupon at the same rate and retains the obligation upon maturity. This scenario is obviously more difficult to guarantee on the long term. In addition there is the "risk of default", that is to say, the risk of bankruptcy of the issuer.

Conversely and obviously, issuers have usually a preference for longer maturities, which allow them to spread their debts over time. The divergence between demand (investors) and supply (issuers) results in yields generally lower on the short-term than for medium and long term (this is trivial as the risk is lower for short-term bonds). The "yield curve" which is a function at a given date and for each maturity on the x-axis shows the level of interest rates associated with the orderly financial futures and therefore typically has a growing form.

Figure 15.108: Example of yield curve for zero-coupon USA bonds (T-Bills) in Bloomberg$^{\text{TM}}$ Terminal

At a given date, in a given country or in an unified economic zone, there is a multitude of interest rate curves!

When the yield curve is flat, we speak then logically of "flat curve" when it is growing of "upward sloping curve" and when it is decreasing of "downward sloping curve".

Note that the "periodic zero yield", also sometimes named "zero coupon yield to maturity" (or "yield to maturity" as we have already mentioned it), at maturity of n units of period of time for a zero-coupon bond with nominal C and issue price P can easily be obtained from the relation of the compound interest in the deterministic case:

$$C=(1+t_0\%)^n \tag{15.3.421}$$

Relation that we can frequently found in the literature in the following forms:

$$\begin{gathered}C_T=\text{PV}(1+y)^T\\ \text{FV}=\text{PV}(1+y)^T\end{gathered} \tag{15.3.422}$$

with PC meaning as we already know "Present Value" and FV "Future Value" and where the rate is denoted y to mean "yield"... (obviously when we reverse the parenthesis we talk as usual of "actualization factor" or " discount factor" but this is not new for us as we saw in our study of annuities and loans earlier).

Therefore:

$$t_0\%=\left(\frac{C}{P}\right)^{1/n}-1 \tag{15.3.423}$$

What we sometimes find in the literature rather in the following traditional form (long live to the lack of standards for mathematical notations in finance...!):

$$\boxed{z(T)=\left(\frac{N}{P(T)}\right)^{1/T}-1} \tag{15.3.424}$$

✍**Example:**

The zero-coupon yield to 4 years .... corresponding to a nominal zero-coupon of 100.- of issue price 90.- (under par price) is:

$$t_0\% = \left(\frac{C}{P}\right)^{1/n} - 1 = \left(\frac{100}{90}\right)^{1/4} - 1 \cong 2.67\% \tag{15.3.425}$$

But let us consider a more explicit and realistic case with the following bond rates (remember nominal rate is 100.-):

Bond	Coupon	Maturity	Price
Bond 1	5.0	1	101.00.-
Bond 2	5.5	2	101.50.-
Bond 3	5.0	3	99.00.-
Bond 4	6.0	4	100.00.-

The zero coupon bond prices that we will denote here $B(0,t)$ can be found with the following system of equations:

$$\begin{aligned}101 &= 105B(0,1)\\ 101.5 &= 5.5B(0,1) + 105.5B(0,2)\\ 99 &= 5B(0,1) + 5B(0,2) + 105B(0,3)\\ 100 &= 6B(0,1) + 6B(0,2) + 6B(0,3) + 106B(0,4)\end{aligned} \tag{15.3.426}$$

Then we get:

$$B(0,1) = 0.9619, B(0,2) = 0.9114, B(0,3) = 0.85363, B(0,4) = 0.789 \tag{15.3.427}$$

Their corresponding zero coupon yield rates are given by the relation:

$$B_{(0,t)} = \frac{1}{(1 + r_{(0,t)})^t} \tag{15.3.428}$$

Thus:

$$r_{(0,1)} = 3.96\%, r_{(0,2)} = 4.717\%, r_{(0,3)} = 5.417\%, r_{(0,4)} = 6.103\% \tag{15.3.429}$$

Remark

Among the bonds, only fixed-rate zero-coupon bonds allow to eliminate almost surely the risk rate between two dates (but not risk of bankruptcy). A conventional fixed rate obligation actually generates as much additional rate risk that it has intermediate financial cash flows: the reinvestment rate of each of the coupons from the date of payment and the final repayment date is in fact unknown even if it is implicit in the price of the bond.

There is another common and very convenient way to write the current value of a fixed rate zero-coupon bond! Recall that we have proved earlier above under certain conditions that:

$$C_n = C_0(1 + t_0\%)^n = C_0 e^{nt_n\%} \tag{15.3.430}$$

Therefore:

$$P=\frac{C}{(1+t_0\%)^n}=Ce^{-nt_n\%} \tag{15.3.431}$$

✍**Example:**

The zero-coupon yield to 10 years .... corresponding to a nominal zero-coupon of 100.- of issue price 55.3895.- (under par price) is:

$$t_0\%=\left(\frac{C}{P}\right)^{1/n}-1=\left(\frac{100}{55.3895}\right)^{1/10}-1\cong 6\% \tag{15.3.432}$$

In continuous interest rate it gives (as proved already earlier above) the "continuous actuarial rate zero coupon":

$$t_n\%=-\frac{1}{n}\ln\left(\frac{P}{C}\right)=-\frac{1}{10}\ln\left(\frac{55.3895}{100}\right)\cong 5.908\% \tag{15.3.433}$$

Remark

Investors should pay particular attention to the indication "contingent" on its bond paper, which means that in case of bankruptcy of the debtor (likened to the "issuer risk"), the holder of the obligation will be repaid only after all other creditors... The issuer risk can be avoided by choosing (very) safe bonds as government bonds or renowned companies. The downside is then the low rates offered that we must furthermore put in contrast with inflation (on a rate of 3% over 10 years of a government bond that undergoes an inflation of 2% there remains only 1% of remuneration for example).

Let us indicate that multiple coupons bonds are trendy thanks to the tax system of the States and also by the cost of paperwork they generate. Hence the fact that the zero-coupon are preferred.

✍**Examples:**

E1. Consider a bond of $3,000,000$.- divided into 300 bonds each of nominal $10,000$.- issued in June 12004 (holocene calendar) for a period of 10 years. Subscription: 99.5% of the par value. Redemption at par at maturity. Fixed annual interest: 4.5%.

The values defined above are then expressed as follows:

The nominal value C of the obligation is to $10,000$.-. The number N of bonds is 300. The duration n of the loan is 10 years and the nominal rate is 4.5% per year. The issue price is 99.5% of $10,000$.- that is to say $E=9,950$.- (below par!). The coupon therefore has a value $c=450$.- and the repayment R is made at par and so is equal to $10,000-4,500=5,500$.-.

E2. Given fixed-rate bond, issued at a price of $1,000$.-, and paying an annual coupon of 100.-. The rate used is $100/1,000=10\%$.

Suppose the market rates go to 15%. This means that a new obligation, which is issued for a price of $1,000$.-, serves a coupon of 150.- (because $150/1,000=15\%$).

The new bond is more interesting than the old one, and everyone will want to sell the old to buy new. That is why the price of the old bond will implicitly decrease, until it matches that of a financial product providing 15% or here 666.-. Then, we will have as expected $100/666=15\%$.

Similarly, if market rates fall to 5%, this means that a new obligation, which is issued to a price of $1,000$.- price, will serve a coupon of 50.- (because $50/1,000=5\%$).

The new bond is the less interesting than the old one, and almost no one will buy it. That is why the price of the old obligation will implicitly go up until it match that of a financial product providing 5% rate that is to say here $2,000$.-. So, we will have as expected $100/2,000=5\%$.

Thus, the price of a fixed rate bond decreases when market interest rates rise and rises when market interest rates fall. This is why an investment in bonds is not without risks: one can lose part of the capital. In fact, the only (almost) safe strategy is to buy bonds at the time of issuance, and keep them until maturity.

At any time, the market value of a fixed rate bond or variable rate one must therefore be equal to the sum of the present values of the coupons and of the repayment which it gives the right. The present value is calculated at the bond market rate for bonds of the same type and same duration.

Thus, the present value of a fixed-rate bond (the case being easily generalized to a variable rate) should be seen as an initial capital of which is removed during n remaining periods a certain fixed sum corresponding to the amount of the price of the coupon (facial interest rate multiplied by the nominal):

$$c=t\%C \tag{15.3.434}$$

with C the nominal value of the obligation and total cumulated being periodically subject to market interest rate $t_M\%$ (thus the "rate to maturity") that is considered as constant in the context of a certain (deterministic) future.

Thus, the present value of a fixed-rate bond is initially formed as the present value of the remaining future coupons (often also named "cash flows") during n periods such that:

$$P_c=c\cdot a_{\overline{n}|}=\sum_{i=1}^{n}\frac{c}{(1+t_M\%)^i}=c\sum_{i=1}^{n}\frac{1}{(1+t_M\%)^i}=t\%C\sum_{i=1}^{n}\frac{1}{(1+t_M\%)^i} \tag{15.3.435}$$

relation that we found many times in the specialized literature in the following form:

$$P=cF\sum_{i=1}^{n}\frac{1}{(1+y)^i} \tag{15.3.436}$$

This part of the price of the value of the bond corresponds to the total amount required as we can settle the amount P_c after removing n times (the number of periods remaining) the value c at an interest rate $t_M\%$.

Remark

Let us recall that we have proved in the Section Sequences and Series (see page 1656), that if $t_M\%$ is less than 1 and the sum tends to infinity, then :

$$P_c=\frac{c}{t_M\%}=\frac{t\%C}{t_M\%} \tag{15.3.437}$$

Then the bond is also made of the value of the reimbursement R. Although it is repaid at maturity, it can be seen as a savings capital at a rate equal to that of the market $t_M\%$ as:

$$R=C_0(1+t_M\%)^n=C_0f_c^n\Leftrightarrow C_0=Rf_e^n \tag{15.3.438}$$

The present value of the bond concerning the reimbursement is then:

$$P_R=Rf_e^n \tag{15.3.439}$$

which is the capital for repayment R remaining after the n remaining periods.

Thus, the total price of a fixed-rate bond, also named "non-arbitrage bond price" is:

$$\boxed{P=P_c+P_R=ca_{\overline{n}|}+Rf_e^n=c\sum_{i=1}^{n}\frac{1}{(1+t_M\%)^i}+\frac{R}{(1+t_M\%)^n}} \tag{15.3.440}$$

that is to say, the present value of future coupons and also the present value of the in fine reimbursement. That latter relation is also denoted (CF stands as always for the abbreviation of "cash flow"):

$$P=\sum_{t=1}^{T}\frac{\text{CF}_t}{(1+y)^t} \tag{15.3.441}$$

This relation is important in deterministic quantitative finance, it is necessary to remember it!! In the context above, be aware that the rate equation is often named "yield to maturity at par".

Remark

We can also easily write now the general equation for the price of a bond (aka plain vanilla bonds), often denoted:

$$P=\sum_{t=1}^{T}\frac{C_t}{(1+\text{YTM})^t}+\frac{\text{Par}_T}{(1+\text{YTM})^T} \tag{15.3.442}$$

A bond that has all coupon payments that are constant is named a "straight bond".

The value of a bond, in the point of view of its trading price, may differ from its nominal value set at the issue if interest rates change in the market hence the purpose to calculate its current value.

✍**Example:**

Consider we want to calculate the current price of a bond, with annual coupon of 450.-, with a reimbursement at par in 5 years for $10,000$.-.

The present value P for a market rate between 0% and 100% has the following characteristics:

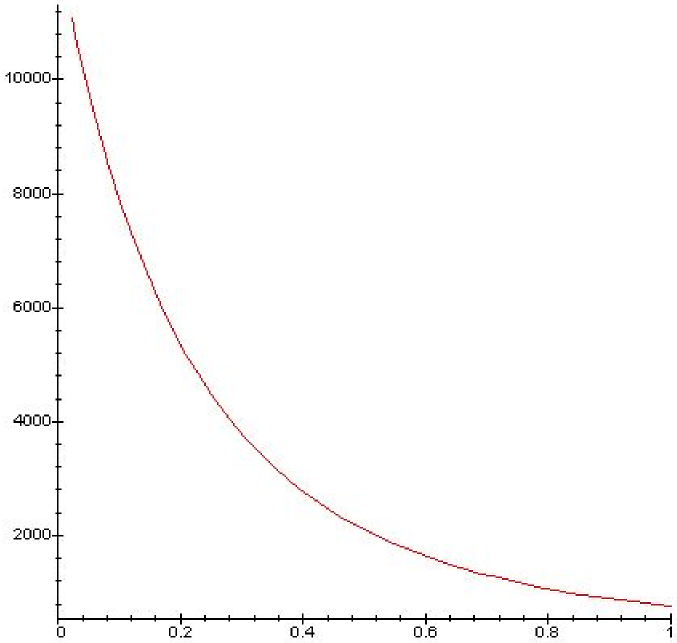

Figure 15.109: **Current value of a bond based on the market rates (yield)**

Thus, a fundamental property of the price of a fixed rate bond is that this is a strictly decreasing function of market rate of return. The finance practitioners (and mathematicians) say than the function is convex: that is to say, when market rates fall, the price accelerates upwards and vice versa when the market interest rates rise, the price is decelerating downwards.

We also guess that at the view of the relation of the non-arbitrage bond price P, that bond prices variations increase with the increase in maturity and with the value of coupons.

✍**Example:**

Today, we buy a fixed rate bond with of 3 years maturity for a nominal price 100.-, the coupon rates are of 5% and the fixed market rate 10%. The cash flows collected are then of 5.-, 5.- and 105.- after respectively 1 year, 2 years and 3 years. The price of this bond is then equal to:

$$P_c = 5\sum_{i=1}^{2}\frac{1}{(1+10\%)^i}+\frac{105}{(1+10\%)^3}\cong 87.57.\text{-} \tag{15.3.443}$$

That can get directly with Microsoft® Excel® 14.0.6129:

```
=PRICE("2013-01-01","2017-01-01",5%,10%,105,1,3)=87.577
```

Evaluate a bond is therefore equivalent to find what should its value in principle in the actual conditions of market, that is to say its potential trading value, by a mathematical operation named "operation of actualization" determining its theoretical present value. It is therefore, as we already know, an actuarial calculation.

The bond investor will of course have for aim to seek the market rate that allows to make the investment a profitable action. Thus, we define the "yield to maturity" x as the interest of the market that can satisfy the following relations, depending on the remaining time periods n of the bond among N periods.

Thus, when the bond is issued:

$$E = ca_{\overline{N}|} + Rf_e^N = \frac{c}{1+x} + \frac{c}{(1+x)^2} + \ldots + \frac{c}{(1+x)^N} + \frac{R}{(1+x)^N} \tag{15.3.444}$$

or on any date $n < N$:

$$P = ca_{\overline{n}|} + Rf_e^n = \frac{c}{1+x} + \frac{c}{(1+x)^2} + \ldots + \frac{c}{(1+x)^n} + \frac{R}{(1+x)^n} \tag{15.3.445}$$

The yield to maturity of a bond is then the rate x that cancels the difference between the value of the issue price E and the present value of future cash flows it generates. This rate is calculated at the date of settlement and must appear in the emission brochures. For the buyer of the obligation, the actuarial rate represents the rate of return achieved if keeping the bond until its repayment and reinvesting the interests at the same actuarial interest rate.

Remark

We have seen above that for a straight bond:

$$P = \sum_{t=1}^{T} \frac{C}{(1+\text{YTM})^t} + \frac{\text{Par}_T}{(1+\text{YTM}^T)}$$

Using the relation proved at page 7564:

$$a_{\overline{n}|} = \sum_{t=1}^{n} f_e^t = f_e^1 \frac{1-f_e^n}{1-f_e} = f_e \frac{1-f_e^n}{1-\dfrac{1}{f_c}} = \frac{1}{f_c} \frac{1-f_e^n}{\dfrac{f_c-1}{f_c}} = \frac{1-f_e^n}{f_c-1} = \frac{1-f_e^n}{t\%}$$

The latter can be rewritten:

$$P = \frac{C}{\text{YTM}} \left(1 - \frac{1}{(1+\text{YTM})^T}\right) + \frac{\text{Par}_T}{(1+\text{YTM})^T}$$

And as for a perpetual bond $T \rightarrow +\infty$, then we get the pricing formula for a perpetual bond:

$$\boxed{P_{\text{perp.}} = \frac{C}{\text{YTM}}}$$

Let us see some other useful definitions of bonds:

Definitions (#15.3.686):

D1. The "expired coupon" (EC), also named "net coupon", of a bond is paid to the owner after deduction of the anticipated taxes AT% (AT being the abbreviation for: Anticipated Taxes). Thus the calculation of the annual net coupon of bonds traded at P_c (monetary value) with a yield of $t_0\%$ is trivially given by:

$$\text{EC} = P_c t_0\%(1 - \text{AI}\%) \tag{15.3.446}$$

D2. The "accrued interest" (AI) is the amount of interest (fraction) that has been accumulated since the last date of payment of interest, but which is not yet due. It is won by a bond since its last term and is determined on a sale or inventory. Or in other words it is method when interest that is either payable or receivable has been recognized, but not yet paid or received. Accrued interest occurs as a result of the difference in timing of cash flows and the measurement of these cash flows.

Its calculation is trivially given by an application of rules of simple interest such as:

$$\text{AI} = P t_0\% \frac{\Delta d}{\Delta T} \tag{15.3.447}$$

where Δd is the time since last coupon payment and ΔT the period of coupons (both must be obviously in the same units).

So to get the effective value of a bond (the "present value" as we know), we add to its traded value, named "clean price", the accrued interest (in green in the figure below) since the last coupon payment.

Change in Present Value through Coupon Date

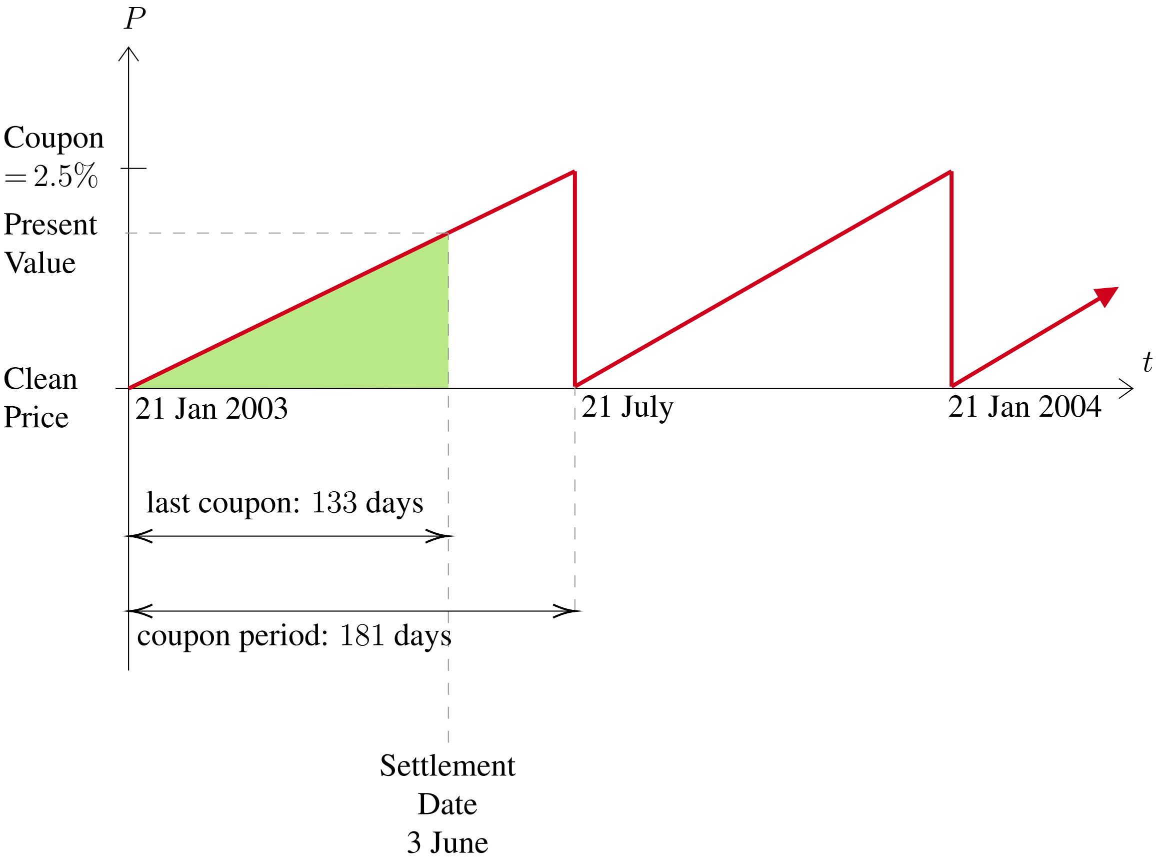

Figure 15.110: Schematic principle behind the bond accrued interest

D3. By extension, if we seek to calculate the net value of n (parallel) coupons with a same yield of $t_0\%$ of a bond which nominal value is P with an anticipated tax of AI%, we then can calculate the "net annual coupon at maturity" (NEC) by the following trivial relation:

$$\text{NEC} = nPt_0\%(1-\text{AI}\%) \tag{15.3.448}$$

D4. Suppose now we have two bonds with different maturities (say t and T, with $T > t$) and "spot interest rates" (actual rate) $r_{(0,t)}$ and $r_{(0,T)}$. The additional rate between t and the maturity $r_{(t,T)}$ is named the "forward interest rate" and is traditionally denoted as $F_{(0,t,T-t)}$.

Obviously the latter can be written:

$$(1+r_{(0,T)})^T = (1+r_{(0,t)})^t(1+F_{(0,t,T-t)})^{T-t} \tag{15.3.449}$$

and rearranged into:

$$\boxed{F_{(0,t,T-t)} = \left(\frac{(1+r_{(0,T)})^T}{(1+r_{(0,t)})^t}\right)^{1/(T-t)} - 1} \tag{15.3.450}$$

The concepts of "spot rate" and "forward rate" are now known to us, but we must be aware that the vocabulary and notation in the field of modern portfolio theory is a bit different and it is important to learn why these two rates are so important for the pricing of financial tools like Futures and Swaps!

As companion example, let us consider the final capital C_n and a risk-free market yield of $t\%$ for a given periodic basis. We then know that the present value is:

$$C_0 = \frac{C_n}{(1+t\%)^n} \tag{15.3.451}$$

Now if the rate varies from period to period, assuming these rates are evenly spaced, we have:

$$C_0 = \frac{C_n}{(1+t_1\%)(1+t_2\%)\ldots(1+t_n\%)} \tag{15.3.452}$$

Traditionally in the financial markets (but not always in textbooks!), the rate that is closest to today's date is named the "spot rate" and other future rates are named "forward rates" such as:

$$C_0 = \frac{C_n}{(1+s_1\%)(1+f_2\%)\ldots(1+f_n\%)} \tag{15.3.453}$$

We can then finally give the usual definition: A "forward rate" is a rate that discounts a future amount to another point in the future while the "spot rate" is a rate that discounts a future amount to the daily value.

However, in the financial markets, the spot rate and forward rates are not necessarily paid at regular intervals (yes ... it would be too easy otherwise...!).

Consider for example an investment over 5 periods with a rate market offering a spot rate for the first 4 periods and a forward rate during the last period starting from the 4th. We have then according to usual notations:

$$C_0 = \frac{C_5}{(1+s_4\%)^4(1+{}_1f_4)} \tag{15.3.454}$$

Or we can have three different rates offered on the market such as:

$$C_0=\frac{C_5}{(1+s_1\%)(1+{}_2f_1)^2(1+{}_2f_3)^2} \tag{15.3.455}$$

which means that we will first have a first spot rate s_1 during the first period (from 0 to 1), then we will have a particular forward rate for 2 periods (1 to 2 and 2 to 3) after this first period of ${}_2f_1$ and that finally we will have another particular forward rate for 2 periods (3 to 4 and 4 to 5) after the period 3. We understand via this last example much better this usual notation.

Now what is very important to understand is that in the markets, in the absence of arbitration opportunity, we should have for equal instruments the following equality if we take again the two examples above :

$$(1+s_1)(1+{}_2f_1)^2(1+{}_2f_3)^2=(1+s_4)^4(1+{}_1f_4) \tag{15.3.456}$$

The financial analysts are then interested in using all the market rates (using regression or interpolation techniques as seen in the section on Numerical Methods or other empirical techniques like the Nelson-Siegel model or other...) to construct a curve of spot rates (the "spot curve") for each future period and obviously this rate curve also corresponds to the rate that would pay a zero-coupon bond hence the reason for which the two terms "curve of spot rates" and "curve of zero-coupon rates "are equivalent!

In the case above, we will thus have for the first period the two points:

$$\{(1,1+s_1),(1,1+s_4)\} \tag{15.3.457}$$

for the second period:

$$\left\{(2,(1+s_1)(1+{}_2f_1))\,,\left(2,(1+s_4)^2\right)\right\} \tag{15.3.458}$$

For the third period:

$$\left\{\left(3,(1+s_1)(1+{}_2f_1)^2\right),\left(3,(1+s_4)^3\right)\right\} \tag{15.3.459}$$

For the fourth period:

$$\left\{\left(4,(1+s_1)(1+{}_2f_1)^2(1+{}_2f_3)\right),\left(4,(1+s_4)^4\right)\right\} \tag{15.3.460}$$

and finally for the fifth:

$$\left\{\left(5,(1+s_1)(1+{}_2f_1)^2(1+{}_2f_3)^2\right),\left(5,(1+s_4)^4(1+{}_1f_4)\right)\right\} \tag{15.3.461}$$

It is therefore easy to understand why this curve is increasing in a risk-free universe since the terms of ordinates that multiply each other are greater than 1. Indeed, in the latter case (without risk), we simply have an exponential curve of the type of traditional compound interest. On the other hand, in a universe with risk, which corresponds to the reality of the market, from a certain time horizon the risk premiums are such that the yield curve has a horizontal asymptote because the risk cancels the gain. And at a very distant horizon, the yield curve even decreases (the risk being higher than the interest rates!).

Thus forward rates can be calculated using spot rates of the spot rate curve and vice versa. This is why financial analysts sometimes talk about "spot rate curve" or "forward rate curve" and for the latter we sometimes talk about "implicit forward rates". For example in a simple case with a continuous rate we must have:

$$e^{s_2T_2}=e^{s_1T_1}e^{{}_1f_1(T_2-T_1)} \tag{15.3.462}$$

Therefore, the forward rate in 1 month is trivially given by taking the logarithm of both sides of the equality that are well known to us and that lead to a famous relation available in quite a significant percentage of textbooks (but without proof or explanations!):

$$\boxed{{}_1f_1=\frac{s_2T_2-s_1T_1}{T_2-T_1}} \tag{15.3.463}$$

Remark

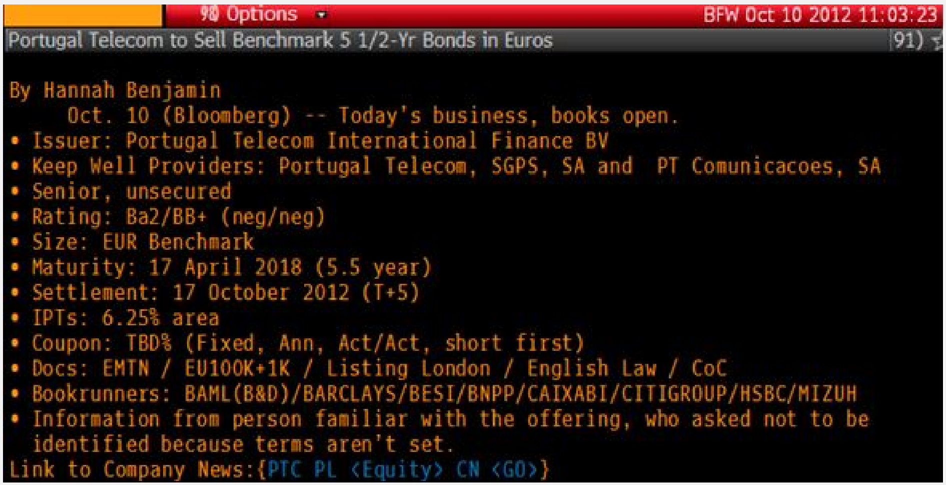
National banks generally communicate the mathematical model used to communicate the interest rate yield curve (the last well-implemented model is named the "Svensson model").

At the opposite of to the calculation of accrued interest of the coupons of a bond, the calculation of the accrued dividend of a stock is veeeery difficult to estimate. The stock price, however, is influenced by the more or less near the date of the dividend payment.

Remark

Let us indicate that the market in which the issuers selling their bonds (new) by auction, syndication or by direct placement to investors is named "primary market". The market in which investors exchange among themselves bonds (sometimes the same obligations which are offered at different prices) already in circulation (second hand market) is named "secondary market".

Below an example of announcement of bond issuance by syndication on Bloomberg™ through a news:



```
Portugal Telecom to Sell Benchmark 5 1/2-Yr Bonds in Euros

By Hannah Benjamin
     Oct. 10 (Bloomberg) -- Today's business, books open.
• Issuer: Portugal Telecom International Finance BV
• Keep Well Providers: Portugal Telecom, SGPS, SA and  PT Comunicacoes, SA
• Senior, unsecured
• Rating: Ba2/BB+ (neg/neg)
• Size: EUR Benchmark
• Maturity: 17 April 2018 (5.5 year)
• Settlement: 17 October 2012 (T+5)
• IPTs: 6.25% area
• Coupon: TBD% (Fixed, Ann, Act/Act, short first)
• Docs: EMTN / EU100K+1K / Listing London / English Law / CoC
• Bookrunners: BAML(B&D)/BARCLAYS/BESI/BNPP/CAIXABI/CITIGROUP/HSBC/MIZUH
• Information from person familiar with the offering, who asked not to be
  identified because terms aren't set.

Figure 15.111: **Current value of a bond based on the market rates (yield)**

On the secondary market bonds are quoted as a percentage of their face value (i.e. when they are traded on 100% of the nominal we, as we already know, that they are "au pair") and the quoted price market (traded price) is sometimes named as we also already know the "clean price", to get the overall price ("dirty price") of the transaction (purchase or sale) we must added the accrued interest of the coupon and other taxes and trading costs.

15.3.10.3.2.1 MacCaulay Duration, Modified Duration and Convexity

The "modified duration" is a measure (rate of change) of the price sensitivity of an asset in relation to the change in one unit of the market rate (unfortunately, contrary to what its name might suggest it does not give a time duration contrary to the Macaulay duration that we will see further below). Obviously, the higher the duration of a bond, the more sensitive it is to yield changes. Conversely, the lower the duration of a bond, the less sensitive it is to yield changes. In general, we speak of the calculation of "interest rate risk".

The modify duration can also be reported in dollars when multiplied by the spot price of the concerned asset, and then we refer to the term "dollar duration" (D.D.), or "Bloomberg risk", and we denote it DV01 (we will see further below that DV01 corresponds in the fields of derivatives to the "delta").

The concept of modified duration can of course be applied to any instrument sensitive to interest rates with fixed or non-fixed cash flows.

There are several ways of introducing this indicator - which is available in several variants - which mainly allows measuring the sensitivity in percent of a bond's clean price to changes in the risk-free return of the market or as an empirical indicator of any obligation with its zero-coupon theoretical equivalent (more generally bonds paying coupons at a different pace but with identical rates).

A first approach is to go through an elegant mathematical method that uses Taylor's serial developments and which shows that the "Duration" can also be used to measure the convexity of bond prices (or, if you prefer, their sensitivity to changes in interest rates).

Let us first recall that:

$$P=\sum_{t=1}^{T}\frac{\mathrm{CF}_t}{(1+y)^t} \qquad (15.3.464)$$

Remark

Obviously in the case of a zero-coupon bond (i.e. a single payment for recall) we can move approximately to a continuous rate such that $P=\mathrm{CF}e^{-yT}$, which simplifies the calculations considerably but is then only a special case.

In the case of a Taylor series development (see section Sequences and Series page 1696) we have for any continuous function in the discrete case:

$$\Delta P=\frac{\mathrm{d}P}{\mathrm{d}y}\Delta y+\frac{1}{2}\frac{\mathrm{d}^2}{\mathrm{d}y^2}(\Delta y)^2+\ldots \qquad (15.3.465)$$

If the variation is really small compared to the reference rate y, we will use the first term (linear approximation), if the variation is considered to be relatively large we will take both (quadratic approximation) otherwise the approximation is bad as soon as we move away from the y value:

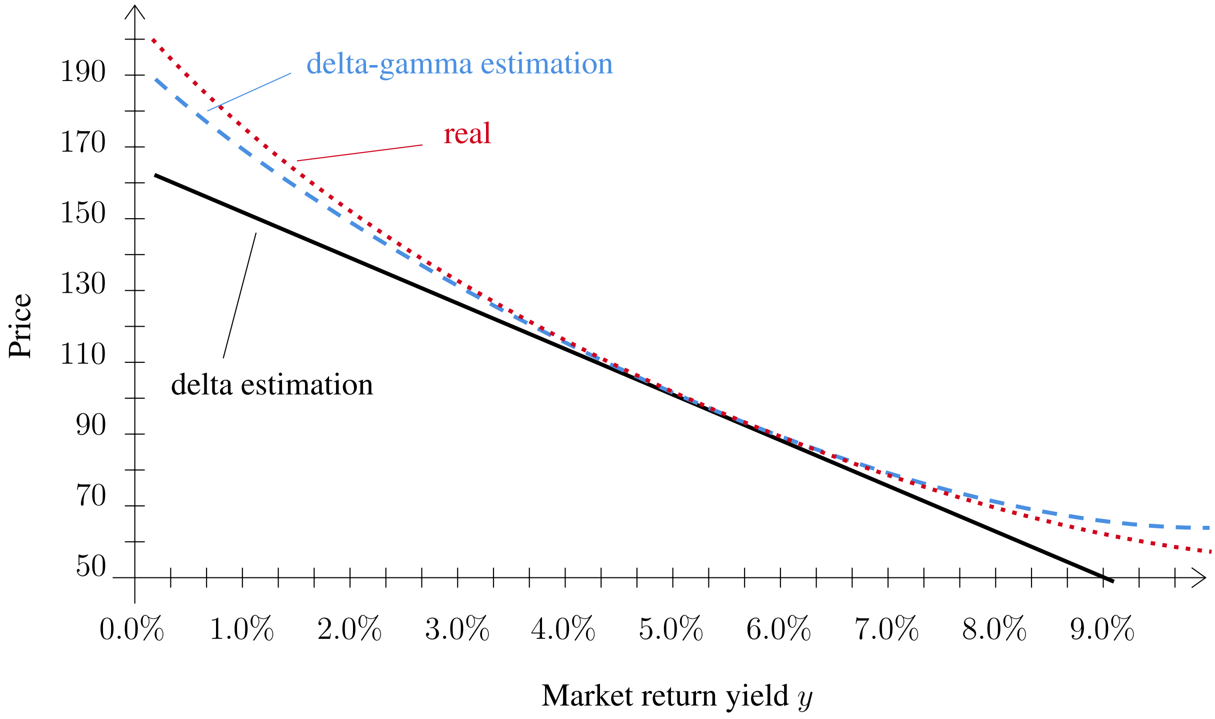

Figure 15.112: **Delta and Delta-Gamma Modified duration approach**

The relative variation of the price in percentages is then given by:

$$\boxed{\frac{\Delta P}{P}\cong\frac{1}{P}\frac{\mathrm{d}P}{\mathrm{d}y}\Delta y+\frac{1}{2}\frac{1}{P}\frac{\mathrm{d}^2P}{\mathrm{d}y^2}(\Delta y)^2}\qquad(15.3.466)$$

Remark

Because in the case of the derivatives that we will discuss below, some of the above factors reveal what we name the "delta" and "gamma" if we change the rate y above by the value of the underlying S of the derivative, we name this method (even when not applied to derivatives): "delta-gamma method".

In finance we write this relation in several forms:

$$\begin{aligned}\frac{\Delta P}{P}&=-\frac{1}{P}\text{DD}\Delta y+\frac{1}{2}\text{Convexity}(\Delta y)^2\\&=-D^*\Delta y+\frac{1}{2}\text{Convexity}(\Delta y)^2\\&=-\frac{1}{P}\text{DVBP}+\frac{1}{2}\text{Convexity}(\Delta y)^2\\&=-\frac{D}{1+y}\Delta y+\frac{1}{2}\text{CVX}(\Delta y)^2\\&=-\frac{D}{1+y}\Delta y+\frac{1}{2}\frac{1}{P}\text{DC}(\Delta y)^2\end{aligned}\qquad(15.3.467)$$

where DD is the "dollar duration" (already mentioned just before), D^* the "modified duration", DVBP the "dollar value by basis point", D is the "compound duration" named more often the "Macaulay duration" (also sometimes denoted MacD) and finally DC the "convexity dollar" (for CVX it's trivial!).

In short, to sum up we have for the first term where there are the more variations of writing in practice (because the units are not the same!):

$$\boxed{\begin{aligned}\text{DD}=\text{Dollar Duration}&=-\frac{\mathrm{d}P}{\mathrm{d}y}\\ D^*=\text{Modified Duration}&=-\frac{-\frac{\mathrm{d}P}{P}}{\mathrm{d}y}=-\frac{1}{P}\frac{\mathrm{d}P}{\mathrm{d}y}\\ \text{DVBP}=\text{Dollar value by basis point}&=-\frac{\mathrm{d}P}{\mathrm{d}y}\Delta y\\ D=\text{Macaulay Duration}&=-\frac{1}{P}\frac{\mathrm{d}P}{\mathrm{d}y}(1+y)=D^*(1+y)\end{aligned}} \tag{15.3.468}$$

Let us open a parenthesis with the expression:

$$\frac{\mathrm{d}P}{P}=-D^*\mathrm{d}y \tag{15.3.469}$$

In practice, assets are often given as yield volatility rather than price volatility. The previous relation will allow us to get one from the other. For this we will demonstrate further that under the hypothesis of a log-normal distribution of the rates we have:

$$\mathrm{d}X_t=\mu X_t\mathrm{d}t+\sigma X_t\mathrm{d}W_t \tag{15.3.470}$$

And under the assumption that what we name the "drift" (μ) is zero (which makes sense since the rate of assets like bonds or securities is fixed in advance!!!), then we have with our notations:

$$\frac{\mathrm{d}y}{y}=\sigma\mathrm{d}W\Leftrightarrow\mathrm{d}y=y\sigma\mathrm{d}W \tag{15.3.471}$$

Then we have:

$$\frac{\mathrm{d}P}{P}=-D^*\mathrm{d}y=-D^*y\sigma\mathrm{d}W \tag{15.3.472}$$

Then by analogy, we define the volatility of assets rates by:

$$\sigma_P=|-D^*y\sigma| \tag{15.3.473}$$

Or to avoid any notation confusion:

$$\sigma_P=|-D^*y\sigma_y| \tag{15.3.474}$$

For what follows, let us take one of these 4 indicators randomly (in fact it is not really random as it is the only one that really gives a duration in the "temporal" sense of the term):

$$D=-\frac{1}{P}\frac{\mathrm{d}P}{\mathrm{d}y}(1+y)=\sum_{t=1}^{T}t\frac{\text{CF}_t/(1+y)^t}{P}=\frac{1}{P}\sum_{t=1}^{T}t\frac{\text{CF}_t}{(1+y)^t}=\frac{1}{\displaystyle\sum_{t=1}^{T}\frac{\text{CF}_t}{(1+y)^t}}\sum_{t=1}^{T}t\frac{\text{CF}_t}{(1+y)^t} \tag{15.3.475}$$

Remark

In many textbooks the previous relation is denoted:

$$\text{MacD}=\frac{1}{\text{PV}}\sum_{t=1}^{T}t\frac{\text{CF}_t}{(1+\text{YTM})^t} \tag{15.3.476}$$

where for recall PV is the abbreviation of Present Value and YTM of Year To Maturity.

For a zero-coupon bond we then have the logical result (reason why this time indicator has a particular name!):

$$D=\frac{1}{P}t\frac{\text{CF}_1}{(1+y)}=\frac{1}{P}tP=t \tag{15.3.477}$$

We can give a simplified generalized economic interpretation of the Macauley's duration indicator by manipulating a little the relation obtained above:

$$D=-\frac{1}{P}\frac{\mathrm{d}P}{\mathrm{d}y}(1+y)=\sum_{t=1}^{T}\frac{\text{CF}_t/(1+y)^t}{P}=\sum_{t=1}^{T}\frac{\text{CF}_t/(1+y)^t}{\displaystyle\sum_{t=1}^{T}\frac{\text{CF}_t}{(1+y)^t}}=\sum_{t=1}^{T}tw_t \tag{15.3.478}$$

where the weights w_t represent the ratio of the discounted value of each cash flow (CF) relative to the total cash flow (thus normalization to the unit). It is therefore a weighted average! So the Macaulay's duration represents the weighted average of the time to wait to get all the cash flows.

The figure below lays out the present value of the cash flows of a 6% coupon, 10-year bond. Given a duration of 7.80 years, this coupon-paying bond is equivalent to a zero-coupon bond maturing in exactly 7.80 years:

For bonds with fixed coupons, duration is less than maturity. With a zero coupon, Macaulay duration is equal to maturity. Higher coupons place more weight on prior payments and therefore reduce duration.

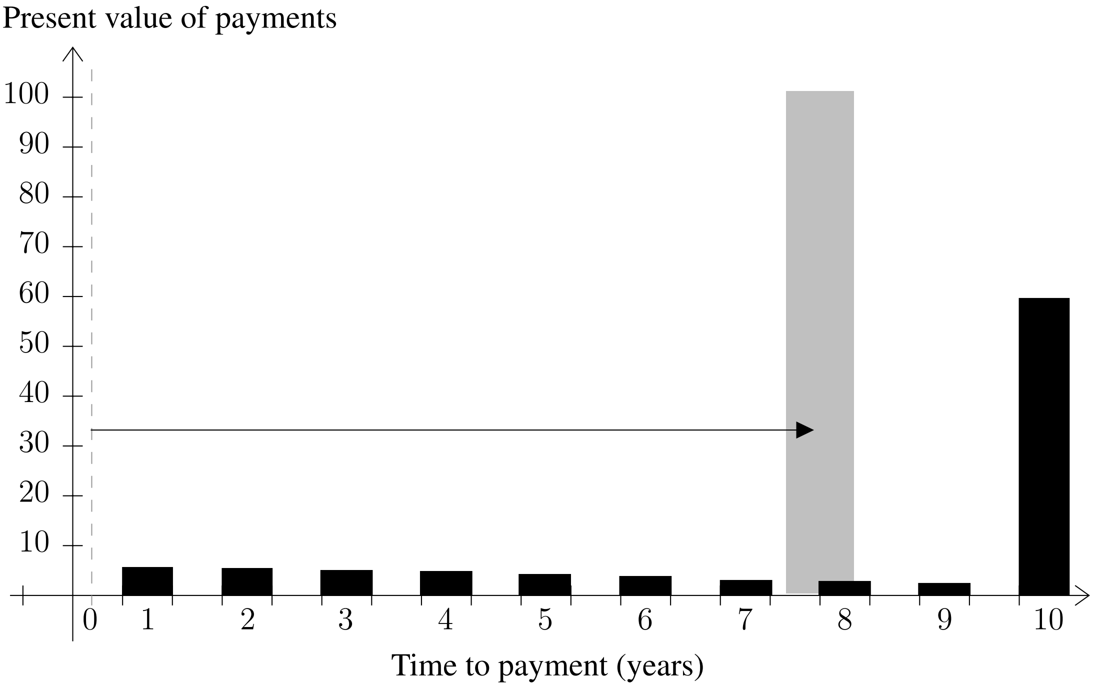

Figure 15.113: **Duration as the Maturity of a Zero-Coupon Bond**

Obviously, the longer the Macaulay's duration, the more the bond is sensitive to changes in interest rates (the longer the time at maturity, the longer the duration).

Remark

The modified duration is not additive (hence we have not been able to prove the opposite), it is then quite natural to define the modified duration of a portfolio as the weighted sum of durations of the assets that compose it.

We can also introduce the convexity duration. The calculation is defined as following:

$$\begin{aligned}\mathrm{CVX}&=\frac{1}{P}\frac{\mathrm{d}^2P}{\mathrm{d}y^2}=\frac{1}{P}\sum_{t=1}^{T}\frac{t\mathrm{CF}_t}{(1+y)^{t+1}}=\frac{1}{P}\sum_{t=1}^{T}\frac{\mathrm{CF}_t t(t+1)}{(1+y)^{t+2}}\\&=\frac{1}{\displaystyle\sum_{t=1}^{T}\frac{\mathrm{CF}_t}{(1+y)^t}}\sum_{t=1}^{T}\frac{\mathrm{CF}_t t(t+1)}{(1+y)^{t+2}}=\frac{1}{\displaystyle\sum_{t=1}^{T}\frac{\mathrm{CF}_t}{(1+y)^t}}\sum_{t=1}^{T}\frac{t(t+1)}{(1+y)^2}\frac{\mathrm{CF}_t}{(1+y)^t}\\&=\sum_{t=1}^{T}\frac{t(t+1)}{(1+y)^2}\frac{\mathrm{CF}_t/(1+y)^t}{\displaystyle\sum_{t=1}^{T}\frac{\mathrm{CF}_t}{(1+y)^t}}=\sum_{t=1}^{T}\frac{t(t+1)}{(1+y)^2}w_t\end{aligned}\tag{15.3.479}$$

✍**Examples:**

E1. Let us recall that for a zero-coupon bond we have proved (see page 7624) the following present value:

$$P = Ce^{-nt_n\%} \tag{15.3.480}$$

Adapting to the notation above we rewrite this relation as:

$$P = Ce^{-Ty} \tag{15.3.481}$$

Then:

$$D^* = -\frac{1}{P}\frac{\mathrm{d}P}{\mathrm{d}y} = -\frac{1}{Ce^{-Ty}}\frac{\mathrm{d}\left(Ce^{-Ty}\right)}{\mathrm{d}y} = -\frac{1}{Ce^{-Ty}}(-T)Ce^{-Ty} = T \tag{15.3.482}$$

The duration of a zero-coupon bound equals then the negative of its years to maturity. As:

$$\frac{\Delta P}{P} \cong -D^*\delta y \tag{15.3.483}$$

then an increase in the bond's yield will cause its value to fall approximately.

The convexity of the zero-coupon bond is therefore equal to:

$$\text{CVX} = \frac{1}{P}\frac{\mathrm{d}^2P}{\mathrm{d}y^2} = \frac{T^2Ce^{-Ty}}{Ce^{-yT}} = T^2 \tag{15.3.484}$$

E2. Consider a 2-year bond with face value of $\$100$, a 20% semi-annual coupon, and a yield of 4% semi-annually compounded. The total PV will be:

$$\begin{aligned} P &= \sum_{i=1}^{n}\text{PV}_i = \sum_{i=1}^{n}\frac{\text{CF}_i}{(1+y/k)^{k\cdot t_i}} = \sum_{t=1}^{4}\frac{10}{(1+0.04/2)^t} + \frac{100}{(1+0.04/2)^4} \\ &= 9.804 + 9.612 + 9.423 + 9.238 + 92.385 = 130.462 \end{aligned} \tag{15.3.485}$$

The Macaulay duration is then:

$$\begin{aligned} D &= \frac{1}{P}\sum_{t=1}^{T} t\frac{\text{CF}_t}{(1+y/k)^t} \\ &= 0.5\cdot\frac{9.804}{130.462} + 1.0\cdot\frac{9.612}{130.462} + 1.5\cdot\frac{9.423}{130.462} + 2.0\cdot\frac{9.238}{130.462} + 2.0\cdot\frac{92.385}{130.462} \\ &= 1.777\ \text{[years]} \end{aligned} \tag{15.3.486}$$

The modified duration, measured as percentage change in price per one percentage point change in yield, is:

$$D^* = \frac{D}{(1+y/k)} = \frac{1.777}{(1+0.04/2)} = 1.742\% \tag{15.3.487}$$

The DV01, measured as dollar change in price for a $\$100$ nominal bond for a one percentage point change in yield, is:

$$\text{DV01} = \frac{D^*\cdot P}{100} = \frac{1.742\%\cdot 130.462}{100} = 2.27 \tag{15.3.488}$$

where the division by 100 is because modified duration is the percentage change.

And finally the convexity is given by:

$$\begin{aligned}\text{CV}&=\sum_{t=1}^{T}\frac{t(t+1)}{(1+y)^2}\frac{\text{CF}_t/(1+y)^t}{\displaystyle\sum_{t=1}^{T}\frac{\text{CF}_t}{(1+y)^t}}=\sum_{t=1}^{4}\frac{t(t+1)}{(1+0.04/2)^{2\cdot 2}}\frac{20/(1+0.04/2)^{2t}}{130.462}\\&\cong 0.283+0.785+1.450+2.233=4.751\end{aligned}\tag{15.3.489}$$

The duration of a portfolio is the weighted average duration of the bonds in the portfolio. The weights are calculated by the market value (dirty price) of each bond divided by the total market of the portfolio.

Then for a portfolio of n assets we have:

$$D_p=\sum_{i=1}^{n}w_iD_i\tag{15.3.490}$$

with obviously $\sum_{i=1}^{n}w_i=1$. The same way we have the definitions:

$$\begin{aligned}D_p^*&=\sum_{i=1}^{n}w_iD_i^*\\\text{CVX}_p&=\sum_{i=1}^{n}w_i\text{CVX}_i\end{aligned}\tag{15.3.491}$$

But let us explicit D_p^* assuming for a portfolio of N assets, each asset represent a portion π_j (in currency amount!) of the portfolio:

$$\begin{aligned}D_p^*&=\sum_{i=1}^{n}w_iD_i^*=\sum_{i=1}^{n}w_i\frac{D_i}{(1+y_i/k_i)}=\sum_{i=1}^{n}w_i\frac{\displaystyle\frac{1}{P_i}\sum_{t=1}^{T_i}t\frac{\text{CF}_t}{(1+y_i/k_i)^t}}{(1+y_i/k_i)}\\&=\sum_{i=1}^{n}\left[\left(\frac{\pi_iP_i}{\displaystyle\sum_{j=1}^{N}\pi_jP_j}\right)\frac{\displaystyle\frac{1}{P_i}\sum_{t=1}^{T_i}t\frac{\text{CF}_t}{(1+y_i/k_i)^t}}{(1+y_i/k_i)}\right]\\&=\sum_{i=1}^{n}\left[\left(\frac{\displaystyle\pi_i\sum_{t=1}^{T_i}\frac{\text{CF}_t}{(1+y_i/k_i)^t}}{\displaystyle\sum_{j=1}^{N}\left(\pi_j\sum_{t=1}^{T_j}\frac{\text{CF}_t}{(1+y_j/k_j)^t}\right)}\right)\frac{\displaystyle\frac{1}{\displaystyle\sum_{t=1}^{T_i}\frac{\text{CF}_t}{(1+y_i/k_i)^t}}\sum_{t=1}^{T_i}t\frac{\text{CF}_t}{(1+y_i/k_i)^t}}{(1+y_i/k_i)}\right]\end{aligned}\tag{15.3.492}$$

A recurring wish of bond portfolio managers is to modify the allocation of a portfolio so that it has a given modified duration and a given convexity. We then used the definition of modified duration and the convexity of a portfolio given for recall by:

$$\begin{aligned} D_p^* &= \sum_{i=1}^{n} w_i D_i^* \\ \text{CVX}_p &= \sum_{i=1}^{n} w_i \text{CVX}_i \sum_{i=1}^{n} w_i \quad = 1 \end{aligned} \tag{15.3.493}$$

Put in the form of a linear system that gives:

$$\begin{bmatrix} D_1^* & \dots & D_n^* \\ \text{CVX}_1 & \dots & \text{CVX}_n \\ 1 & \dots & 1 \end{bmatrix} \begin{bmatrix} w_1 \\ \vdots \\ w_n \end{bmatrix} = \begin{bmatrix} D_p^* \\ \text{CVX}_p \\ 1 \end{bmatrix} \tag{15.3.494}$$

So the system is extremely easy to solve to find the corresponding weights:

$$\begin{bmatrix} w_1 \\ \vdots \\ w_n \end{bmatrix} = \begin{bmatrix} D_1^* & \dots & D_n^* \\ \text{CVX}_1 & \dots & \text{CVX}_n \\ 1 & \dots & 1 \end{bmatrix}^{-1} \begin{bmatrix} D_p^* \\ \text{CVX}_p \\ 1 \end{bmatrix} \tag{15.3.495}$$

15.3.10.3.2.2 Equivalence of a Bond rate for a Treasury bill

Some instruments are traditionally traded not by interest rate (yield) but by discount rate. In the context of financial markets this means that it is traded on the interest rate earned on the final value of the instrument (therefore the gain is calculated in $\%$ of the final value) and not on the initial price of the instrument.

Thus, consider a treasury bill bought 900.- which generated 180.- of profit (cash flow). Consequently its corresponding simple interest is trivially 20% of the initial value according to the trivial relation and the notations of use:

$$I = \frac{\text{CF}}{\text{TB}} \tag{15.3.496}$$

On the other hand as the final value is 1080.- $(900+180)$ then 180.- represents 16.66% of the final value according to the trivial relation:

$$t\% = \frac{\text{CF}}{\text{TB}+\text{CF}} \tag{15.3.497}$$

In general, the simple interest rate equivalent to the discount rate is then obviously higher than the latter.

We therefore deduce the relation between simple interest rate and discount rate:

$$I = \frac{\text{CF}}{\text{TB}} = \frac{\dfrac{t\%\text{TB}}{1-t\%}}{\text{TB}} = \frac{t\%}{1-t\%} \tag{15.3.498}$$

So here we fall back on a simplified version of the commercial discount relationship that we demonstrated during our study of simple and compound interest earlier above (see page 7555).

The discount rate for a treasury bill that has a maturity of 6 months or less (in the USA 6-month treasury bills is 182 days) is frequently compared to the simple interest rate for a bond that will also soon reach maturity and therefore pay its last coupon (the rate corresponding to the last coupon being then also named "discount rate").

The objective is then to transform the discount rate of a treasury bill on a 365 day time base into a simple interest rate on a bond whose time base for the last coupon is $30/360$ at Wall Street (known as "discount base").

During our study of discounts we demonstrated that if the rate $t\%$ communicated from the start is not the rate corresponding to the entire duration of n but the rate of the corresponding time unit, then we have the following relation:

$$I=\frac{t\%}{n(1-t\%)}=\frac{nt'\%}{n(1-nt'\%)}=\frac{t'\%}{(1-nt'\%)} \tag{15.3.499}$$

So as in finance the treasury bills have a discount rate given in annual and that n is in days, we have on a $30/360$ basis the corresponding rate as simple daily interest rate below (the second equality is simply a traditional notation...):

$$I_d=\frac{\dfrac{t'\%}{360}}{1-n\dfrac{t'\%}{360}}=\frac{t\%}{1-n\dfrac{t\%}{360}}\frac{1}{360} \tag{15.3.500}$$

Then, as it is a simple interest and traditionally the rates of the treasury bills are given annually over a 365-day year, we then have:

$$I_y=365\frac{t\%}{1-n\dfrac{t\%}{360}}\frac{1}{360}=\frac{t\%}{1-n\dfrac{t\%}{360}}\frac{365}{360} \tag{15.3.501}$$

We fall back on the relation given in Microsoft English for the function named `T.BILLEQ()`.

✍**Example:**

Consider a treasury bill emitted at the price of 98.- the 11999-03-30 (holocene calendar) and with maturity 11999-06-01 (hence 63 days) and with maturity price of 100 (hence an increase of 2.-) what is the bond equivalent discount rate of this treasury bill?

First we can easily calculate:

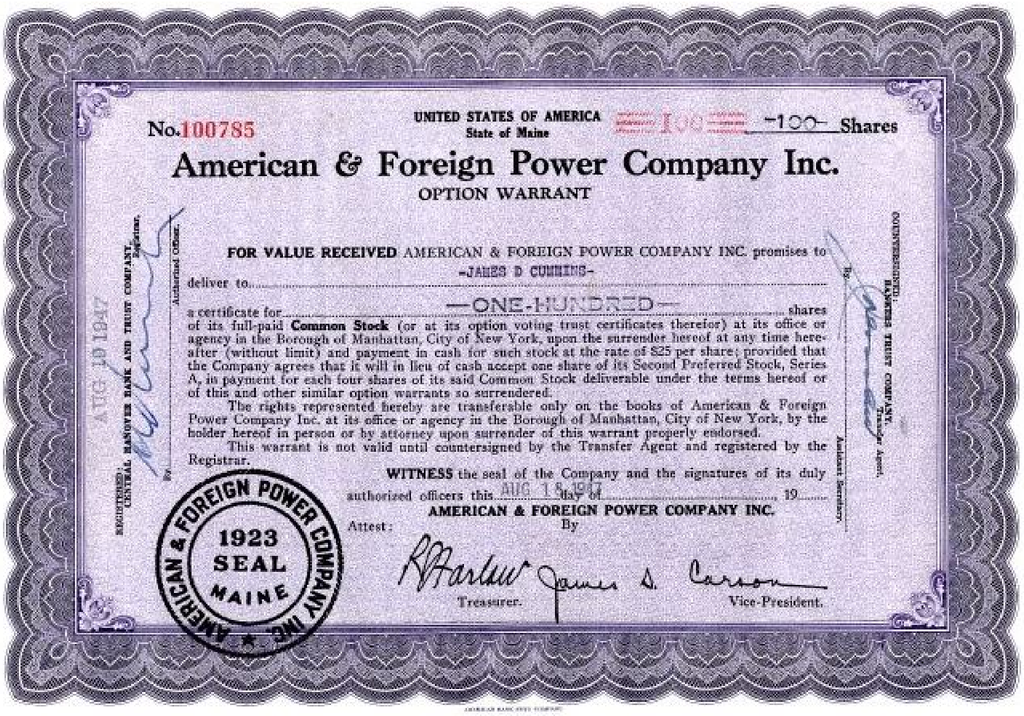
$$t\%=\frac{\text{CF}}{\text{TB}_A+\text{CF}}=\frac{2}{98+2}=20\% \tag{15.3.502}$$

and now we compute:

$$\begin{aligned} i_{\text{a}} &= \frac{t\%}{1-n\dfrac{t\%}{360}}\frac{365}{360} = \frac{20\%}{1-63\dfrac{20\%}{360}}\frac{365}{360} \\ &= \texttt{TBILLEQ(11999-03-30,11999-06-01,20\%)} = 21.01324\% \end{aligned} \tag{15.3.503}$$

15.3.10.3.3 Warrants

Definition (#15.3.687): Basically a "warrant" or "option warrant" ("stock-warrant" or "equity warrant"... as their are many type of warrants it is important to precise!) is the privilege sold by one party to another, that gives the buyer the right, but not the obligation, to buy (Call) or sell (Put) at an agreed-upon price (often an average of stock prices before the issuance of the warrants) within a certain period or on a specific date another financial underlying security that has to be issued (share, bond or any other good...). As these both financial instrument are linked to an underlying they therefore belong both to the category of derivatives instruments.



No. 100785

UNITED STATES OF AMERICA
State of Maine

100 -100- Shares

American & Foreign Power Company Inc.

OPTION WARRANT

REGISTERED:
CENTRAL HANOVER BANK AND TRUST COMPANY, Registrar.
By Authorized Officer.
AUG 19 1947

FOR VALUE RECEIVED AMERICAN & FOREIGN POWER COMPANY INC. promises to deliver to -JAMES D CUMMINS- a certificate for —ONE-HUNDRED— shares of its full-paid **Common Stock** (or at its option voting trust certificates therefor) at its office or agency in the Borough of Manhattan, City of New York, upon the surrender hereof at any time hereafter (without limit) and payment in cash for such stock at the rate of $25 per share; provided that the Company agrees that it will in lieu of cash accept one share of its Second Preferred Stock, Series A, in payment for each four shares of its said Common Stock deliverable under the terms hereof or of this and other similar option warrants so surrendered.

The rights represented hereby are transferable only on the books of American & Foreign Power Company Inc. at its office or agency in the Borough of Manhattan, City of New York, by the holder hereof in person or by attorney upon surrender of this warrant properly endorsed.

This warrant is not valid until countersigned by the Transfer Agent and registered by the Registrar.

WITNESS the seal of the Company and the signatures of its duly authorized officers this AUG 18 1947 day of ...., 19......

AMERICAN & FOREIGN POWER COMPANY INC.

Attest: By

Treasurer. James D. Carson Vice-President.

COUNTERSIGNED:
BANKERS TRUST COMPANY, Transfer Agent.
By Assistant Secretary.

1923
SEAL
MAINE

Figure 15.114: Warrant old style paper version

✍Example:

The warrant of a given company X gives to possibility to subscribe for one share of the company at a price of 500.- until April 30, 12004 (holocene calendar). If the share of X exceeds the level of 525.-, the warrant that allows in this situation the right to purchase one share at a lower cost to the stock market proves a winning placement. If the action is so for example traded at 525.- in April 30, 12004 (holocene calendar), the gain will be worth 25.-.

In addition, Warrants (also Call Options), are financial assets with low risk since there is no obligation to apply them and they were offered... it could also be noted that many companies cancel employee Warrants when they leave the company too early...

Even if we don't have seen yet what are Call Options (see further below) it seems to us important to make already the DEFAULT difference between Warrants and Call Options as they are very similar. For instance, many warrants confer the same rights as equity options and warrants often can be traded in secondary markets like options. However, there also are several key differences between warrants and stock options (or more generally equity options):

- The main default difference is straightforward and we already know it. It's the "dilutive effect" (see definition during our study of shares). Indeed an option is the right to purchase an existing share of a company's stock from the company at a specific price (usually the fair market value of that share on the date of issue), whereas a warrant gives the holder the right to purchase a share that will need to be issued (that is, "created") in the future. Therefore there is a boosting int the total share count.
- Warrants are issued by private parties, typically the corporation on which a warrant is based, rather than a public options exchange.
- Warrants are considered over the counter instruments and thus are usually only traded by financial institutions with the capacity to settle and clear these types of transactions.
- A warrant's lifetime is measured in years (as long as 15 years), while options are typically measured in months. Even LEAPS (Long-Term Equity Anticipation Securities), the longest stock options available, tend to expire in two or three years.
- Warrants are not standardized like exchange-listed options.
- The tax rules governing options and warrants are completely different.

Remark

The big problem with warrants is that because the supply is limited, brokers can do all sorts of nasty things to manipulate the price of the warrants. Because anyone can issue an option, there are fewer nasty things that you can to do manipulate their price.

The warrant (as Call Options) allows to be interested in the rise or fall of a security without having to devote the same amount of money than buying shares directly. Therefore, on acquisition, if the underlying security has a higher value than on the warrant, the buyer will make a profit named "surplus value acquisition". After the buyer that now owns the underlying securities may well sell them when the price is higher than when it made the acquisition and then it creates a (pseudo) second benefit named "cession plusvalue gain".

Remark

So, one warrant can be attached to the issue of a share or obligation. Therefore, depending on the case, we speak about "shares warrants to purchase shares" (SWPS) or "bonds warrants to purchases shares" (BWPS), but also of "bonds warrants to purchase bonds" (BWPB) or about "shares warrants to purchase bonds" (SWPB).

Since the issuance of these composed instruments, all split into parts: the stocks or the bonds become again classic titles and warrants has its own life. They are traded separately after the issuance.

For the mathematical point of view the pricing future value of warrants is not easy as we can not apply the Black & Scholes equation that we will prove later as:

- A warrant has a long life (2-4 years) and makes it difficult to accept the consistency of the hypothesis of constant interest rates used by the Black & Scholes model.

- Any operation of the issuer that changes the underlying security value affects the value of the warrant. Indeed, companies have the legal right to issue a new contract for the Warrants and to change their value and the time period of their validity!

- If the underlying warrant is a bond, the price of this latter changing over time and knowing that the more a bond approaches maturity, the more its value tends toward its redemption price. Its volatility is gradually reduced, which renders inapplicable the Black & Scholes model which postulates the constancy of volatility in time!

Therefore if Black & Scholes assumptions are not valid the only one simple thing we know so far is to build some naive mathematical model to computer their actual value.

In order to see how this works we need some simple notation (all values are those actual time t):

1. E is the value of the firm's equity at time t.
2. S is the common share price of the outstanding shares at time t.
3. N is the number of old common shares outstanding prior to any exercise of the warrants.
4. W is the value of the warrant at time t.
5. M is the actual number of warrants.
6. X is the exercise price of the warrants.

The choice of whether to exercise a warrant at maturity can be based on the following criteria. We exercise if:

$$X<\frac{E+MX}{N+M}\Leftrightarrow X<\frac{E}{N} \tag{15.3.504}$$

That is to say that we exercise the warrant if the average value per share of the company is greater than the actual value of the warrant (obvious!).

If the stock price after all the warrants are exercised is greater than the warrant's exercise price, all holders of the warrants will exercise. Hence the payoff of a warrant at maturity is:

$$\max\left(\frac{E+MX}{N+M}-X,0\right)\equiv\left(\frac{E+MX}{N+M}-X,0\right)^{+}\equiv\left(\frac{E}{N}-X,0\right)^{+} \tag{15.3.505}$$

This is quite different than the payoff of a regular Call Option as we will see later in that the payoff depends on the number of warrants outstanding.

Remark

The development of liquidity in the equity and bond markets has prompted financial institutions to issue warrants to acquire securities (underlying) existing independently of the financial operations of the concerned company. These warrants relate only to investors and are issued only by banks between them and do not allow the business financing (so this is pure speculation!). These warrants (also traded) are named "covered warrants" because on issue, the financial institution covered itself by purchasing shares on the market.

If necessary here is a small summary of main differences between options and warrants:

OPTIONS vs WARRANTS	
Options	**Warrants**
Options are exchange-traded products. They are regulated by the exchange, and features of the different options are also fixed by the exchange	Warrants are generally over-the-counter (OTC) products. A few companies may list them on exchange as well though in order to publicize the underlying stock for marketing purposes, but mostly they are traded by broking firms
Options have a variety of underlying products like, bonds, equities, interest, rates, currency or even commodity, and sometimes secondary derivatives having swaps as underlying (in which they are named "swaptions")	Warrants generally have underlying as stocks of the company which issues warrants
The seller of an option can be any party trading on the market, need not necessarily be the issuer of the underlying security	In case of warrants, the seller is the company itself which issues the underlying stocks that buyer can buy on a future date
As the product is exchange-traded, price of the option can be discovered and tracked	Price of the warrant is difficult to be discovered as it is an OTC product, and may be based on discretion of the seller..
Options may be traded for shorter period of time, as they are very volatile products	Warrants are generally traded for long periods (in years)
Options are standardized products since they are exchange-traded, and the features are set by exchange	Warrants are not standardized - features depend upon the issuer or the seller, and accordingly profits to be made are determined by buyer
There is no intention by the seller to market the underlying by selling the option. It may just be for the purpose of hedging their risk, or speculation or even arbitrage	Upon selling a warrant, the issuing company may link it to their bonds issued or to publicize selling of the underlying share which is to be introduced into markets in future
Options can be easily traded by approaching the exchange or hiring a broker/intermediary party. They can be traded in volumes with a purpose of hedging risk/speculation/arbitration, and which may also lead to a bubble in economy	Issuance of warrants is very much controlled by the issuing entity, and does not lead to uncontrollable trading

Table 15.46: **Differences between Options and Warrants**

15.3.10.3.4 Futures & Forwards

When we think about selling and buying commodities/currencies we target two types of markets:

1. An immediate physical cash settlement market also named "spot market" involving producers and consumers.
2. A physical market at maturity also named "Forward/Future market" involving producers and that have for desire to hedge price risks consumers and speculators that want to play with the trend of the underlying to make money.

Definition (#15.3.688): A "Forward contract" (or "commodity Forward") and a "Future contract" (or "commodity Future") are both contracts to buy or sale a financial product/underlying (therefore they belong both to the category of derivatives instruments), passed between two counterparties, all of whose characteristics are fixed in advance: settlement date Forward prices, etc. The price entered is named "Forward price" or respectively "Future price" or simply "fair value" for the both, and the exchange and also the payment will be mandatory at that price regardless of the current market price underlying (also named "spot price") on the date of delivery (i.e. maturity date)!

Fundamentally, Forwards and Futures contracts have the same function: both types of contracts allow people to buy or sell a specific type of asset at a specific time at a given price. The purpose of Futures and Forwards for stakeholders is obviously to freeze the prices over the future: it is in this case a hedge (hedging) in the point of view of the seller.

However, it is in the specific details that these contracts differ:

1. Futures contracts are exchange-traded and, therefore, are standardized contracts. Forward contracts, on the other hand, are private agreements between two parties and are not as rigid in their stated terms and conditions. Because Forward contracts are private agreements, there is always a chance that a party may default on its side of the agreement. Futures contracts have clearing houses that guarantee the transactions, which drastically lowers the probability of default to almost never.
2. Specific details concerning settlement and delivery are quite distinct. For Forward contracts, settlement of the contract occurs at the end of the contract. Futures contracts are marked-to-market daily, which means that daily changes are settled day by day until the end of the contract. Furthermore, settlement for Future contracts can occur over a range of dates. Forward contracts, on the other hand, only possess one settlement date.
3. Lastly, because Future contracts are quite frequently employed by speculators, who bet on the direction in which an asset's price will move, they are usually closed out prior to maturity and delivery usually never happens (closed out prior is not authorized with Forwards). On the other hand, Forward contracts are mostly used by hedgers that want to eliminate the volatility of an asset's price, and delivery of the asset or cash settlement will usually take place. Today, around 97% of Futures trading is done by speculators.

4. Forward don't have brokers margins. Indeed, margin are set by the futures exchanges to lower the risk exposure. Therefore the higher is a future margin the higher is the volatility of the underlying. As distinction is made between:
   - Initial Margin: That is the amount of money that is required to open a buy or sell position on a Future contract.
   - Margin Maintenance: That is the amount of money where a loss on your Futures position requires you to allocate more funds to bring the margin back to the initial margin level.
   - Margin Calls: A margin call on Future contracts is triggered when the value of your account drops below the maintenance level. The investor has then the option of taking and opposite positions to eliminate the margin call to pay the difference. In any case if the buyer don't pay the broker bears the cost. If the broker then defaults the clearing house bears the cost!

To summarize, the different types of futures/forwards contracts are generally divided into two main groups that are commodities futures/forwards and financial futures/forwards. Commodity futures/forwards cover traditional agricultural, metal and petroleum products. Finance futures/forwards include stocks, bonds and currencies and the main difference are:

FORWARD:	**FUTURES**:
Contracts executed by banks	Contracts executed by brokerage houses
Private contract (unregulated)	Traded on organized exchanges
Not standardized contract	Standardized contract (regulated)
High counterparty risk	Low counterparty risk
No initial payment required	Initial margin payment required
Normally one specified delivery date	Range of delivery date
Settle and the end of maturity	Daily settled
Traded 24 hours a day	Traded $4-8$ hours a day
No cash exchange prior to maturity	Profit/Loss are paid in cash
More than 90% of contract settled by actual delivery of assets Delivery or final cash settlement usually takes place	Not more than 5% of contract settled by actual delivery of assets
	Contract normally closed out prior to the delivery

Figure 15.115: Future Equity description in Bloomberg™ Terminal

In 12003 (holocene calendar), there would have been $2,848$ million Forward contracts exchanged on markets respectively 2.06% for exchange rates, 17.08% for raw materials (43.9% for food, 10% for metals, 45.8% for fuels and 0.3% other), 25.48% for shares and bonds and 55.37% on interest rates.

✍**Example:**

A Swiss industrialist knows that he must receive an important amount of money in euros in six months. To hedge against a falling of euro (...), he buys a Forward contract of sale, with maturity six months on euro, in swiss franc (if financial operators also know that the euro will fall, the contract Forward sales will have a high enough cost so that the purchase contract is not interesting). Note that this currency hedging operation may be adversely to him if in six months, the contract gives less than the future spot exchange rate.

As we have already mention it, the major difference between Futures and Forwards is that the gains and losses in relation to underlying fluctuations are paid to the counterparty on a daily basis for Futures ("daily mark to market margin" or "daily mark to market settlement") !!! This means that the gain or loss is already almost entirely / disbursed the day of the settlement date (only remains to adjust the difference of the last day).

✍**Example:**

Consider a contract about $1,000$ tons of apples for delivery on a given settlement date. A future contract is available for a future price of 200.- by $1,000$ tons. The initial margin is of 20.- and the maintenance margin of 10.-.

Let's say that on first trading day the traded value of the future value is 195.-. Obviously the buyer of the 200.- contract will feel sad and the seller will feel smart! But the principle behind the mark to market is the margin will help the seller to avoid that the buyer close the position. Indeed, as there is 20.- margin, the 5.- loss can be taken on this margin and theoretically nothing is lost and the 200.- Future will be reset to 195.- because remember that if the seller don't do that the buyer will close is positions. Then it remains 15.- margin.

Let's say that on second trading day the traded value of the Future value is 188.-. Obviously the buyer of the now 195.- contract will feel once again sad and the seller will feel smart! But the principle behind the mark to market is the margin will help again the seller to avoid that the buyer close the position. Indeed, as there is 15.- margin remaining, the 7.- loss can be taken on this margin and theoretically nothing is lost and the 195.-. Future will be reset to 188.- because remember that if the seller don't do that the buyer will close is positions. Then it remains 8.- margin. But now as the remaining margin is less than the maintenance margin of 10.-, through a margin call, the buyer has the option to put 12.- again to be at the initial value of 20.- or to close the position.

If the buyer refuses to add the extra 15.- dollar. The contract is unbound. So the seller can sell his contract to someone else. The loss of the buyer is 20.-. In a "good" contract those 20.- aren't lost by the buying or selling party. The margin is just there as an assurance to both parties that ensure they will keep their position until the end of the deal (or lose 20.-).

At the opposite if the spot price goes up, then the seller has to transfer that difference by which the price increased to the buyer in order to cancel the changes in price. The seller also has a margin not only the buyer!

It must be understood that if the price of the contract goes down to 100.-, then the buyer only pays 100.-, but then adds on an extra 100.- in the margin account. If the final value of the contract is 200.- then the seller and the buyer take back the 20.- initial margin.

As we can not cancel ("opt-out") a Future contract, "closing out" a Future contract means that you enter into a contract that is opposite to the one you initially entered. In this example, the losing party (the buyer) would sell a contract for delivery at 185.-.

Thanks to this example we can see that the margins reduce volatility by eliminating counter-party risk, that is to say the risk that the exchange will end up buying the product because the original buyer disappears without having paid anything.

We see with the above example that the Future contract is something very safety for the seller of the commodity (farmer typically), assimilated to the "hedger", as he will have anyway at least his 200.- if the market price decrease (but if the market price raise he will virtually loose money as he will not get the positive difference, therefore pricing Future correctly is important to be at the best right price!!).

But how do speculators make money with Futures because of this mark to market margin????? Simple! Imagine they buy at day d the Future contract for $200.-$ plus the margin hoping that the price of commodity will increase. If n days after, the price of the commodity increase of δ (the seller has to give us the δ day by day thanks to the mark to market margin) so will do the old contracts and new investors coming in the market will have the choice to buy a completely new Future contract (issue by the farmer) with the price $200+\delta$ and a given margin or an old contract in possession of a speculator who's spot price is also equal to $200+\delta$ plus the margin. And therefore the speculator has make a profit of δ!!! In fact the speculator wins and keeps the day to day cumulative margin!!!!!!!

Two types of executions may occur:

1. The "physical settlement" the underlying is really exchanged (which is rare in the virtual economy, but in the real economy should be a reality...).
2. The "cash settlement": if the price of the underlying is below the set price, the buyer supplied himself on the market he wants and pays the difference to the seller and vice versa.

In practice, speculators, named "index managers", for which the raw material representing the underlying matter is of no interest, have the mission to reposition their portfolios before settlement to avoid physical delivery. This procedure, named "roll-over". The roll-over is normally done on the last day or last week of the month preceding the start of the period of delivery period.

A Future or Forward contract must refer to the role of each participant (buyer or seller), an official reference market - underlying - (stocks, indexes, bonds, currency market, interest rates, etc.) - whose spot price at time t will be denoted S_t, the settlement date reference denoted T, the nominal price K, the notional amount N to which the transaction of the Futures of Forwards is targeted (which is therefore a quantity for physical settlement and that is mathematically almost always reduced to unity), payment instructions (physical or cash settlement) and for Futures the various requires margins M_i (initial margin), and M_m (maintenance margin).

At maturity T, the gain or "payoff" of the contract is in both cases as we will see in the table below (whether for a Forward or Future):

$$\boxed{F_T=S_T-K} \tag{15.3.506}$$

This value[21] simply refers to losses or realized gains (we will reverse the sign depending on whether the trader is a buyer or seller). Indeed, it can be understood better by seeing the cash flow amount in the table below (this also helps to explain why the losses or gains are daily for Futures and that if in the case of gains we can reinvest them quickly on the market):

---

[21] Future prices are sometimes denoted $\mathcal{F}_t$ in textbooks

Time	Forward	Future
0	0	0
1	0	$S_1 - K$
2	0	$S_2 - (K - (K - S_1)) = S_2 - S_1$
3	0	$S_3 - (S_2 - (S_2 - S_1)) = S_3 - S_2$
4	0	$S_4 - S_3$
5	0	$S_5 - S_4$
$\ldots$	0	$\ldots$
$\ldots$	0	$\ldots$
$\ldots$	0	$\ldots$
$T-1$	0	$S_{T-1} - S_{T-2}$
T	$S_T - K$	$S_T - S_{T-1}$
Total:	$S_T - K$	$S_T - K$

Table 15.47: **Cash Flow of Forward and Future of the point of view of a buyer**

15.3.10.3.4.1 Futures & Forwards naive pricing

The pricing of Forward or Future contracts as part of a naive approach is quite simple if the underlying yield is deterministic and the average geometric return of the market as often assumed to be known .... But we must be honestly agree on one thing ...: the final price of a Forward contract or its Future equivalent (at least in the conditions seen before...) must be constituted at final only of the risk premium that will take upon him the seller of the contract.

For the pricing let start with the first element: there is a first information needed from the perspective of contract vendor, it will already actualize K (fixed term value of the contract) to the free risk rate of the to already know the lower limit of price that it will ask today to get K when the time comes (if the seller does not ... other vendors will offer lower prices to the buyer - competition does its job - or the buyer will do the calculation work himself). That is to say:

$$\frac{K}{(1+t\%)^T} \tag{15.3.507}$$

And of course if the sale of the contract is done later than the date of issue, we have:

$$\frac{K}{(1+t\%)^{T-t}} = K(1+t\%)^{-(T-t)} := K(1+t\%)^{-\tau} \tag{15.3.508}$$

What will be written in the continuous case (and adapting traditional notation that of continuous rate of return):

$$Ke^{-r\tau} \tag{15.3.509}$$

Therefore this is the lower limit to apply at any time t for a potential contract buyer (waiting the maturity of this amount of money will be placed in an investment considered as safe). However, this is not strictly speaking the risk premium and thus, the contract price in the sense we usually hear it. Indeed, the seller of the contract will have to buy the underlying of contract. If for example the sale of the contract is made just at its issue (that is to say at time T before maturity), then we have the actualized price of the assumed (projected) value of the underlying at maturity knowing it will have himself intrinsic yield (that the seller will take in the worst case: that is to say a positive rate) which we will denote y (the "spot-rate") and in non-stochastic framework we can do this calculation only based on something known which is the underlying spot price:

$$S_0 e^{-yT} \tag{15.3.510}$$

That is to say for any time t:

$$S_t e^{-y(T-t)} = S_t e^{-y\tau} \tag{15.3.511}$$

We then have the actualized payoff of a Forward or Future corresponding to the risk premium which is given in any time under the assumptions underlying the previous relations by the difference (obviously buyer point of view!):

$$S_t e^{-y\tau} - K e^{-r\tau} \tag{15.3.512}$$

which is written by tradition in the purpose to make appear the Future or Forward price at each day t:

$$S_t e^{-y\tau} - K e^{-r\tau} = S_t e^{-y\tau} e^{r\tau} e^{-r\tau} - K e^{-r\tau} = (S_t e^{-y\tau} e^{r\tau} - K) e^{-r\tau} \tag{15.3.513}$$

The factor on the left is the risk free actualization factor. Therefore we guess that we can focus only on the parenthesis: $(S_t e^{-y\tau} e^{r\tau} - K)$ that is the non-actualized risk premium. Fro this we conclude that:

$$S_t e^{-y\tau} e^{r\tau} - K = F_t - K \tag{15.3.514}$$

and therefore:

$$\boxed{F_t = S_t e^{-y\tau} e^{r\tau} = S_t e^{(r-y)\tau}} \tag{15.3.515}$$

It is interesting to notice that y is subtracted of the risk free rate r and therefore makes the contract price lower. This is obviously valid if be in possessions of underlying can makes us win money, but if this make us loose money (for example the cost of storage can be very expensive), then y will be negative and will increase the Forward or Future price.

If the underlying pays dividends, then obviously the value above is overestimated. We have logically then to actualize dividends and to subtract it to have the value of the Future or Forward equal to:

$$\boxed{F_0 = S_0 e^{(r-y)T} - \sum_{i=1}^{n} D_i e^{-r(T-t_i)}} \tag{15.3.516}$$

Definitions (#15.3.689):

D1. As for any derivative, we say that the market is "contango" if the option price (in our case: the Future or derivative) is greater than the spot price of the underlying.

D2. As for any derivative, we say that the market is "backwardation" if the option price (in our case: the Future or derivative) is lower than the spot price of the underlying.

Therefore, more explicitly, contango is a situation where the Futures price (or Forward price) of a commodity is higher than the expected spot price. In a contango situation, hedgers (commodity producers and commodity users) or arbitrageurs/speculators (non-commercial investors), are "willing to pay more (now) for a commodity at some point in the future than the actual expected price of the commodity (at that future point). This may be due to people's desire to pay a premium to have the commodity in the future rather than paying the costs of storage and carry costs of buying the commodity today". And a market is "in backwardation" when the Futures price is below the expected future spot price for a particular commodity. This is favourable for investors who have long positions since they want the futures price to rise.

A contango is normal for a non-perishable commodity that has a cost of carry. Such costs include warehousing fees and interest forgone on money tied up (or the time-value-of money, etc.), less income from leasing out the commodity if possible (e.g. gold).

The figure below depicts how the price of a single Forward contract will behave through time in relation to the expected Future price at any point time:

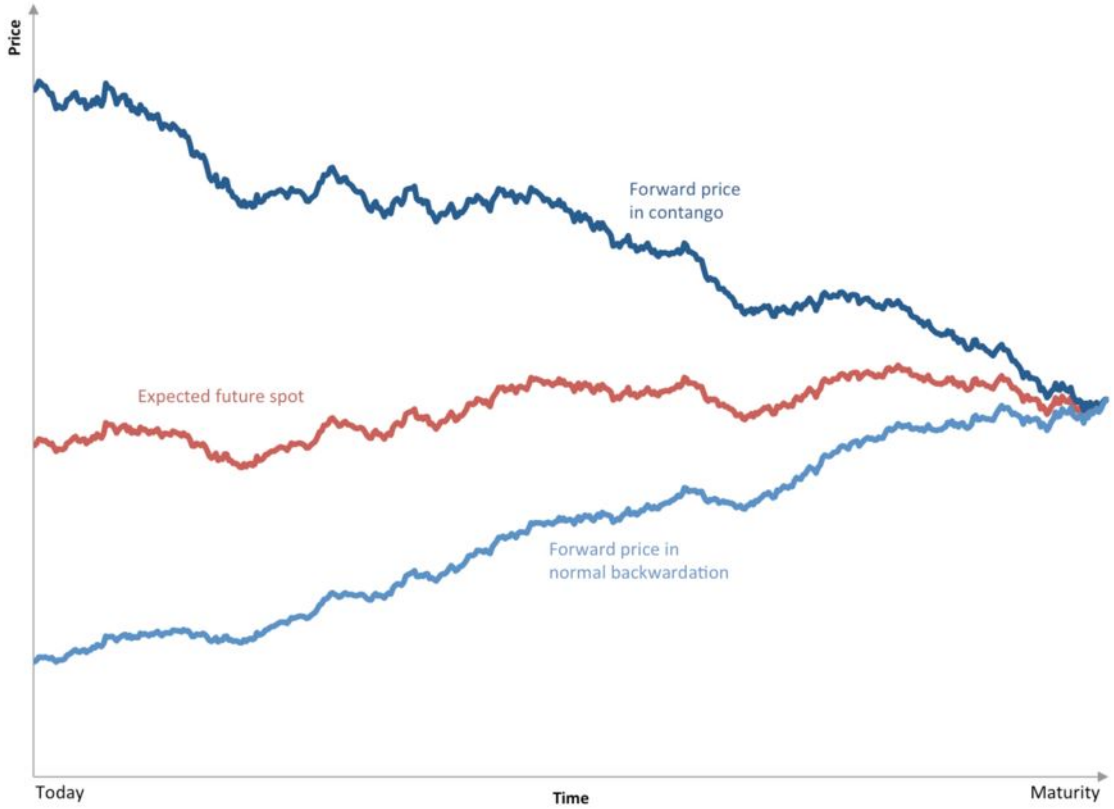

Figure 15.116: **Typical spot price and Future/Forward price dynamics**

✍**Example:**

A customer wants to buy to us in 6 months US dollars with Euros (or in other words he pays in Euros in 6 months a machine that he bought today and we are working in US dollars). We would then protect us already against changes in the raise of the monetary value (bid/ask) of the US dollar (because if the US dollar rises then we lose verbatim money since then 1 Euro is less than 1 US dollar). However, there is available on the market only Futures issued already 6 months before with maturity (cash settlement) in 12 months. Knowing that the market risk-free rate is 3% (in continuous rate...), that the dollar rate is assumed at worst at $+1.5\%$ (also in continuous rate...) and that we want to know the contract price in monetary unit and that the contracts emitted 6 months ago with maturity in 6 months had an exercise price of €1.00.- for \$$1.50$.- and that today the cost of €1.00.- is of \$$1.60$.-, the risk premium that we have to pay is therefore:

$$S_t e^{-y\tau} - Ke^{-r\tau} = S_{0.5}e^{-1.5\%(1-0.5)} - Ke^{-3\%(1-0.5)} = 1.6e^{-0.75\%} - 1.5e^{-1.5\%} \cong 0.11 \tag{15.3.517}$$

dollars per unit of currency in desired Euros (so we pay 11% as a risk premium which is a typical value of what is practised empirically on markets: added to 5% to 15%). That sounds like a lot but it limits our risk and transfers it on the seller of the contract! Moreover, buying the machine we could also see first the risk premiums and adapt price negotiations accordingly.

The spot price of the Future contract is therefore obviously:

$$F_{0.5} = S_{0.5}e^{-y\tau} = S_{0.5}e^{-1.5\%(1-0.5)} = 1.6e^{-0.75\%} \cong 1.612 \tag{15.3.518}$$

that is to say \$$1.612$.- for €$1.00$.- (which corresponds to the result returned by the GUIDE `R` package). So we cannot obviously get \$$1.50$.- for €$1.00$.- and this difference is explained by the risk taken by the seller of the Future contract.

So the total price of the Future is finally $1.612 + 0.11 = \$1.722$.- while the spot price is \$$1.60$.-. The difference, omitting the risk premium, is of \$$-0.012$ and is named the "basis" or "cost of carry" and it indicates to a future buyer that market agents are planning an increase if the basis is negative ("under") and a decrease if positive ("over").

Remark

In practice, as with many financial instruments, the risk premium is included in a broader terminology fees we name "margin money" which includes transaction costs, risk premium, insurance costs for bankruptcy of the buyer of the Future/Forward contract, etc. Some institutions, however, use the term "cost of carry" for all types of costs and then the risk premium alone is named "net cost of carry".

We will not look now the mathematical tools for the pricing of Futures/Forward contracts using stochastic return, because as they are "only" a special case of the pricing of options that we will see later it would be redundant to present every theorems twice while there is only a small change to make for in the Black & Scholes model to get one from the other.

Indeed, as we will see an option is a derivative that does not necessarily result in an execution due to its optional character in relation to a Future/Forward contract where the settlement date is fixed in advance.

15.3.10.3.4.2 Cox-Ingersoll-Ross equality of the Future/Forward price

Under a specific condition and a given strategy it is possible to demonstrate that the price of a Future is equal to that of a Forward at maturity (we own this proof to J.C. Cox, J.E. Ingersoll and S.A. Ross in their article of 11981 according to holocene calendar).

Let us suppose that the market risk-free rate is r and that the latter is constant and that each day i we apply the very special strategy of selling Futures in a quantity e^{-ri} in the so-named "CIR conditions" (these are the initials of the names of the authors of this strategy).

So in the beginning we sell Forward but we have to actualize the price, so the actualized price is then:

$$e^{-r}(F_1-K)e^{-r(T-1)}=(F_1-K)e^{-rT} \tag{15.3.519}$$

On the second day, we sell contracts that must also be actualized:

$$e^{-2r}(F_2-F_1)e^{-r(T-2)}=(F_2-F_1)e^{-rT} \tag{15.3.520}$$

And we quickly see that we will have in total:

$$(F_1-K)e^{-rT}+(F_2-F_1)e^{-rT}+(F_3-F_2)e^{-rT}+\ldots+(S_T-F_{T-1})e^{-rT} \tag{15.3.521}$$

This is simplified immediately to:

$$(S_T-K)e^{-rT} \tag{15.3.522}$$

We thus fall back on the actualized of the payoff of the forward according to the table seen earlier above. Obviously, this equality is valid only if the return of the risk-free market is constant and in the strategy mentioned above, which is not the case (realistic) the majority of time!

As far as we knew, even if this theoretical result is interesting, practical implications, however, of this observation are minimal.

15.3.10.3.4.3 Futures & Forwards commodity hedging

A company will prefer Future/Forwards to Options if its purpose is to know its costs in advance so that it is 100% certain to consume the underlying! Even if the purchase of an Option requires obviously the payment of a risk premium that generates a cost of opportunity. In the case where the company is not sure to use the underlying, it will prefer the Option that can be executed or not, which means that the management reserves a good result whatever happened but they will pay in counterpart the option risk premium.

Let us study now an interesting case of risk hedging of raw materials. Imagine that a company needs to buy for a total amount S a raw material but for which there is sadly no Forwards or Futures contracts available (and no partner agree to make an OTC contract). This company wish to hedge against an increase in the price of the raw material that it is interested for and therefore at least two typical strategies are available to it:

1. Found Future or Forward contracts of a commodity positively correlated to the raw material of interest. Therefore, hoping that this commodity replicates well the behaviour of the raw material of interest and that when its price will increase the other one will also probably do same (and if possible in the same proportions)... and the idea is to have a buyer (long) position of contract to buy at maturity the commodity to a value less than the spot price and hope to find someone to sell the latter to people interesting to buy quickly and use the payoff to buy the raw material of interest with a minimum loss (an in the ideal case with a loss equal to zero or even a positive remainder).

2. Found Future or Forward contracts of a commodity negatively correlated to the raw material of interest. Therefore, hoping that this commodity replicates well the behaviour of the raw material of interest and that when its price will decrease the other one will probably increase (and if possible in the same proportions)... and the idea is to have a seller (short) position of contract to sell at maturity the commodity to a value more than the spot price and use the payoff to buy the raw material of interest with a minimum loss (an in the ideal case with a loss equal to zero or even a positive remainder).

Mathematically the strategy consists to write in the both cases (we will see later what sign corresponds to which strategy):

$$\boxed{\Delta V=\Delta S\pm N\Delta F} \tag{15.3.523}$$

where ΔS is the variation of the raw material price on the market and ΔF is the payoff of the contracts that replicates positively or negatively the variation (increase) of the price S. We have ΔV that is the difference of the good or bad replication and that must in the ideal case tends to zero. Another way to see the context, more common as it encompass the point that makes problem (that is to say: the volatility!!!), is to write this strategy with the information available on the market such that we take the variance of the previous relation:

$$\sigma_{\Delta V}^2=\sigma_{\Delta S}^2+N^2\sigma_{\Delta F}^2\pm 2N\sigma_{\Delta S,\Delta V} \tag{15.3.524}$$

and to search the value N that minimize the variance ΔV in function of the correlation of the both commodities (that we will have to make appear) and of their volatility (containing implicitly the quantity as we will see). We have then by derivating relatively to N:

$$\frac{\partial\sigma_{\Delta V}^2}{\partial N}=2N\sigma_{\Delta F}^2\pm 2\sigma_{\Delta S,\Delta V}=0 \tag{15.3.525}$$

Which gives using the relation between the covariance and the linear correlation coefficient proved in the section Statistics (see page 597):

$$N^*=\pm\frac{\sigma_{\Delta S,\Delta V}}{\sigma_{\Delta F}^2}=\pm\frac{\text{cov}_{\Delta S,\Delta V}}{\sigma_{\Delta F}^2}=\pm\frac{R_{\Delta S,\Delta V}\sigma_{\Delta S}\sigma_{\Delta F}}{\sigma_{\Delta F}^2}=\pm\frac{R_{\Delta S,\Delta V}\sigma_{\Delta S}}{\sigma_{\Delta F}} \tag{15.3.526}$$

As the standard deviations are positive and N must be positive (and be rounded to the nearest integer to be a realistic physical solution), it is obvious that the correlation coefficient should always be of opposite sign to the type of the chosen strategy. This is why we have finally for tradition to take (as it still remains the same) the positive sign such as:

$$\boxed{N^*=\frac{R_{\Delta S,\Delta V}\sigma_{\Delta S}}{\sigma_{\Delta F}}} \tag{15.3.527}$$

and always take the correlation coefficient as positive (absolute value). Therefore N^* is the number of Futures or Forward contracts that whatever the strategy, will minimize the total variance.

Figure 15.117: **Correlation matrix for various currencies in Bloomberg™ Terminal**

However, it is customary to bring this expression such that we have not the variance of the price change, but in the change in rates especially in the purpose to make appear the quantity!!! Thus, as we have:

$$\begin{gathered}\underbrace{S}_{\substack{\text{total price of}\\ \text{raw material}}}=\underbrace{Q_S}_{\substack{\text{quantity of}\\ \text{raw material}}}\cdot\underbrace{s}_{\substack{\text{unit price of}\\ \text{raw material}}}\\ \underbrace{F}_{\substack{\text{cost price of}\\ \text{Future contracts}}}=\underbrace{Q_F}_{\substack{\text{quantity of}\\ \text{Future contracts}}}\cdot\underbrace{f}_{\substack{\text{unit price of}\\ \text{a Future contract}}}\end{gathered}\tag{15.3.528}$$

Therefore it comes:

$$\begin{gathered}\sigma_{\Delta S}=\sigma(\Delta S)=\sigma(\Delta(Q_S\cdot s))=Q_S\sigma(\Delta s)=sQ_S\sigma\left(\dfrac{\Delta S}{s}\right)\\ \sigma_{\Delta F}=\sigma(\Delta F)=\sigma(\Delta(Q_F\cdot f))=Q_F\sigma(\Delta f)=fQ_F\sigma\left(\dfrac{\Delta F}{f}\right)\end{gathered}\tag{15.3.529}$$

Hence:

$$N^*=R_{\Delta S,\Delta F}\frac{\sigma_{\Delta S}}{\sigma_{\Delta F}}=R_{\Delta S,\Delta F}\frac{sQ_S\sigma\left(\dfrac{\Delta S}{s}\right)}{fQ_F\sigma\left(\dfrac{\Delta F}{f}\right)}=\left(R_{\Delta S,\Delta F}\frac{\sigma\left(\dfrac{\Delta S}{s}\right)}{\sigma\left(\dfrac{\Delta F}{f}\right)}\right)\frac{sQ_S}{fQ_F}\tag{15.3.530}$$

That it is customary to write in the following condensed form:

$$\boxed{N^*=\beta_{\Delta S,\Delta F}\frac{sQ_S}{fQ_F}=\beta_{SF}\frac{sQ_S}{fQ_F}} \tag{15.3.531}$$

The variance V therefore becomes using this optimum (we take again the double sign ± that will be useful to us!):

$$\begin{aligned}\sigma^{*2}_{\Delta V}&=\sigma_{\Delta S}+N^{*2}\sigma^2_{\Delta F}+2N^*\sigma_{\Delta S,\Delta F}=\sigma^2_{\Delta S}+\left(\pm\frac{\sigma_{\Delta S,\Delta F}}{\sigma^2_{\Delta F}}\right)^2\sigma^2_{\Delta F}+2\left(\pm\frac{\sigma_{\Delta S,\Delta F}}{\sigma^2_{\Delta F}}\right)\sigma_{\Delta S,\Delta F}\\&=\sigma^2_{\Delta S}+\frac{\sigma^2_{\Delta S,\Delta F}}{\sigma^2_{\Delta F}}\pm 2\frac{\sigma_{\Delta S,\Delta F}}{\sigma^2_{\Delta F}}\end{aligned} \tag{15.3.532}$$

Obviously, the only one sign that seems to have a physical meaning is the "$-$" sign that will decrease the global variance (as it is the purpose of the both strategies). Then we have:

$$\begin{aligned}\sigma^{*2}_{\Delta V}&=\sigma^{*2}_{\Delta S}-\frac{\sigma^{*2}_{\Delta S,\Delta F}}{\sigma^{*2}_{\Delta F}}=\sigma^{*2}_{\Delta S}-\frac{(R_{\Delta S,\Delta F}\sigma_{\Delta S}\sigma_{\Delta F})^2}{\sigma^{*2}_{\Delta F}}=\sigma^{*2}_{\Delta S}-R^2_{\Delta S,\Delta F}\sigma^2_{\Delta S}\\&=\left(\sigma\left(\frac{\Delta S}{s}\right)sQ_S\right)^2-R^2_{\Delta S,\Delta F}\left(\sigma\left(\frac{\Delta S}{s}\right)sQ_S\right)^2=\left(\sigma\left(\frac{\Delta S}{s}\right)sQ_S\right)^2(1-R^2_{\Delta S,\Delta F})\end{aligned} \tag{15.3.533}$$

Thus Finally:

$$\boxed{\sigma^*_{\Delta V}=\sigma\left(\frac{\Delta S}{s}\right)sQ_S\sqrt{1-R^2_{\Delta S,\Delta F}}} \tag{15.3.534}$$

✍**Example:**

Let us consider that an airline company needs $10,000$ tons of fuel (which the current price is 277.- / ton) for its aircraft fleet in 3 months and wants to hedge against possible price increases of this transformed raw material and that there are no direct Future contracts directly fuel.. The airline company then wants to hedge risk by using another specific commodity for which there exists Future contracts which underlying quantity is $42,000$ tonnes (0.6903.- / ton). We would like to calculate the decrease of the fuel variance price by taking a purchase position (Call) on this Futures (so we do a down bet for the replicating commodity) knowing that the variance at 3 months of fuel is estimated to be 21.17% and that of the replicating commodity being of 18.59% over obviously the same period and that their correlation is in absolute value of equal to 0.8242.

Then we have:

$$N^{*}=\left(R_{\Delta S,\Delta F}\frac{\sigma\left(\dfrac{\Delta S}{s}\right)}{\sigma\left(\dfrac{\Delta F}{f}\right)}\right)\frac{sQ_S}{fQ_F}=\left(0.8243\frac{0.2117}{0.1859}\right)\frac{277\cdot 10,000}{0.6902\cdot 42,000}\cong 89.7\cong 90 \tag{15.3.535}$$

As we have for the volatility of the fuel in money:

$$\sigma_{\Delta S}=sQ_S\sigma\left(\frac{\Delta S}{s}\right)=277\cdot 10,000\cdot 0.2117=586,409.- \tag{15.3.536}$$

And once covered by the replicating commodity, it becomes:

$$\sigma_{\Delta V}=\sigma\left(\frac{\Delta S}{s}\right)sQ_s\sqrt{1-R_{\Delta S,\Delta F}^2}=0.2117\cdot 277\cdot 10,000\sqrt{1-0.8243^2}\cong 331,997.- \tag{15.3.537}$$

The hedging by Future contracts reduce the volatility of cash of a factor around 43.38%.

Remark

Some practitioners use the following empirical indicator named "Ederington efficiency" as hedging quality:

$$E=\frac{\sigma_{\Delta S}^2-\sigma_{\Delta V}^{*2}}{\sigma_{\Delta S}} \tag{15.3.538}$$

Which is nothing more than the ratio of the difference of the non-hedged variance with the hedged one by the non-hedged variance. In the example above its value is 67.49%. More this ratio is close to unity, the better it is!

When the relation:

$$N^{*}=\beta_{\Delta S,\Delta F}\frac{sQ_S}{fQ_F}=\beta_{SF}\frac{sQ_S}{fQ_F} \tag{15.3.539}$$

is applied not with a numerator that corresponds to a raw material but to stock portfolio, this technique is named "stock portfolio hedging by replication" or more simply "equity portfolio hedging" and is then rather denoted as follows:

$$N^{*}=\beta_{AB}\frac{V_A}{V_B} \tag{15.3.540}$$

where V stands for "value" (absolutely no relation with the notation of the variance!!!). Or even in the following form (P being the value of the portfolio and F that of Futures):

$$N^{*}=\beta\frac{P}{F} \tag{15.3.541}$$

✍**Example:**

A trader has a portfolio of $2,000,000$.- of IBM stocks. He would like to hedge this portfolio thinking that the market will go down on the S&P 500. Therefore he sells ("short") Futures for an amount of $225,000$.- and he know that the beta correlation between IBM and S&P 500 is equal to 1.1 (a beta less than 1 indicates that the investment is less volatile than the market, while a beta more than 1 indicates that the investment is more volatile than the market). The number of Futures to sale is then (therefore if the portfolio value goes down with the same magnitude as the S&P 500 the trader will lose nor gain anything):

$$N^*=\beta_{AB}\frac{V_A}{V_B}=1.1\frac{2,000,000}{225,000}=9.78\cong 10 \tag{15.3.542}$$

If the trader has purchased Futures to protect himself from the decrease he expected to happen (bet down price and therefore "short" strategy for recall...) then if IBM shares lost 10%, but the index S&P 500 index lost more than what the beta indicated such for example 15%, so even if the IBM portfolio had lost $200,000$.- of its value, the fact that the S&P 500 has lost 15%, thanks to the Futures, the trader will have made an indirect gain of:

$$225,000\cdot 15\%\cdot 10=337,500\text{.-} \tag{15.3.543}$$

So ultimately a gain for the trader of $137,500$.- (like what... sometimes... bet down is good).

Let us recall now that during our previous study of modified duration (see page 7633) we have define that latter, denoted as D^* as being:

$$\frac{\mathrm{d}P}{P}-D^*\mathrm{d}y \tag{15.3.544}$$

Hence:

$$\mathrm{d}P=-D^*P\mathrm{d}y \tag{15.3.545}$$

That can also obviously be written:

$$\Delta P=-D^*P\Delta y \tag{15.3.546}$$

Similarly let us then write:

$$\Delta S=(-D_S^*S)\Delta y \qquad \Delta F=(-D_F^*F)\Delta y \tag{15.3.547}$$

where D_S^* and D_F^* are the modified duration of S and F respectively.

So we can rewrite:

$$\Delta V=\Delta S\pm N\Delta F=(-D_S^*S)\Delta y+N(-D_F^*F)\Delta y=-[(D_S^*S)+N(D_F^*F)]\Delta y \tag{15.3.548}$$

Which is zero when the net exposure, represented by the term between bracket is zero, that is:

$$(D_S^*S)+N(D_F^*F)=0 \tag{15.3.549}$$

Hence:

$$N^*=-\frac{D_S^*S}{D_F^*F} \tag{15.3.550}$$

In other words, the optimal hedge ratio is simply minus the ratio of the dollar duration of cash relative to the dollar duration of the hedge.

More generally, we can use N as a tool to modify the total duration of the portfolio. If we have a target duration of D_V^*, this can be achieved simple by writing:

$$\Delta V=-D_V^*V\Delta y=-[(D_S^*S)+N(D_F^*F)]\Delta y \tag{15.3.551}$$

Therefore after rearranging:

$$N=\frac{D_V^*V-D_S^*S}{D_F^*F} \tag{15.3.552}$$

We can see that the previous relation with N^* is just a special case of that latter relation!

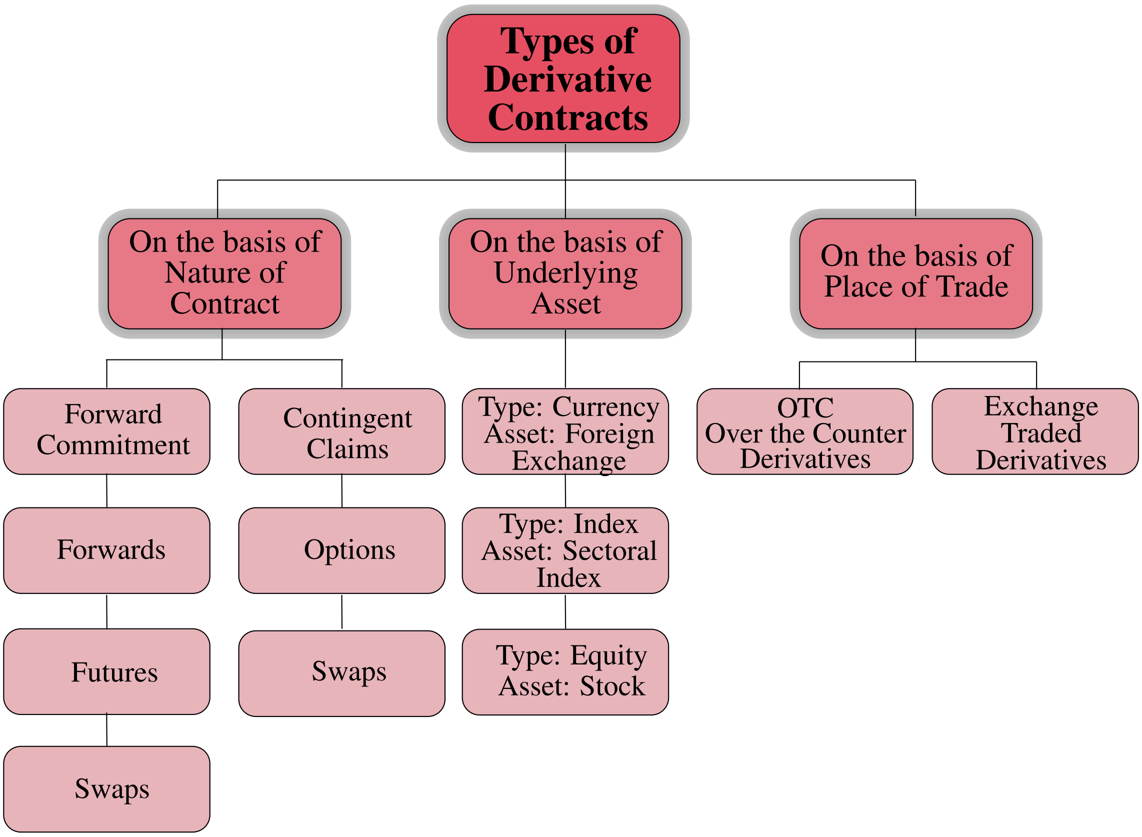
Remark

We will see further below on page 7757 how to hedge a portfolio with Commodities and Futures but based on the CAPM (Capital Asset Pricing Model).

15.3.10.3.4.4 Options

Options are "contingent asset" (also named "contingent claim[22]"), that is to say, a particular form of a title (contract) giving the holder in counterpart of payment the right, but not the obligation to buy or sell a given amount of a financial asset (stock, bond or foreign exchange), at a given date or up to a given date (expiry or maturity) to a price fixed in advance.

It is primarily as Futures and Forwards (also derivatives!) that options permits to hedge the risk of market fluctuations and to speculate. For example, if Boeing sells aircraft in euros but produces in the dollar zone. The sale price is fixed today, but the sale is made on delivery! Boeing must therefore protect itself against the risk of the exchange rate (which can sometimes be of a magnitude 100% in a few years). Generally, most big companies protect themselves from these risks by purchasing in banks derivatives such as options.



Types of Derivative Contracts
On the basis of Nature of Contract
On the basis of Underlying Asset
On the basis of Place of Trade
Forward Commitment
Contingent Claims
Type: Currency Asset: Foreign Exchange
OTC Over the Counter Derivatives
Exchange Traded Derivatives
Forwards
Options
Type: Index Asset: Sectoral Index
Futures
Swaps
Type: Equity Asset: Stock
Swaps

Figure 15.118: **Derivatives contracts viewed on various basis**

In 12003 (holocene calendar) there would have been $5,210$ million of options traded on the markets and respectively 0.98% for raw materials, 0.28% for exchange rates, 5.80% for the interest rates and 92.94% in securities and bonds.

---

[22] In finance, a "contingent claim" is a derivative whose future payoff depends on the value of another underlying asset, or more generally, that is dependent on the realization of some uncertain future event. These are so named, since there is only a payoff under certain contingencies. Any derivative instrument that is not a contingent claim is named a "forward commitment".

Remarks

R1. We will return further below in detail on the mathematics of the options that are important products as also many other derivatives relies on the same mathematical properties.

R2. Options involve zero-sum game (see section Game Theory page 7378) in the sense that for every seller there is a buyer and what one wins, the other lose it (and vice versa).

R3. The main difference between options and Futures lies in the fact that options represent a right to buy or sell at the contract maturity while Future represent the obligation to exercise the contract at maturity.

Figure 15.119: **Forward commitment vs Contingent claims**

Definitions (#15.3.690):

D1. An "option" is a derivative product that gives the right, but not the obligation, to buy ("Call option", also just "Call") or sell ("Put option", also just "Put") a specified amount of an underlying asset S (share, bond, stock index, currency, row material, another derivative product, etc.) to a predetermined price named "strike price" denoted by K or "exercise price" and therefore denoted by E and during (until to) a given time named "maturity" denoted by T in exchange of a "risk premium" depending (denoted by C or P for the Call to Put) on the intrinsic value at maturity of the option named "flow" or more often "terminal payoff" (and by some practitioners: "stochastic target"). The determination of the premium with mathematical models is what we name the "pricing of the option". An option is therefore a kind of "insurance policy" to protect against variations in costs by transferring the risk to a person willing to sell the option in exchange of a risk premium ... this latter being also often named "insurance premium".

D2. We talk about "spot price" or just "spot" to designate the current market price S of the underlying asset at the time of an immediate transaction of the option (Call or Put). If the underlying is a foreign currency exchange rate, then we speak of "cross over" or simply "cross".

D3. If the intrinsic value[23] of an option according to some hypothesis) of an option is positive with respect to the spot price, it is said to be "in-the-money". In the case of the purchase of a Call for example, it means that the exercise price of the Call is below the spot price. It is possible therefore to buy cheaper than the traded value at the execution date (maturity most of time) of the option (which is a date between the option issue date and maturity date of the option for recall!!!).

D4. If the intrinsic value of an option is not advantageous compared to the spot price, it is said to be "out-the-money". In this case, the exercise price is above the current spot price for a Call for example. It would therefore be unwise to exercise the Call at the due date (either before), because that would be more expensive to apply the Call than to buy at the spot price on that date!

D5. If the intrinsic value at a given date of the underlying is equal to its current spot at maturity, the intrinsic value is zero and the value of the option is said to be "at-the-money" and abbreviated in many softwares obviously: ATM (we will see later the mathematical implications of this).

D6. If the intrinsic value of an option is very far form the stock price it is then referred as "deep in-the-money" or "deep out-the-money".

Given the above definitions and the example about Boeing the options can be naively summarized by the following figure:

---

[23] An option's premium is the sum of "intrinsic value" and "extrinsic value" (also known as "time value"). Intrinsic value is reflective of the actual value of the strike price versus the current market price. Extrinsic value is made up of time until expiration, implied volatility, dividends and interest rate risks.

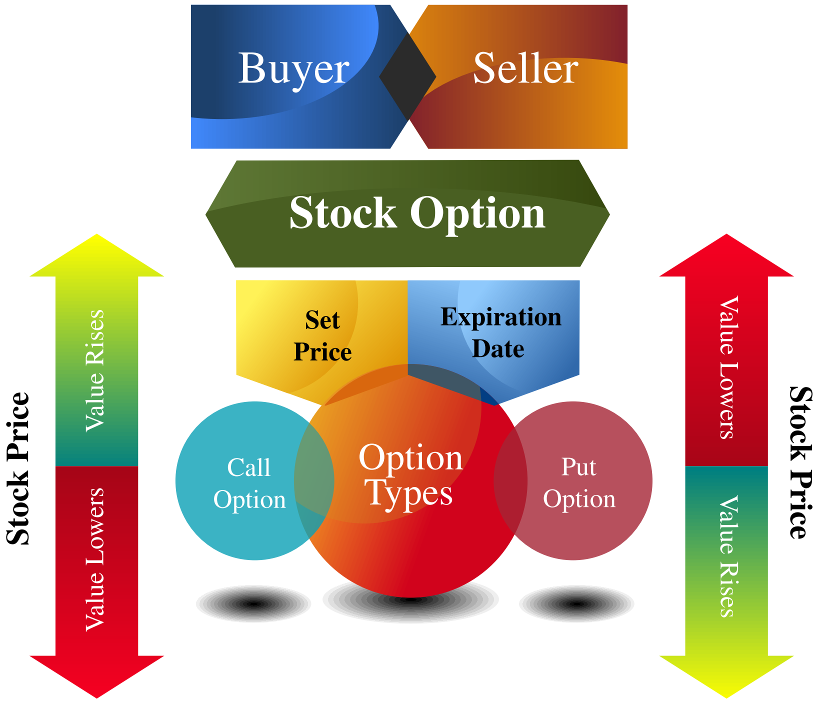

Figure 15.120: **Options graphical concept summary**

Remarks

R1. The usefulness of the existence of Options are the same as for the Futures and Forwards: they can be viewed as an artificial way to create assets (in this case: derivatives) to increase financial volatility (standard deviation or "loss / gain deviation") of market and thus guarantee his equilibrium.

R2. The holder or buyer of an option contract is said to be in a "long position" while its counterpart, the issuer or seller of the contract is said to be in a "short position".

R3. If the option can be exercised at any time prior to maturity, we talk about "American option", if the option can be exercised at maturity, we talk about "European option". One unexercised option is considered as "abandoned" (lost). These two families of options in their Call/Put version are in practice grouped under the term "plain vanilla options" as these are the most common (such as ice cream with vanilla... that are anything but exotic...).

Alongside the classic options (vanilla options), like:

- "Stock options" are options on individual stocks, also named "equities options". They are among the most popular type of options.
- "Exchange-listed options" are available widely on traded stocks and an option on any stock can potentially be created on the over-the-counter market.
- "Index options" on stock market indices (S&P 500, Down Jones, NASDAQ, etc.) are well known, not only in the investment community but also among many individuals who are not even directly investing in the market.

- "Bond options" are found almost exclusively in the over-the-counter market and are almost always options on government bonds.
- "Interest rate options" are options on interest rates like the LIBOR for example.
- "Currency options" in the same idea of interest rate options allows the holder to buy (if a call) or sell (if a put), an underlying currency at a fixed exercise rate, expressed as an exchange rate.
- "Future options" gives the holder the right to enter (call) or get out (put) into/from a long/short futures contract at a fixed future price.
- "Commodity options" are options on which the underlying asset is a commodity, such as oil, gold, wheat, or soybeans. There are exchange-trader as well over-the-counter versions.

appear since the years 11990s (holocene calendar), on the markets, options named "exotic options" sometimes characterized by the name of the place where they were created and the manner of determining the exercise price at maturity (so there exists at most as many mathematical models as there are types of options...) as the:

- "Asian options" whose exercise price is based on the average of the underlying price during the life of the option
- "Parisian options" that can be activated or cancelled if the underlying traded price remains above a given threshold value during a given time range
- "Russian options" which are perpetual American options that guarantee to get the maximum margin observed between the issue and the exercise date
- "Binary/Digital options" that gives the right to the amount fixed in advance if the underlying at maturity exceeds the exercise price
- "Lookback options" that give the right at maturity to the difference between the value of the traded underlying at maturity and the value of the min or max during the life of the option
- "Quantile options" that are a refinement of lookback options because the rule of the game is based on a quantile, not on the max or min
- "Barrier options (knock out, knock in)" whose exercise is permitted if the traded value of the underlying cross or doesn't cross a certain threshold
- "Quanto options" that are options on foreign underlying, but paid in local currency (then you should take into account the exchange rate)
- "Ratchet options" that gives the buyer the right to block its gains realized on the underlying during determined intervals during the life of the option
- "Compound options" or "chooser options" that are options on options, etc.

Remark

In the general case (more advanced models, other types of options), the price of an option can not be obtained from an analytical closed formula. Then we need to make use of numerical methods to price the option. Common numerical methods to price are: Binomial method (see further below), Monte Carlo method (see the `R` companion book), Finite difference method, Radial basis function method, Finite element method, Fourier method, Least squares calibration method, etc.

Here is a small summary of all derivatives that we have mentioned so far (maybe be useful before we continue):

FORWARD:

- Contracts executed by banks
- Private contract (unregulated)
- Not standardized contract
- High counterparty risk
- Unlimited profit for a buyer with limited loss, unlimited loss for a seller with limited profit
- No initial payment required
- Normally one specified delivery date
- Settle and the end of maturity
- Traded 24 hours a day
- No cash exchange prior to maturity
- More than 90% of contract settled by actual delivery of assets
- Delivery or final cash settlement usually takes place

FUTURES:

- Contracts executed by brokerage houses
- Traded on organized exchanges
- Standardized contract (regulated)
- Low counterparty shared risk
- Unlimited profit for a buyer with limited loss, unlimited loss for a seller with limited profit
- Initial margin payment required
- Range of delivery date
- Daily settled
- Traded $4-8$ hours a day
- Profit/Loss are paid in cash
- Not more than 5% of contract settled by actual delivery of assets
- Contract normally closed out prior to the delivery
- Contract seller has obligation to sell/buy if buyer exercise right
- Preferred by speculators or arbitrageurs

OPTIONS:

- Contracts executed by brokerage houses or private ("dealer options")
- Traded on organized exchanges or private
- Standardized or non-standardized contract
- High counterparty risk borne by one party only
- Unlimited profit for a buyer with limited loss, unlimited loss for a seller with limited profit
- Initial margin payment required (but less than Futures)
- Execution date fixed or variable
- Settled maturity of range of date
- Traded 24 hours a day
- Profit/Loss are paid in cash
- Contract normally closed at maturity
- Contract seller has obligation to sell/buy if buyer exercise right
- Preferred by hedgers

Here is a summary table between Call and Put:

Call			Put	
Buyer of a Call (Long Call)	Seller of a Call (Short Call)		Buyer of a Put (Long Put)	Seller of a Put (Short Put)
Has the right, but not the obligation, to buy the underlying stock at the predetermined price until the due date.	Has the obligation to sell the underlying asset at the predetermined price if the Call is exercised the due date.		Has the right, but not the obligation, to buy the underlying stock at the predetermined price until the due date.	Has the obligation to buy the underlying stock at the predetermined price if the Put is exercised

Table 15.48: **Differences between Put and Call**

So there is obviously an enormous important mathematical difference between Options and Stocks/Bonds. Indeed, Options have an exercise date, their price dynamic can be statistically predictable and this prediction is even better when we are close to their date of exercise and this is not applicable for the Stocks/Bonds because we never know at the strategic level when they will be sold or respectively purchased.

While the naive theoretical models for valuation of options (such as Black & Scholes) assume a constant historical volatility whatever the price of the underlying. In reality the graphical representation of the price of an Option based on their underlying price is not a horizontal line but a curve that is usually named a "volatility smile". We will come back later in detail on this concept for which we have an illustration below:

Remark

As we will prove why further the Options that are said to be "non-path-dependent options" (NPDO) have their price which depends (among others...) only on the final price at maturity of the underlying K, while others Options that are said to be "path-dependent options" (PDO) have their price which depends on all the values of the underlying during the term of the Option contract.

Let us formalize things now! But without going into too much detail at first time (we keep the details for the study of the Black & Scholes model later that consists to determine the premium price[24] of an option according to some hypothesis.). We consider first for simplicity options on a single underlying not paying dividends.

We will denote the price of the underlying asset of the concerned option by S_t (trade/exchange rate value) at time t and maturity T and will disregard the difference between continental Put and Calls (American and European).

Let us imagine a Call, which gives the holder the right (but not the obligation) to buy the underlying asset at any time between today $t=0$ and the $t=T$ at the (maturity) exercise price K set in advance. Let us take the practical common case of a Call option that protects a business against the rise of the euro/dollar exchange rate for example. Acquired today by the firm, it will therefore give it the right (but not the obligation!) to buy \$1 in exchange of K euros (the strike price at maturity K is a fixed characteristic of the contract) to the future date T (maturity date).

If the exchange rate has for value S_t at time t (that is to say today $\$1=S_t$ EUR), this insurance comes from the perspective of the firm to save an amount (a payoff Call from the perspective of buyer):

$$\max(S_T-K,0) \tag{15.3.553}$$

also denoted by practitioners:

$$(S_T-K)^+ \tag{15.3.554}$$

in euros at maturity T (the traded price/rate being a maturity denoted by S_T obviously...). At any time, two major cases occur once for our Call buyer:

1. $S_t<K$: in this case, the Call gives the right to buy the underlying at the price K that we could buy cheaper on the market. In the case of our Call for the dollar/euro it would be better for the buyer to apply the exchange market rates rather than exercise him Call since otherwise he will have less euros for one dollar (that's why a Call has a zero intrinsic value in this situation at maturity). But we will lose the risk premium we paid to purchase Call and this risk premium has also to be taken into account before not exercising the Call.

   The reader most not forget that for European Options we only exercise at maturity. Therefore we don't write the condition $S_t<K$ but instead $S_T<K$.

---

[24] Remember that an option's premium is the sum of "intrinsic value" and "extrinsic value" (also known as "time value"). Intrinsic value is reflective of the actual value of the strike price versus the current market price. Extrinsic value is made up of time until expiration, implied volatility, dividends and interest rate risks.

2. $S_t > K$: in this situation, the Call gives us the possibility to purchase the underlying cheaper than the market price/rate. We probably will exercise that opportunity (the profit being the difference between the two prices plus we have to take into consideration the paid risk premium). In the case of our Call for the dollar/euro exchange we will exercise our right at the lower rates guaranteed by the Option contract ($\$1 = K$ EUR).

From the perspective of the counterparty (seller of the Call), in the situation (1) it does not pay anything to the buyer, and all is forgotten (the contract expires, any contractual relationship between the two parties disappear). In case (2), the vendor is assigned, it must sell to his counterparty the underlying at price K. If it does not hold this underlying, it must first buy it at a most expensive price on market (at the price $S_t > K$). However, in both cases the counterparty (seller of the Call) has get the cash of the risk premium per unit of Call (cash that will perhaps avoid it to loose to much money).

Thus, in the first case, the buyer and seller do not pay anything. In the second case, it is as if the buyer of the Call buy the underlying on the market and received at the same time the amount $S_t - K$ (for the seller it is obviously the reverse). So with these derivatives is the seller of the Call (or Put) which assumes almost all the market risk and of course the interest is quite high to neutralize this risk by using a mathematical formalism to determine the risk premium price (using typically the Black & Scholes model).

Let us see now an example of the investment perspective (risk-taking is evident in this example):

✍**Example:**

Imagine the case of a share which is currently worth $1,000$.- (regardless of the currency) and it is expected to increase by 12% in a year (typically what people expect on stock options plans).

Let us imagine also that an investor has the alternative of buying the stock at $1,000$.- or buy the corresponding Call option at exercise (strike) price of $1,000$.- (therefore assumed to be equal to the actual price of the share, which is not necessarily always the case in practice obviously...) for a premium of 40.- (remember that we will see later how to calculate risk premiums). Obviously, the investor can then for $1,000$.- buy 25 Call options rather than a single stock option if he wants but after he will have to find the money to but the 25 underlyings... (or found someone else that will buy them).

The question is to find the most interesting investment: Thus, an increase of 120.- on one year in the case of buying a share represents a return on investment of 12% per year, while the purchase of a Call option will have a return on investment 80.- (120.- gains on the sale price less the premium paid of 40.-) hence 200% of return!!!

It is clear from this example that the purchase of a Call with a same investment has a profitability significantly higher than the purchase of the underlying at least since the option risk premium does not exceed a certain threshold.

Now lets discuss in detail and with an example another major concept that we have already implicitly presented in the preceding paragraphs and that requires our attention because it is often mentioned by analysts! This is the "leverage effect" of Options that is a double-edged weapon or a portfolio mass destruction weapon (if leverage is not calculated in advance and even approximately)!!!

When we talk about the options, we often retain only the right to buy or sell a financial instrument (at a fixed price and during a given time), neglecting the obligation by the seller of the option. However, the leverage that characterizes these financial instruments can make this a devastating obligation for the seller.

Ok let us see more in detail what we are speaking about:

- First with the case of a Call:

  The buyer of a Call on a share (for example) limit its risk to the option risk premium price for unlimited earning potential. The seller of a Call is in exactly the opposite position: he is collecting the option risk premium price amount, but takes unlimited risks.

  As theoretical introduction... let us take the example of a share traded 350.- at the mid-October. An investor bets on the rising of the share and buys 12.50.- a Call option on it with a risk premium with a maturity to next year in January at the exercise price of 380.-. A graphical representation allows to easily show the relation between the evolution of the share price (on the x-axis) and its effect on the buyer or seller of the Call option.

  - Let us consider first the buyer of the Call:

    As long as the share price remains below 380.- ("leverage value"), exercise price, the buyer of the Call will have no interest in exercising his option, which is said as we already know "out of the money" (OTM). By cons, if the share price increased and exceeds the exercise price, the option is said to be as we also know "in the money" (ITM) and it becomes interesting to exercise the option. When the option exercise price is equal to the underlying price of the stock exchange, we say that the option is "at the money" (ATM) as we also already know. As soon as the share price exceeds 392.50.-, hence the sum of the exercise price and the option risk premium at the mid-October ($380+12.50$), the holder of the Call begins to earn money on his initial investment. If the share price rises suddenly to 500.-, an increase of just over 30%, the gain will be much more than proportional: for 12.50.- invested, the purchaser will realize a profit of 107.50.- a gain of 860%: this is the famous "leverage effect".

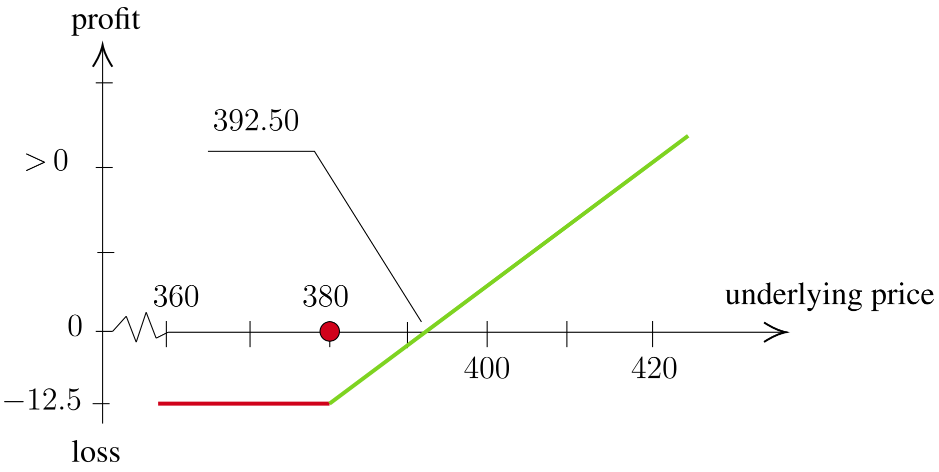

Figure 15.122: **Leverage effect for the buyer of a Call (simple Call payoff diagram)**

We can see above that the payoff of a Call from the buyer's point of view is a convex function (see section Functional Analysis page 2280).

- Let us consider now the seller of the Call:

  As the long as the share remains below 380.- ("leverage value" for recall...), the Call seller makes a profit of 12.50.- representing the option risk premium. Starting from 380.-, the seller may be obliged to deliver the share at the strike price, that is to say 380.-. Starting from 392.50.-, it starts to lose money on the transaction, since the share that he will undoubtedly have to deliver will worth be more expensive than the sum of the initial exercise price and of the option risk premium received. If unfortunately for him the share actually goes up to 500.- and he does not have the underlying, he will have to go buy it on stock market to honour the exercise request from the holder of the Call, loosing at the same time 107.50.- on the deal, thus more than eight times the premium received!!!!! With the leverage effect, it is possible to lose more than the risk premium received. We then say that we are experiencing a "margin call" and we better understand the importance to find an approximate martingale to evaluate the risk premium at its best.

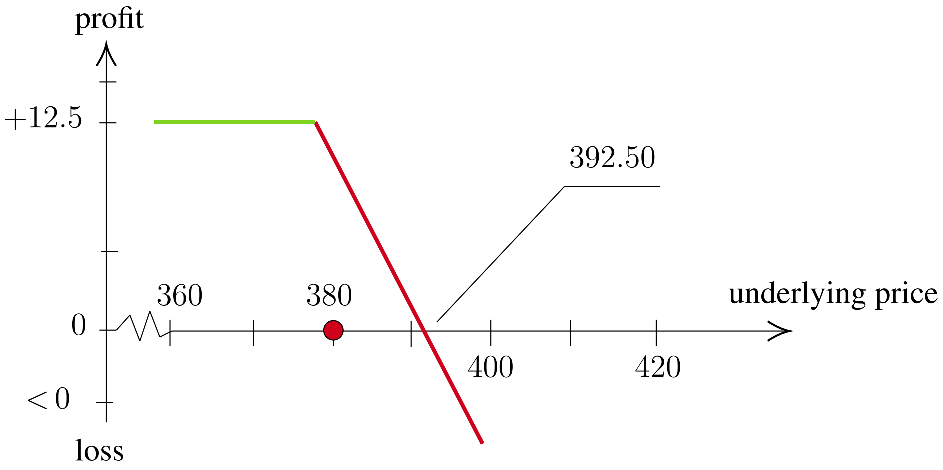

Figure 15.123: Leverage effect for the seller of a Call (simple Call payoff diagram)

We can see above that the payoff of a Call from the seller's point of view is a concave function (see section Functional Analysis page 2280).

Thus, if the underlying price increases of 3.29%, the seller of the Call loose 100%. We speak then of a leverage effect of 3.29 for 100 or more simply of a leverage corresponding to a ratio $100/3.29$ thus a leverage of about 30.39 (it is the same of course for the gain!).

- Second (and last) with the case of a Put:

  - Let us consider the buyer of the Put: The buyer of a Put limits its exposure to that of the cost of the option premium for a potential gain far more important. In front of him, the seller of the Put is in exactly the opposite position: he takes the option premium but takes a much greater risk. If we take the same share X traded at 350.- at mid-October, we are now with an investor that bets on the fall of the share price. So he buys for 49.50.- ("premium" price) the Put of maturity in December at an exercise price of 390.-.

The buyer of the Put begins to make a profit if the share price falls below 340.50.-, that is to say the strike price minus the option price $(390 - 49.50)$. Between 340.50.- and 390.- the option is not profitable but permits to reduce the loss. Above the at-the-money price (390.-) the exercise of the Put really offers no interest anymore and we say when then as we know that the Put option is out-the-money.

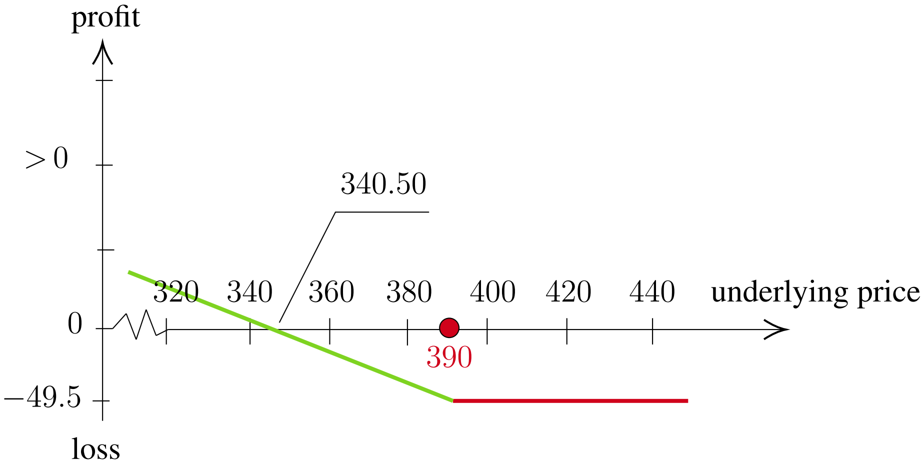

Figure 15.124: **Leverage effect for the buyer of a Put (simple Call payoff diagram)**

- Let us consider now the seller of the Put:

  The seller of the Put first get the cash of option premium that is to say 49.50.-. As long as the traded price remains above 390.- he is a winner. If the traded price of the option is between 340.50.- and 390.- and it loses some of its risk premium cash but he is still winning. Below 340.50.- the seller of the Put will be forced upon maturity to pay 390.- to the buyer of the Put (by selling the underlying and by paying the difference in one way or another). Obviously if the underlying price falls to zero, the seller of the Put may lose up 340.50.- of capital.

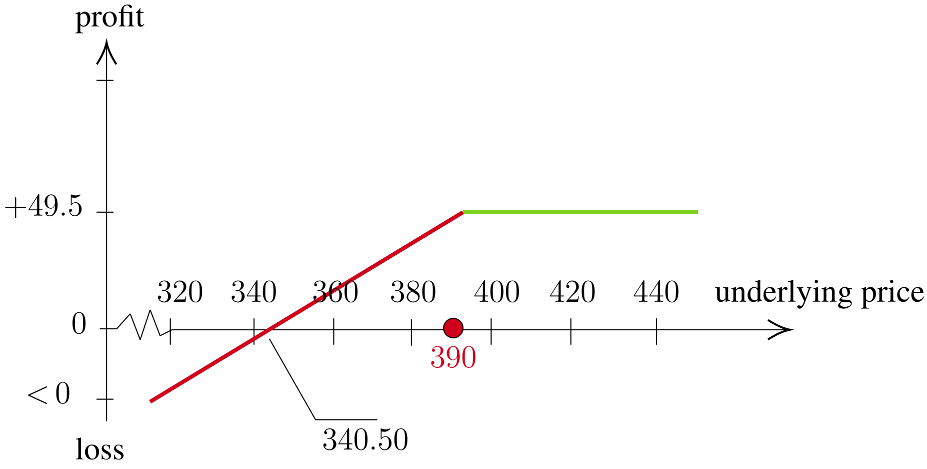

Figure 15.125: **Leverage effect for the seller of a Put (simple Call payoff diagram)**

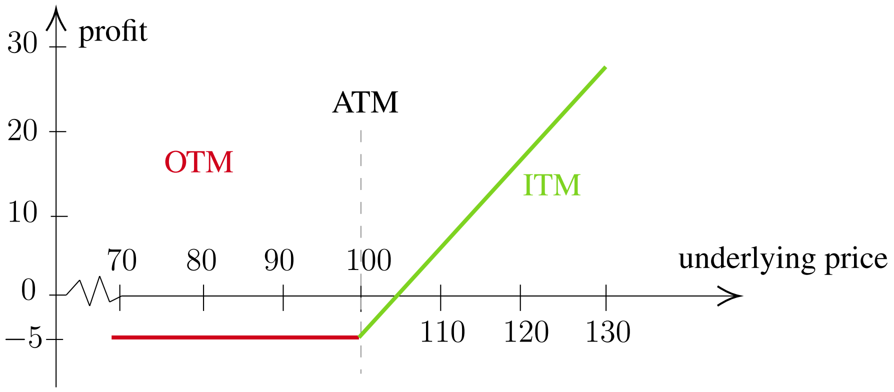
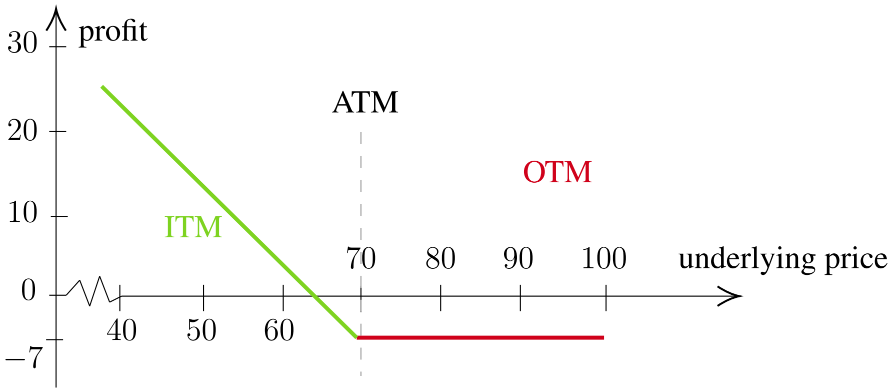
At the vocabulary level, here below is an excellent summary diagram (top buyer of a Call, down buyer of a Put) knowing that the "moneyness" is defined as the ratio between the price of the underlying S and the strike price K:





Moneyness	Call	Put
< 0.94	deep ITM	deep OTM
$0.94 - 0.97$	ITM	OTM
$0.97 - 1.00$	ATM	ATM
$1.00 - 1.03$	ATM	ATM
$1.03 - 1.06$	OTM	ITM
> 1.06	deep OTM	deep ITM

Table 15.49: **Basic vocabulary of a situation of option payoff (source:Fast Calibration in the Heston Model, BAUER Rudolf, p. 14)**

If we think for a moment, a possible strategy is to buy Put and Call of the same underlying with the same strike price and the same expiration date (maturity). This type of strategy is named a "straddle" or "straddle purchase" or "bottom straddle". We will study options strategies mixtures much further below in details.

Thus, if the traded price of the underlying is near the strike price K at the expiration date T then the straddle generates a net loss (as we will not use either the Put or Call and we will have lost the amount equivalent to the options premium). However, if the underlying price is quite far from the strike at maturity the profit can be very important!

This is pure speculation of investment banks derivatives strategies and this should be objectively prohibited... but let see anyway the principle through an example...

✍**Example:**

Let us consider an underlying that is traded actually 69.- will shift violently within three months. We can set up a straddle strategy by buying both a Call and a Put with strike of 70.- and maturity in 3 months. Let us suppose that the Call cost 4.- and the Put 3.-.

If at maturity, the underlying value is that of strike K, for the speculator it is the worst situation as it will have lost the sum of the two risk premiums, that is to say 7.- because he did not have any interest in exercising the Call using its Put (since there is no difference between the both).

If the underlying traded value remains at 69.- we lost 6.- because the Call has no value anymore at maturity (at least as it makes lose money it would be unwise for a pure speculator to exercise it) and the Put is only worth 1.- (as we will be able to sell at 70.- something that has a value of $69.-$ and it will make a small gain of 1.-). Therefore:

$$(-4+(-3))+1=-7+1=-6.- \tag{15.3.555}$$

If the price of the underlying rises to 90.- (or down to 50.-), we will realize a profit of 13.- thanks to the Put as:

$$(-4-3)+(90-70)=13.- \tag{15.3.556}$$

It is hoped that the speculator will bet correctly on a strong variation ignored by most of the market players, otherwise the option risk premiums will be obviously high enough that his gain will be anyway equal to zero! Graphically ... the Straddle strategy is often represented as follows (the vertical axis is the gain, the horizontal axis is the underlying price):

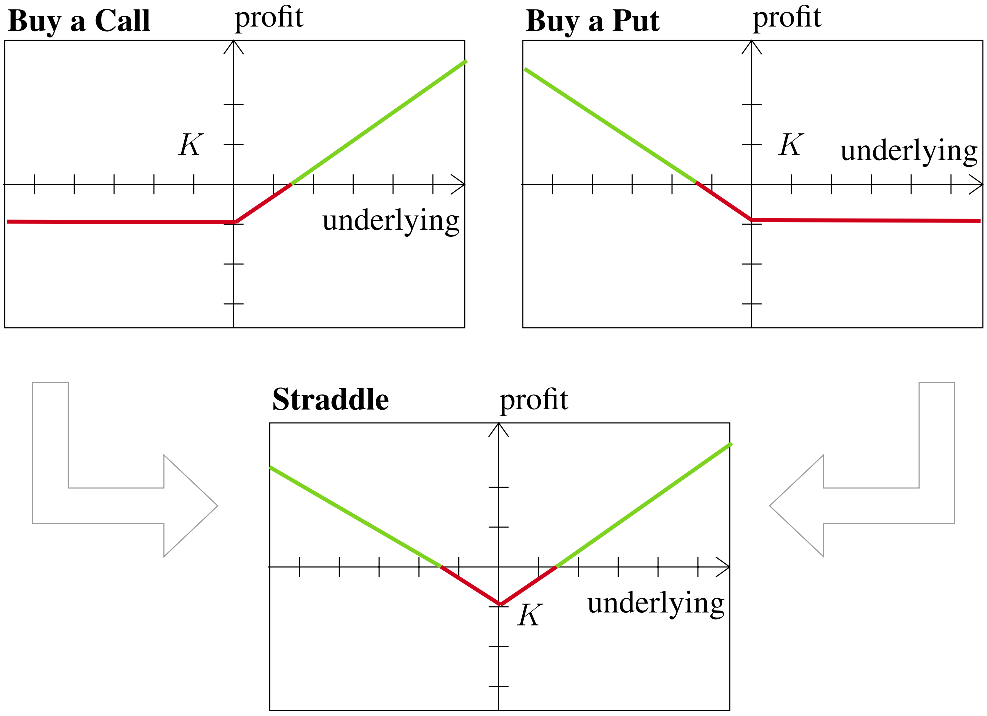


Figure 15.126: **Payoff diagram of a straddle strategy**

We can summarize these properties under the form of the following table:

Strategy	Trend anticipation	Potential Gain	Potential Loss	Profit curve
Buy a Call	upward trend (bullish trend)	"Illimited"	Limited	Buy a Put	falling trend (bearish trend)	Limited	Limited	Sell a Call	Stable or weakly bearish	Limited	"Illimited"	Sell a Put	Stable or weakly bullish	Limited	Limited	
Table 15.50: **Different elementary Call-Put strategies**

The "option plans", better known as the "stock option plans" or "employees stock option plan (ESOP)" are warrants (or Call Options) issued by packages (nominatives) for good employees of a company and have for purpose to strengthen the partnership of development between the same company and its employees. Thus, the latter on the acquisition of securities will be full-fledged stockholders receiving dividends and may participate in stockholders meetings. What is supposed to increase the motivation of the employees (...). This motivation is mainly done by the fact that the Warrants (also Call Options) that are given to employees will be very interesting to exercise if the company performs with them, and therefore the underlying price far exceeds the Exercise price of the Warrant. Thus, employees will exercise their Warrant and selling the underlying to get a profit (it is a common practice in USA for start-ups with limited financial resources in the beginning to hire specialists by offering warrants - like 10,000 warrants were distributed in the case of Microsoft later these employees became millionaires after the exercise of the Call they owned).

As we will see a little bit further below there is a huge difference between stock options and warrants relatively to the property of "dilution effect" and then we say that the warrant is not a "compensatory vehicles"!!!

15.3.10.3.5 Returns and Investments rates

To define the objective pursued by the owner of financial assets, we will refer to the economic motivation of any act of investing. This practice is to make currently an expense by expecting an increase of the asset in the future.

Of two or more investment strategies, the best at the individual level is the one that maximizes the final capital invested.

Then there exist different types of return rates on investment following the object of study. Thus, we differentiate in finance (before seeing the details):

1. The financial asset returns on a given economic horizon (return on investment) and their yield (rate of return, continuous or not, nominal or not).
2. The returns on investment compared to an average geometric rate of the market and the limit of the corresponding rate of return (internal rate of return).

Then we have to consider other rate of return approaches. Besides the two above-mentioned two other classics are portfolio management (before we see the details further below):

1. The "money weighted rate or return (M.W.R.R.)" for invested capital which has the advantage over the internal rate of return to take into account investments made outside the classical periods of time.
2. The "time of weighted rate of return (T.W.R.R.)" which is a useful tool for measuring the performance of fund managers because it does not take into account the flows (withdrawals or investment) of investors that are uncontrollable most of time.

Remark

We strongly recommend the reader to come back on the Capitalization and Actualization (see page 7547) subsection where we treat in details of: interest rates, nominal rates effective rates.

Let us see a bit all this in details:

15.3.10.3.5.1 Return on Investment (R.O.I.)

In practice, we will define the objective of the investor as of maximizing the growth of its initial fortune, whatever the modalities of this increase. This increase is named commonly "return on investment" (ROI) or, more briefly, just "return R" at time t and is defined by the (logical) following logical relation in the field of asset management by:

$$\boxed{R_t = (P_t - P_{t-1}) + C_t} \qquad (15.3.557)$$

where R_t is the return of the financial asset for the period (ending time) t, P_t the market price at time t of the financial asset and C_t the cash income attached to the holding of the financial assets during that same period (typically dividends). Obviously the practitioner must take care to take into account the various government taxes or trading fees when calculating this return, this is why when fees and taxes are not removed we speak rather of "total return"!

The income C_t is assumed to be received at time t, or, if it is perceived between time $t-1$ and t it is not supposed to be reinvested before time t (otherwise we must calculate it's future value). The market price P at time $t-1$ is a value "ex coupon" that is to say a value recorded immediately after the perception of the dividends. Empirically, the assumption of non-reinvestment until the elementary time period used is short (maximum one month) to avoid excessive statistical distortions in the treatment of historical data.

To facilitate comparisons between investment, we use a measure expressed in relative terms (as always) the "(short) rate of return" logically defined by:

$$\boxed{r_t = \frac{(P_t - P_{t-1}) + C_t}{P_{t-1}}} \qquad (15.3.558)$$

where r_t is the rate of return for period t.

The latter relation can also be found in the following form:

$$\text{TSR} = \frac{(P_1 - P_0) + D}{P_0} \qquad (15.3.559)$$

name the "total stock return" where P_1 is the initial stock price, P_0 the ending stock price (period 1), and D the dividends.

Never forget that we have proved in the section of Statistics that:

$$\mu_g < \mu_a \qquad (15.3.560)$$

ie the average long term period of return over-estimates the "real" average return given by the geometric mean (see section Statistics page 565)!

We will come back during our study of the mathematical model of asset pricing on these tools.

15.3.10.3.5.2 Internal Rate of Return (I.R.R.)

The use of a financial capital to enable the realization of real economic transactions (that is to say, devoting directly or indirectly, the financial capital for the acquisition or to build production tools, in the broadest sense of the term) can therefore produce over time positive or negative cash flows.

The actuarial calculus gives us the possibility to build a decision criterion to compare investments with different returns. Indeed, we define (logically but without being completely realistic) the risk-taking by the "net present value" as proved in the section of Quantitative Management (see page 8050):

$$\text{NPV}=\sum_{i=1}^{n}\frac{C_i}{(1+t\%)^i}+\frac{V_n}{(1+t\%)^n}-V_0 \tag{15.3.561}$$

where $t\%$ is supposed to be the risk free rate!

Obviously if there is no residual value this reduce to:

$$\boxed{\text{NPV}=\sum_{i=1}^{n}\frac{C_i}{(1+t\%)^i}-V_0} \tag{15.3.562}$$

where the C_i can sometimes be negative (intermediate investments). So the three decision criteria are for recall:

- $\text{NPV}<0$ corresponds to an investment that should be probably avoided
- $\text{NPV}=0$ then we are in front of an undecidable investment
- $\text{NPV}>0$ corresponds then probably to a good investment

Most of time the investor is interested to know in comparison to all its periodic investments and withdrawals (gains) what is the rate that cancels the NPV and after to compare this rate to that of the market risk free rate or some other portfolios or hedge funds rates. We know from our study on the section of Quantitative Management that this rate named "Internal Rate of Return" (IRR) is the average geometric rate (discount rate) $t\%$ such that it is the smallest positive root of the polynomial that satisfied:

$$\boxed{\text{NPV}=\sum_{i=1}^{n}\frac{C_i}{(1+t\%)^i}-V_0=0} \tag{15.3.563}$$

So if we consider that the smallest positive root of this polynomial equation is denoted IRR than for an initial investment V_0 and some wanted cash flows C_i, then if a banks offers us a given

TSR investment strategy (Total Stock Return) such that TSR $\geq$ IRR then we should probably consider this offer seriously.

We will see further below during our study of the Black & Scholes model much more sophisticated ways to consider investment strategies that are not purely deterministic as before but stochastic.

A firm's required rate of return on investments is often referred to as its "hurdle rate" because all projects must earn a rate of return high enough to clear this rate. Otherwise, a project will not cover its cost of financing, thereby reducing shareholder wealth.

15.3.10.3.5.3 Modified Internal Rate of Return (M.I.R.R.)

The "Modified Internal Rate of Return" (MIRR) is an empirical indicator for comparing financial flows with reinvestment. Even if the name seems to have a connection with the simple internal rate of return (IRR) seen earlier above it has almost nothing to do with it! The approach is totally different and the calculations of IRR and MIRR can give very different results.

Rather than theoretically speaking of this concept, a companion example is better than a thousand words.

Consider that a project is defined by the following flows:

Period	Cash Flow
0	$-1,000$
1	$-4,000$
2	$5,000$
3	$2,000$

To calculate the MIRR, we will assume that the borrowing rate (credit) is 10% and the risk-free rate of return of the market (potential reinvestment rate) is 12%.

We can then calculate what is the negative present value of the project:

$$\text{PV}_{\text{neg CF}}=-1000+\frac{-4000}{(1+10\%)^1}=-4,636.36.\text{-} \tag{15.3.564}$$

So far there is no difference with the usual implicit calculation in the calculation of the IRR through the NPV (Net Present Value). The previous sum of money therefore corresponds initially to the sum of money actually spent under the assumption that the first amount of $1,000$.- was already available in the form of a cash reserve and the second is a loan of $4,000$.- initiated at the beginning of the project and therefore the repayment is done at the end of the period relating to this loan (we can already see that it is therefore an extremely simplified scenario!).

On the other hand, for positive cash flows, the approach will be radically different to that of the NPV! We will not calculate their present value but their future value! It comes then (on the assumption that the analysis is done on the duration of the project only):

$$\text{FV}_{\text{pos CF}}=5000(1+12\%)^1+2000=7,600.00.\text{-} \tag{15.3.565}$$

This amount of money corresponds to the gain obtained if you had placed the positive cash flows in an investments with a return rate of 12% without risk (again it is super simplified because normally it is necessary to involve the probabilities and a given number of additional mathematical parameters...).

Once we have these two amounts of money $textPV_{\text{neg CF}}$ and $\text{FV}_{\text{pos CF}}$, then the idea of the MIRR, which then differs again considerably from that of the IRR, is to consider that the MIRR rate is empirically defined indirectly by:

$$\text{FV}_{\text{pos CF}} = |\text{PV}_{\text{neg CF}}|(1+\text{MIRR})^3 \tag{15.3.566}$$

Like the internal rate of return, the modified internal rate of return cannot be validly used to rank-order projects of different sizes, because a larger project with a smaller modified internal rate of return may have a higher present value. However, there exist variants of the modified internal rate of return which can be used for such comparisons.

Therefore with our companion example we get:

$$\text{MIRR} = \sqrt[3]{\frac{\text{FV}_{\text{pos CF}}}{|\text{PV}_{\text{neg CF}}|}} - 1 = \sqrt[3]{\frac{7,600}{|-4,636.36|}} - 1 \cong 17.91\% \tag{15.3.567}$$

Hence in Microsoft® Excel® 14.0.7106:

```
=MIRR({-1000,-4000,5000,2000},10%,12%)=17.91%
```

The general expression is:

$$\boxed{\text{MIRR} = \sqrt[n]{\frac{\text{FV}_{\text{pos CF}}}{|\text{PV}_{\text{neg CF}}|}} - 1} \tag{15.3.568}$$

Also denoted in different ways:

$$\text{MIRR} = \sqrt[n]{\frac{\text{FV}_{\text{CF+}}}{|\text{PV}_{\text{CF-}}|}} - 1 = \sqrt[n]{\frac{\text{Cash Inflows}}{|\text{Cash Outflows}|}} - 1 = \sqrt[n]{\frac{\text{Terminal cash flow}}{|\text{Outlay}|}} - 1 \tag{15.3.569}$$

Or even more explicit:

$$\text{MIRR} = \sqrt[n]{\frac{\text{FV(positive CF,reinvstment rate)}}{|\text{PV(negative CF, finance rate)}|}} - 1 = \sqrt[n]{\frac{\text{FV(positive CF,reinvstment rate)}}{-\text{PV(negative CF, finance rate)}}} - 1 \tag{15.3.570}$$

So in other words, the MIRR is the rate that corresponds to a capitalization during the periodic period of the project of the discounted (real) investment capital of the negative flows and which would yield the equivalent of the positive flows of the project.

15.3.10.3.5.4 Money Weighted Rate of Return (M.W.R.R.)

We will now introduce a kind of internal rate of return different the one related to NPV and that applies best to portfolio management (dynamics) than the internal rate of return see just before (for which we recall that one of the assumption is that cash flows are at periodic intervals).

Let us consider a fund F and the following information:

1. The value of the fund $F_0 \in \mathbb{R}^+$ just before time 0.
2. The value of the fund $F_1 \in \mathbb{R}^+$ just after the time 1.
3. A total net cash value $N \in \mathbb{R}$ invested during the period $[0,1]$ paid in two halves at the beginning and at end of period (to simplify the example ...).

The data that will interest us are:

1. The value:
$$F_0 + N/2$$
that represents the total value of the fund and part of the investment at time 0.
2. The value:
$$N/2(1+t\%)^{-1}$$
that represents the capital that we should have been gathering at time 0 to arrive at end of period to the value $N/2$ when the market free-risk rate is at $t\%$.
3. The value:
$$(1+t\%)^{-1}F_1$$
that represents at time 0 the value of the fund we would like to reach so we have at the end of period the value F_1 when the market free-risk rate is at $t\%$.

The difference:

$$(1+t\%)^{-1}F_1-(1+t\%)^{-1}\frac{N}{2}=(1+t\%)^{-1}\left(F_1-\frac{N}{2}\right) \tag{15.3.571}$$

gives the value that should have been capitalized to the get the sum $\left(F_1-\dfrac{N}{2}\right)$.

What is trivially interesting for an investor is then to know the rate $t\%$ such as the first investment equalizes its annual target. That is to say:

$$F_0+\frac{N}{2}=(1+t\%)^{-1}\left(F_1-\frac{N}{2}\right) \tag{15.3.572}$$

Hence after rearranging:

$$\boxed{F_0+\frac{N}{2}-(1+t\%)^{-1}\left(F_1-\frac{N}{2}\right)=0} \tag{15.3.573}$$

relationship is named "Hardy's relation".

If this relationship holds for F_0, N known and given F_1, an investor will have nothing to gain or to lose by investing in the fund or to capitalize at the market rate $t\%$.

If Hardy's relation is not equal to zero but positive then the investment in the fund is probably not interesting. If it is negative, then it is probably better to invest in the fund.

Using elementary algebra, this leads us to the relation:

$$F_0+\frac{N}{2}-(1+t\%)^{-1}\left(F_1-\frac{N}{2}\right)=0\Rightarrow t\%=\frac{2I}{F_0+F_1-I} \tag{15.3.574}$$

with:

$$I=F_1-F_0-N \tag{15.3.575}$$

Indeed:

$$t\%=\frac{F_1-\dfrac{N}{2}}{F_0+\dfrac{N}{2}}-1=\frac{F_1-\dfrac{N}{2}-F_0-\dfrac{N}{2}}{F_0+\dfrac{N}{2}}=\frac{2(F_1-F_0-N)}{2F_0+N}=\frac{2(F_1-F_0-N)}{F_0+F_1-(F_1-F_0-N)} \tag{15.3.576}$$

The rate $t\%$ is often named in fund management the "Money Weighted Rate of Return" (M.W.R.R.) or "Weighted Return Rate by Invested Capital" (W.R.R.I.C) and therefore represents the performance of a fund (portfolio) with consideration of inputs and outputs during the evaluation period.

Therefore the relation of money weighted rate of return that we got above:

$$\text{MWWR}=t\%=\frac{2I}{F_0+F_1-I} \tag{15.3.577}$$

can obviously also be written:

$$\text{MWWR}=\frac{F_1-F_0-N}{N/2} \tag{15.3.578}$$

And by changing the notation, as in some textbooks, this is rewritten:

$$\boxed{\text{MWWR}=\frac{V(T)-V(t_0)-F}{\bar{V}(t_0,T)}} \tag{15.3.579}$$

where F represents the net cash transactions recorded during the related time period (t_0,T); $V(t_0)$ the initial value of the fund; $V(T)$ the value of the fund at the end of the period of observation; $\bar{V}(t_0,T)$ the average capital the client has invested.

✍**Example:**

A fund had the following income during 12006 (holocene calendar):

- Value at 1 January 12006 (holocene calendar): 30 M$
- Investment in the fund during the year: 18 M$
- Withdrawals from the fund: 30 M$
- Value of the fund at 31 December 12006 (holocene calendar): 21 M$

and we want to know what is the effective rate (M.W.R.R.) of this fund in year 12006 (holocene calendar)?

We then as initial data $F_0 = 30$, $F_1 = 21$, $N = 18 - 30 = -12$ which gives if we accept the assumptions about N:

$$I = 21 - 30 - (-12) = 3 \tag{15.3.580}$$

and therefore:

$$\text{MWRR} = \frac{2 \cdot 3}{21 + 30 - 3} \cong 12.5\% \tag{15.3.581}$$

Let us consider now that we know that investments took place the $3/8$th part of the year and the withdrawals the $3/4$th part of the year.

The M.W.R.R. is then the rate of the following cash flows sequence ($C_i = (t, V_i)$):

$$\text{CF} = \{(0,30),(3/8,18),(3/4,-30),(1,21)\} \tag{15.3.582}$$

We must then find $t\%$ as:

$$30 = 21\left((1+t\%)^{-1} - 18(1+t\%)^{-3/8} + 30(1+t\%)^{-3/4}\right) \tag{15.3.583}$$

Solving this equation with Maple™ 4.00b gives:

$$\text{MWRR} = t\% = 8.875 \tag{15.3.584}$$

With a spreadsheet software like Microsoft® Excel® 14.0.7173 this is given by:

```
=XIRR(-30,-18,30,21,0,136.88,273.75,365)
```

We see that in considering the cash flow and the fractional times when they take place (thus more accurate and rigorous analysis) the M.W.R.R. is smaller. Moreover, the last calculation is more rigorous than the first, it is the latter that the investor want to know at the end of the year.

We see that from the above example in the more accurate M.W.R.R. example it comes that finally the M.W.R.R. is given by the $t\%$ that satisfies:

$$\boxed{F_0 = \sum_i \frac{\text{CF}_i}{(1+t\%)^{t/\Delta t}}} \tag{15.3.585}$$

This rate is therefore an effective measure of the increase funds rate, giving the impact of cash flow weight on the fund's value. It is therefore just a generalization of the I.R.R. (Internal Rate of Return).

Remark

In Switzerland, some insurance foundations of the LPP (Law of retirement provisions) communicate the annual or quarterly M.W.R.R. on the 5 to 10 past years.

15.3.10.3.5.5 Time Weighted Rate of Return (T.W.R.R.)

We will now discuss another financial tool for portfolio management also used to judge the performance of an investment.

Let us consider a fund such as (the years in the table below are given according to the holocene calendar):

	December 31 12000	**T1 12001**	**T2 12001**	**T3 12001**	**T4 12001**
Starting value of the fund		$1,000$.-	370.-	81.-	7.8.-
Profit or (loss) for the quarter in $\%$		10%	3%	-4%	6%
Profit or (loss) for the quarter (in .-)		100.-	11.1.-	-3.2.-	0.5.-
Quarterly cash flow Inflows/Outflows		-730.-	-300.-	-70.-	0.-
Fund value	$1,000$.-	370.-	81.1.-	7.8.-	8.3.-

Table 15.51: Time Weighted Rate Of Return

The 31 December 12000, the fund has a value of $1,000$.- value. During the first quarter T1 of 12001 it has a $+10\%$ return but we imagine that this value is far from what was expected, then the investor withdraws 730.- of the fund (portfolio based on the funds). During the second quarter T2, the fund gained $+3\%$ and an additional amount of 300.- were withdrawn of the fund by the investor. In the third quarter T3 the fund lost -4% and 70.- were removed from the fund. The last quarter T4, the fund gained $+6\%$ and no funds have been withdrawn.

We then have the overall increased (return) on the whole period (year) that is given by:

$$\text{TWRR} = (1+0.1)(1+0.03)(1-0.4)(1+0.06)-1 = 15.3\% \tag{15.3.586}$$

We see well that this value is independent of the cash flows of the investor's portfolio. We name the value of 15.3% the "Time Weighted Rate of Return" (T.W.R.R) on a quarterly basis.

In other words, the T.W.R.R. simply indicates the performance of a portfolio without taking into account the inflow and outflows during the evaluation period.

This specific case can be written generally as:

$$\boxed{\text{TWRR} = \prod_{i=1}^{n}(1+r_i)-1} \tag{15.3.587}$$

It should be remembered that if we wanted to calculate the average fund performance by quarter, we would have simply used the geometric mean (see section Statistics page 565)!

The T.W.R.R. is a practical tool to measure the performance of fund managers because it does not take into account the investors cash flows that are most of time uncontrollable. Thus, we have a measure of the quality of the dynamics of the fund independent of the choice of the investors that could consider withdrawals or investments and that would be used to calculate an I.R.R. which would more or less be meaningless compared to the dynamics of the fund.

Remark

In Switzerland, some insurance foundations of the LPP (Law of retirement provisions) communicate the annual or quarterly T.W.R.R. on the 5 to 10 past years but on a daily basis.

15.3.10.3.6 Theory of Speculation

After these many contextual definitions, the goal now is to introduce basic stochastic speculative mathematical techniques used in finance. Indeed, finance has become over time a domain increasingly competitive, the margins on standard products tend to be reduced, the premium is on innovation and automation. This has led to an increasing sophistication of financial products, thus making use of advanced mathematical concepts, primarily based on probability models introduced by Louis Bachelier in his *Theory of Speculation* (11900 according to holocene calendar) but really used massively in practice only since 11973 (holocene calendar) through different work of Black & Scholes and Merton (who have earned the Nobel Prize in economics).

Let us look to start what are the developments proposed by Louis Bachelier in his thesis to determine the predictive mathematical expectation and the estimated standard deviation of a financial asset (result that we will use as part of our study of the Black & Scholes evaluation model).

Let us denote by $p_{x,t}$ the probability density function of the price of an asset is traded x at time t. Therefore, the elementary cumulative probability that the current value lies within the elementary interval $[x, x + \mathrm{d}x]$ at time t is of the form:

$$p_{x,t}\mathrm{d}x \tag{15.3.588}$$

which integral on the whole domain of definition will have obviously to be equal to 1.

Under the fourth axiom of Probabilities (see section of the same name page 476), the elementary cumulative probability that the price moves of a certain value to another one (temporal Markov chain in continuous time), will be equal to the product of the density probability that value is traded x in a given time interval at the time t_1 that is to say:

$$p_{x,t_1}\mathrm{d}x \tag{15.3.589}$$

multiplied by the elementary cumulative probability that the price being treated at the value x at the time t_1, is traded z during a time interval $t_1 + t_1$, that is to say, multiplied by:

$$p_{z-x,t_2}\mathrm{d}z \tag{15.3.590}$$

The desired elementary cumulative probability is then obviously:

$$p_{x,t_1}p_{z-x,t_2}\mathrm{d}x\mathrm{d}z \tag{15.3.591}$$

This notation supposes that trading values are independent random variables...

As the traded value can be found at time t_1 in all the intervals $\mathrm{d}x$ included between $\pm\infty$, the cumulative probability that the traded value is z at the time $t_1 + t_2$ will be (the integration is relatively to $\mathrm{d}x$):

$$\int\limits_{-\infty}^{+\infty} p_{x,t_1}p_{z-x,t_2}\mathrm{d}z\mathrm{d}x \tag{15.3.592}$$

As the probability that the value z in the time interval t_1+t_2 has for expression:

$$p_{z,t_1+t_2}\mathrm{d}z \tag{15.3.593}$$

Then we have:

$$p_{z,t_1+t_2}\mathrm{d}z=\int\limits_{-\infty}^{+\infty} p_{x,t_1}p_{z-x,t_2}\mathrm{d}z\mathrm{d}x \tag{15.3.594}$$

or after simplification:

$$p_{z,t_1+t_2}=\int\limits_{-\infty}^{+\infty} p_{x,t_1}p_{z-x,t_2}\mathrm{d}x \tag{15.3.595}$$

Such is the equation that must satisfy the probability distribution function p that we seek. This equation is true, as we will see it, under some strong assumptions, by the function:

$$p(x,t)=Ae^{-B^2x^2} \tag{15.3.596}$$

But do not forget that this is a special solution (this why this model is sometimes named "Bachelier's Gaussian model") ... and nothing guarantees us that two independent random variables follow the same probability distribution...

The both assumptions to build the model seen so far (independence and identical distribution) are often indicated in finance under the name of "independence and stationary assumptions" and this is why the time variable does not appear anymore!

That said, we have then of course to require (probability axioms oblige!):

$$\int\limits_{-\infty}^{+\infty} p\mathrm{d}x=A\int\limits_{-\infty}^{+\infty} e^{-B^2x^2}\mathrm{d}x=1 \tag{15.3.597}$$

We recognize in the second term above the Gauss Integral that has for value (see section Statistics page 695):

$$A\int\limits_{-\infty}^{+\infty} e^{-B^2x^2}\mathrm{d}x=A\frac{\sqrt{\pi}}{B}=1 \tag{15.3.598}$$

We must therefore necessarily have for the normalization:

$$B=A\sqrt{\pi} \tag{15.3.599}$$

It results:

$$p(x,t)=Ae^{-\pi A^2x^2} \tag{15.3.600}$$

By putting $x=0$, we get $A=p_0$, that is to say that A equals the actual traded price.

We must now check that relation:

$$p(x,t)=p_0e^{-\pi p_0^2x^2} \tag{15.3.601}$$

satisfies well:

$$p_{z,t_1+t_2}=\int\limits_{-\infty}^{+\infty} p_{x,t_1}p_{z-x,t_2}\mathrm{d}x \tag{15.3.602}$$

under the given assumptions!!!!

Given the quantities p_1,p_2 the quantities corresponding to p_0 and relative to times t_1,t_2 then we must prove that the expression:

$$\int\limits_{-\infty}^{+\infty} p_1e^{-\pi p_1^2x^2}p_2e^{\pi p_2^2(z-x)^2}\mathrm{d}x \tag{15.3.603}$$

can be put under the form $Ae^{-B^2z^2}$ where A, B depends of the time!

This integral becomes by noting that z is not an integration variable (we assume that it is independent of x as you have understand from the beginning!):

$$p_1p_2e^{-\pi p_2^2z^2}\int\limits_{-\infty}^{+\infty} e^{-z(p_1^2+p_2^2)x^2+2\pi p_2^2zx}\mathrm{d}x \tag{15.3.604}$$

Now we will change the shape of the integral (we also change the exponential notation otherwise it becomes unreadable):

$$p_1p_2\exp\left(-\pi p_2^2z^2+\frac{\pi p_2^4z^2}{p_1^2+p_2^2}\right)\int\limits_{-\infty}^{+\infty}\exp\left(\pi\left(x\sqrt{p_1^2+p_2^2}-\frac{p_2^2z}{\sqrt{p_1^2+p_2^2}}\right)^2\right)\mathrm{d}x \tag{15.3.605}$$

and let us put:

$$x\sqrt{p_1^2+p_2^2}-\frac{p_2^2z}{\sqrt{p_1^2+p_2^2}}=u \tag{15.3.606}$$

Then we will have:

$$\frac{p_1p_2\exp\left(-\pi p_2^2z^2+\dfrac{\pi p_2^4z^2}{p_1^2+p_2^2}\right)}{\sqrt{p_1^2+p_2^2}}\int\limits_{-\infty}^{+\infty}e^{-\pi u^2}\mathrm{d}u \tag{15.3.607}$$

The integral:

$$\int\limits_{-\infty}^{+\infty}e^{-\pi u^2}\mathrm{d}u=2\int\limits_{0}^{+\infty}e^{-\pi u^2}\mathrm{d}u \tag{15.3.608}$$

having for value 1 we get finally:

$$\frac{p_1p_2\exp\left(-\pi p_2^2z^2+\dfrac{\pi p_2^4z^2}{p_1^2+p_2^2}\right)}{\sqrt{p_1^2+p_2^2}}=\frac{p_1p_2}{\sqrt{p_1^2+p_2^2}}\exp\left(\frac{-\pi p_1^2p_2^2}{p_1^2+p_2^2}z^2\right) \tag{15.3.609}$$

This expression has the desired shape since assuming $p_1 > 0, p_2 > 0$ a numerical integration gives:

$$\int_{-\infty}^{+\infty} \frac{p_1 p_2}{\sqrt{p_1^2+p_2^2}} \exp\left(\frac{-\pi p_1^2 p_2^2}{p_1^2+p_2^2} z^2\right) \mathrm{d}z = 1 \tag{15.3.610}$$

This relation expresses the fact that the total cumulative probability that the random variable z can take any value is equal to unity.

We must conclude that the probability that the asset is traded z at time $t_1 + t_2$ is expressed by the relation:

$$p = p_0 e^{-\pi p_0^2 x^2} = \frac{p_1 p_2}{\sqrt{p_1^2+p_2^2}} \exp\left(\frac{-\pi p_1^2 p_2^2}{p_1^2+p_2^2} z^2\right) \tag{15.3.611}$$

That can be written:

$$p = p_0 e^{-\pi p_0^2 x^2} = \frac{p_0(t_1) p_0(t_2)}{\sqrt{p_0^2(t_1)+p_0^2(t_2)}} \exp\left(\frac{-\pi p_0^2(t_1) p_0^2(t_2)}{p_0^2(t_1)+p_0^2(t_2)} z^2\right) \tag{15.3.612}$$

and this proves our initial hypothesis.

We see that the probability is then still governed by a Normal centered reduced distribution type (see section Statistics page 692)! This is a remarkable result obtained by Louis Bachelier in 11900 (holocene calendar) and which had already been speculated by Jules Regnault in the mid 119th century (holocene calendar)!

Indeed, Jules Regnault compared speculation to a heads or tail game in which the two sides of the coin correspond to the two possibilities, increase or decrease. Assuming that at any time whatsoever, there are never more chance for benefits than for loose. In other words, at each quote value, price has 50% chance of increasing and 50% of decreasing. But every trader has their opinion on the issue... Without this diversity of opinions, there would therefore no trades or price changes. So operators are divided into two groups (bullish, bearish) that make subjective assessments of the future value of the course which necessarily include a margin of error. However, to Jules Regnault, errors speculators are not any, they follow a Normal distribution. Indeed, as shown by Pierre Simon de Laplace, if the probability of error is small and there are numerous independent errors then the results follow a Normal distribution (see section Statistics page 692).

Figure 15.127: Yield distribution analysis in the Bloomberg$^{\text{TM}}$ terminal

The prior previous relations shows that the parameters $p_0=f(t)$ satisfy the functional relation:

$$f^2(t_1+t_2)=\frac{f^2(t_1)f^2(t_2)}{f^2(t_1)+f^2(t_2)} \qquad (15.3.613)$$

Let us differentiate relatively to t_1 and after relatively to t_2. The first member having the same shape in both cases, we get:

$$\begin{aligned}2f'(t_1)&=\mathrm{d}_{t_1}\left(\frac{f^2(t_1)f^2(t_2)}{f^2(t_1)+f^2(t_2)}\right)=\left(\frac{2f(t_1)}{f^2(t_1)+f^2(t_2)}-\frac{2f^3(t_1)}{(f^2(t_1)+f^2(t_2))^2}\right)f^2(t_2)\\ 2f'(t_2)&=\mathrm{d}_{t_2}\left(\frac{f^2(t_1)f^2(t_2)}{f^2(t_1)+f^2(t_2)}\right)=\left(\frac{2f(t_2)}{f^2(t_1)+f^2(t_2)}-\frac{2f^3(t_2)}{(f^2(t_1)+f^2(t_2))^2}\right)f^2(t_1)\end{aligned} \qquad (15.3.614)$$

So after simplification:

$$\left.\begin{aligned}f'(t_1)&=\frac{f(t_1)f^4(t_2)}{(f^2(t_1)+f^2(t_2))'2}\\ f'(t_2)&=\frac{f(t_2)f^4(t_1)}{(f^2(t_1)+f^2(t_2))'2}\end{aligned}\right\}\Rightarrow\frac{f(t_1)f^4(t_2)}{f'(t_1)}=\frac{f(t_2)f^4(t_1)}{f'(t_2)} \qquad (15.3.615)$$

Which finally gives:

$$\frac{f^3(t_2)}{f'(t_1)}=\frac{f^3(t_1)}{f'(t_2)} \qquad (15.3.616)$$

This relation being verified regardless the values of t_1,t_2, the common value of the two ratio is constant and then we have:

$$f'(t)=c^{te}f^3(t) \qquad (15.3.617)$$

A function that satisfies this relation exists and is:

$$f(t) = p_0 = \frac{H}{\sqrt{t}} \tag{15.3.618}$$

Where H denotes a constant or an independent function of time.

Verification:

$$f'(t) = -\frac{1}{2}\frac{H}{t^{3/2}} \qquad f^3(t) = \frac{H^3}{t^{3/2}} \tag{15.3.619}$$

therefore:

$$c^{te} = -\frac{1}{2H^2} \tag{15.3.620}$$

thus we have the final expression for the probability density function of the current traded value x under the above assumptions:

$$\boxed{p = \frac{H}{\sqrt{t}}e^{-\frac{\pi H^2 x^2}{t}} = \mathcal{N}\left(0, \frac{\sqrt{t}}{H\sqrt{2\pi}}\right) = \frac{1}{\sigma\sqrt{2\pi}}e^{-\frac{x^2}{2\sigma^2}} = \mathcal{N}(0,\sigma)} \tag{15.3.621}$$

with x that is for recall greater than or equal to 0.

The reader will have noticed perhaps that for a given value of H and t fixed we always have here as a centered Normal distribution (see section Statistics page 692)!! Financial analysts then say that we are dealing with a "wise chance", this implied that the changes are small and regular.

Let us now obviously calculate the mean and variance of this important distribution function (notice that these two moments should be dependent of time!).

As the traded value should not be negative (in most cases... because in practice we know that it happens very rarely!), we restrict the calculation to the positive mean as being (see section Statistics page 634):

$$\begin{aligned}\mu &= \int\limits_0^{+\infty} \frac{Hx}{\sqrt{t}}e^{-\frac{\pi H^2 x^2}{t}}\mathrm{d}x = \frac{H}{\sqrt{t}}\int\limits_0^{+\infty} xe^{-\frac{\pi H^2 x^2}{t}}\mathrm{d}x = \frac{H}{\sqrt{t}}\left(-\frac{t}{2\pi H^2}e^{\frac{\pi H^2 x^2}{t}}\right)\Bigg|_0^{+\infty} \\ &= \frac{H}{\sqrt{t}}\left(\left[0 - \left(-\frac{t}{2\pi H^2}\right)\right]\right) = \frac{t}{2\pi H^2}\frac{H}{\sqrt{t}} = \frac{\sqrt{t}}{2\pi H}\end{aligned} \tag{15.3.622}$$

by defining:

$$k = \frac{1}{2\pi H} \tag{15.3.623}$$

the "coefficient of instability" (of which we know nothing). So finally we have the positive mean of the traded value that is:

$$\boxed{\mu^+(t) = \int\limits_0^{+\infty} px\mathrm{d}x = k\sqrt{t}} \tag{15.3.624}$$

the expected mean of the traded value is therefore proportional to the square root of time like is the Brownian motion that we studied in the section of Statistical Mechanics (see page 3582)!!

It also follows immediately from this result that the average deviation of the current value at two consecutive times is also proportional to the square root of time between the two times!

We also notice that at the instant where $t=0$, the positive expected mean of the gain is zero, because the value is known with certitude (it is how it should be interpreted).

Let us also calculate the positive variance:

$$\mathrm{V}^{+}(x)=\int\limits_{0}^{+\infty}\frac{Hx^2}{\sqrt{t}}e^{-\frac{\pi H^2x^2}{t}}\mathrm{d}x=\frac{H}{\sqrt{t}}\int\limits_{0}^{+\infty}x^2e^{-\frac{\pi H^2x^2}{t}}\mathrm{d}x \tag{15.3.625}$$

We put:

$$z=\sqrt{\pi}tHx \tag{15.3.626}$$

Therefore:

$$x=\frac{1}{H}\sqrt{\frac{t}{\pi}}\Rightarrow x^2=z^2\frac{t}{H^2\pi} \tag{15.3.627}$$

with:

$$\frac{\mathrm{d}z}{\mathrm{d}x}=\sqrt{\frac{\pi}{t}}H \tag{15.3.628}$$

Therefore it comes:

$$\mathrm{V}^{+}(x)=\int\limits_{0}^{+\infty}\frac{Hx^2}{\sqrt{t}}e^{-\frac{\pi H^2x^2}{t}}\mathrm{d}x=\frac{H}{\sqrt{t}}\frac{1}{H}\sqrt{\frac{t}{\pi}}\frac{t}{H^2\pi}\int\limits_{0}^{+\infty}z^2e^{-z^2}\mathrm{d}z=\frac{t}{H^2\pi\sqrt{\pi}}\int\limits_{0}^{+\infty}z^2e^{-z^2}\mathrm{d}z \tag{15.3.629}$$

But in the section Statistics, we have proved by integration by parts (see section Differential and Integral Calculus page 1532) that:

$$\int\limits_{0}^{+\infty}z^2e^{-z^2}\mathrm{d}z=\left.\frac{-ze^{-z^2}}{2}\right|_{0}^{+\infty}+\int\limits_{0}^{+\infty}\frac{e^{-z^2}}{2}\mathrm{d}z=\frac{1}{2}\int\limits_{0}^{+\infty}e^{-z^2}\mathrm{d}z=\frac{1}{2}\sqrt{\frac{\pi}{4}}=\frac{\sqrt{\pi}}{4} \tag{15.3.630}$$

Thus:

$$\mathrm{V}^{+}(x)=\frac{t}{2H^2\pi\sqrt{\pi}}\frac{\sqrt{\pi}}{4}=\frac{t}{4H^2\pi} \tag{15.3.631}$$

So if we put:

$$K=\frac{1}{2H\sqrt{\pi}} \tag{15.3.632}$$

We have finally:

$$\boxed{\sigma^+ = \sqrt{\int\limits_0^{+\infty} px^2 \mathrm{d}x} = K\sqrt{t}} \tag{15.3.633}$$

Thus the standard deviation is also proportional to the square root of time (and the result would be the same if we had calculated the global standard deviation)!

Remark

The Brownian motion (and its variations) is heavily used by professionals, since many annualized volatility calculations (in % / year) which we find the results in any financial page of the daily press, are only the square root conversions time of periodic volatility calculations (in % / month or % / week) used as the basis of estimation.

Multiplying monthly Standard Deviation by the $\sqrt{12}$ is an industry standard method of approximating annualized Standard Deviations of Monthly Returns.

Therefore by the stability of the Normal law (see section Statistics page 710) we have:

$$\Delta p = \mathcal{N}\left(\mu_2 - \mu_1, \sqrt{\sigma_2^2 - \sigma_1^2}\right) = \mathcal{N}\left(0, \sqrt{\frac{t_2}{4\pi H^2} - \frac{t_1}{4\pi H^2}}\right) \tag{15.3.634}$$

It follows immediately that:

$$\sigma_{\Delta p} = \frac{1}{2H\sqrt{\pi}}\sqrt{\Delta t} \tag{15.3.635}$$

(the variance $\mathrm{V}(\Delta p) \propto \Delta t$ is sometimes named "quadratic variation" in stochastic finance) and:

$$\mu_{\Delta p} = \frac{\sqrt{t_2 - t_1}}{2\pi H} = \frac{1}{2\pi H}\sqrt{\Delta t} \tag{15.3.636}$$

So the traded price variations of a financial asset between two successive times have then obviously a probability distribution described by a Normal centered distribution (thus resulting by the stability property of this law) that is characterized by a positive expected mean and a positive standard deviation proportional to the square root of time!

This mathematically proved result was measured by Jules Regnault fifty years before Bachelier (~11850 according to holocene calendar) by observing that the standard deviation of French bonds was proportional to the square root of time.

That said we have to accept the limitations of this approach. Let us take for example the daily returns of the Dow Jones in 12008 and 12009 (holocene calendar). According to experts having the detailed of this data, it would follow rather follow a Student's T-distribution with 3 degrees of freedom rather than a Normal distribution...!

To give a blatant comparison of the limits of these approach let us remind (see section Statistics page 692) that the cumulative probability of a random variable following a Normal distribution beyond 4σ is $1-99.99366\%$, that is 0.00634%. This means, if the stock market has 252 open workdays, we have certainty of having a large deviation every:

$$\frac{1}{\dfrac{0.00634\%}{252}} \cong 63\,[\text{years}] \tag{15.3.637}$$

we therefore consider (see section Probabilities page 453) pairwise disjoint events.

Finally three major results are to be retained here under the strong assumptions of centered Normality and independence:

1. That the probability distribution function that the price of a financial asset to be x at time t follows a Normal centered distribution... (and hence can the price can go freely negative)!!
2. That positive expected mean and the positive standard-deviation of the value of a financial asset are proportional to the square root of time with a factor about which we don't know anything!!
3. That the expected mean gain is generally zero (which makes it unrealistic model but already provides a working basis...).

Much later below we will compare the Bachelier Call pricing Model and the Black & Scholes Call pricing model. But for this we need to know an assumption that did Bachelier crystallized in his famous dictum:

L'ésperance mathématique du spéculateur est nul

i.e. « *the mathematical expectation of a speculator is zero* ». Therefore as we assume a Normally distribution of the price and the standard deviation and the mean are proportional to the square root of time but that the mean is assumed as zero, we get:

$$\boxed{p=\mathcal{N}\left(0,\sigma\sqrt{t}\right)=\frac{1}{\sigma\sqrt{2\pi t}}e^{-\frac{x^2}{2\sigma^2 t}}} \tag{15.3.638}$$

and this is the relation we will have to use much later below.

Finally, it should be noted that this is a theoretical model...! It must therefore always be compared to real practical values to see if it is valid or not. In this case the observation of financial markets shows that it is only outside of the periods of speculative bubbles that the variations can be modelled by a Brownian motion. We must therefore look for more powerful models and we will see one day (...) that the Brownian movement (also named "Brownian process") that is smooth (continuous) and therefore without sudden jumps (therefore unable to model some sudden event markets like the crash or corrections) is a special case of "Lévy processes".

15.3.10.3.7 Portfolio efficient diversification models

Diversification is a well known way of reduce common known investment risks under the assumptions that the risk must be minimized and a given portfolio construction target is reached.

The most common efficient diversification refers to the organizing principle of portfolio theory, which attempts to maximize portfolio expected return for a given level of portfolio risk. In other words, having enough diversification in an investment portfolio to earn money, while still keeping risks within reasonable bounds.

Here is the definition given by the NASDAQ (`http://marketbusinessnews.com/financial-glossary/efficient-diversification/`) (it is not the best definition as we will see later with the various existing models that are not based only on highest return):

Definition (#15.3.691): "Efficient diversification" is the organizing principle of portfolio theory, which maintains that any risk-averse investor will search for the highest expected return for any particular level of portfolio risk.

There is quite a large number of others empirical models of portfolios diversification strategies. Among the best known (we tried to put them in the order in which they are normally taught at University:

1. Overall minimum variance portfolio (PVGM) also named Markowitz portfolio (see page 7699)
2. Tangent portfolio (TP) (see page 7755)
3. Minimum overall robust variance portfolio (MORVP)
4. Minimum overall robust semivariance portfolio (MORSVP)
5. Maximum Sharpe ratio portfolio (MSRP) (see page 7713)
6. Minimum Tracking error portfolio (MTEP) (see page 7733)
7. Identical weight portfolio (P1/N)
8. Treynor-Black weight portfolio (TBP) (see page 7735)
9. Zero Index portfolio (ZIP)
10. Neutral-Dollar portfolio (sum of weight zero) (NDP)
11. Single Average portfolio (SAP)
12. Time-Invariant Portfolio Protection (TIPP)
13. Zero Beta portfolio (ZBP)
14. Constant Proportion portfolio Insurance (CPPI)

15. Maximum utility portfolio (MUP)
16. Maximum diversification portfolio (MDP) (see page 7734)
17. Black-Litterman portfolio (BLP)
18. Draw-down portfolio (DDP)
19. Equal Risk Contribution optimal weights portfolio (ERC) (see page 7732)
20. Risk Parity portfolio (RPP) (see page 7738)
21. Minimum α-VaR portfolio (MVaRP) (see page 7872)
22. Minimum α-CVaR portfolio (MCVaRP)
23. ...

A number of practical and theoretical problems have limited the use of portfolio diversification models by investment managers. For example, it is often difficult to obtain sufficient high-quality historical data for thorough analysis. In addition, the efficient frontier where optimal portfolios lie tends to shift over time, quickly making these portfolios suboptimal.

For each of the model above we will start with the theoretical aspect and give afterwards a detailed example with Microsoft® Excel®, `R` or MATLAB® depending of what software is the more suited to the corresponding.

15.3.10.3.7.1 Overall minimum variance portfolio (Markowitz portfolio)

They are different approaches for introducing the Markowitz portfolio diversification model. We will start with the one using quadratic optimization.

Given R_p the performance of a portfolio of n assets characterized by their respective performance (return) $R_1, R_2, \ldots, R_n$. We put, as constraint, that each asset i enters the portfolio P in a proportion X_i such that:

$$\sum_{i=1}^{n} X_i = 1 \tag{15.3.639}$$

Remark

A part X_i of an asset may also be negative ... Hold a negative share of an asset is what is already known as being "short-selling" (short sale). This technique consists for recall to borrow a lot of assets (assumed overvalued on the market) to a bank, sell them to make the price of the asset go lower, make a profit by buying them cheaper to give them back to the bank (roughly it can be quite more complex and subtle in the reality but some organized group of people used this strategy to make some companies go bankrupt...).

Therefore the variance of the portfolio is given by (see section Statistics page 597) using the standard variance (we will see later that there is a model using "semivariance"):

$$\text{V}(R_P)=\sum_{i=1}^{n} X_i^2 \text{V}(R_i)+2\sum_{i,j|i<j} X_i X_j \text{cov}(R_i,R_j) \tag{15.3.640}$$

Before going further, let us precise (because it is important in practice!) that we can also write the last relation in matrix form (the reader can easily verify that by taking such two assets that both formulation give an identical result) if we denote by $\vec{X}$ the vector or the portions of assets and $\vec{X}^T$ the correspond transposed vector:

$$\vec{X}=\begin{pmatrix} X_1 \\ X_2 \\ \vdots \\ X_n \end{pmatrix} \qquad X^T=(X_1\, X_2\, \ldots X_n) \tag{15.3.641}$$

and finally c_{ij} is the covariance matrix (remember, that there exist a simple method to move from the covariance matrix to the correlation matrix and vice versa as seen in the section Statistics at page 604):

$$c_{ij}=\begin{bmatrix} \text{cov}(R_1,R_1) & \text{cov}(R_1,R_2) & \ldots & \text{cov}(R_1,R_n) \\ \text{cov}(R_2,R_1) & \text{cov}(R_2,R_2) & & \vdots \\ \vdots & & \ddots & \\ \text{cov}(R_n,R_1) & \ldots & & \text{cov}(R_n,R_n) \end{bmatrix} \tag{15.3.642}$$

Matrix that as we know (see section Statistics page 604) can be simplified directly in:

$$c_{ij}=\begin{bmatrix} \sigma_1^2 & \text{cov}(R_1,R_2) & \ldots & \text{cov}(R_1,R_n) \\ \text{cov}(R_2,R_1) & \sigma_2^2 & & \vdots \\ \vdots & & \ddots & \\ \text{cov}(R_n,R_1) & \ldots & & \sigma_n^2 \end{bmatrix} \tag{15.3.643}$$

we finally get the relation of the variance in condensed matrix form:

$$\boxed{\text{V}(R_P)=\vec{X}^T(c_{ij}\vec{X})} \tag{15.3.644}$$

as we often see it in the literature.

To come back to the algebraic form of the model, since the covariance is symmetric (see section Statistics page 604):

$$\text{cov}(R_i,R_j)=\text{cov}(R_j,R_i) \tag{15.3.645}$$

and that:

$$\text{cov}(R_j,R_j)=\text{V}(R_j) \tag{15.3.646}$$

We can simplify and write the variance:

$$\text{V}(R_P)=\sum_{i=1}^{n} X_i^2 \text{V}(R_i)+2\sum_{i,j|i<j} X_i X_j \text{cov}(R_i,R_j) \tag{15.3.647}$$

as following:

$$\boxed{\text{V}(R_P)=\sum_{i=1}^{n}\sum_{j=1}^{n}X_iX_j\text{cov}(R_i,R_j)} \qquad (15.3.648)$$

as we often see it in the literature of a few decades old...

Select a Markowitz portfolio is therefore equivalent as solving the following constraints under maximization problem:

$$\boxed{\begin{array}{ll}\underset{\text{V}(R_P)}{\text{minimize}} & \text{E}(R_P)=c^{te}\\ \text{subject to} & \sum X_i=1\end{array}} \qquad (15.3.649)$$

using quadratic programming (see section Numerical Methods page 6673) or the Lagrange multiplier method where we have detailed how to resolve this specific case (see section Numerical Methods page 6670).

Remark

The above formulation is also often denoted ($\vec{w}$ is the vector of weights and Σ is the variance-covariance matrix):

$$\begin{cases}\text{minimize} & \sigma_P^2(\vec{w}):\vec{w}^T\Sigma\vec{w}\\ \text{under const.} & \vec{w}^T\vec{\mu}=\mu_0\\ & \sum_i w_i=1\end{cases} \qquad (15.3.650)$$

also sometimes denoted:

$$\begin{cases}\text{minimize} & \sigma_P^2(\vec{w}):\vec{w}^T\Sigma\vec{w}\\ \text{under const.} & \vec{w}^T\vec{R}=R_p\\ & \mathbb{1}^T\vec{w}=1\end{cases} \qquad (15.3.651)$$

either that the investor seeks the vector $\vec{w}$ which minimizes his risk for a given expected return μ_0 (i.e. R_p).

Either reciprocally, opt for the search for $\vec{w}$ which maximizes the expected return of the portfolio given a maximum level of risk σ_0:

$$\begin{cases}\text{maximize} & \mu_P^2(\vec{w}):\vec{w}^T\vec{\mu}\\ \text{under const.} & \vec{w}^T\Sigma\vec{w}=\sigma_0\\ & \sum_i w_i=1\end{cases} \qquad (15.3.652)$$

In practice, we seek not one but all portfolios that for a given expected return minimize the variance! We then obtain a function of the mean return based on the variance for the optimal portfolios. If we plot it on a graph (see below). This function is often assimilated by financial practitioners (rightly!) to a frontier as specified in the following definition.

Definition (#15.3.692): The frontier that characterizes the polygon or the curve of constraints in this situation is named the "(Markowitz) efficient frontier" and in the polygon / curve occur all portfolios to reject that are so named "dominated portfolios". Another way of stating this is to say that the combinations of (performance, risk) of this frontier form an optimum set of Pareto (see section Game and Decision Theory page 7394), that is to say, if one of the elements increases, the other must also increase.

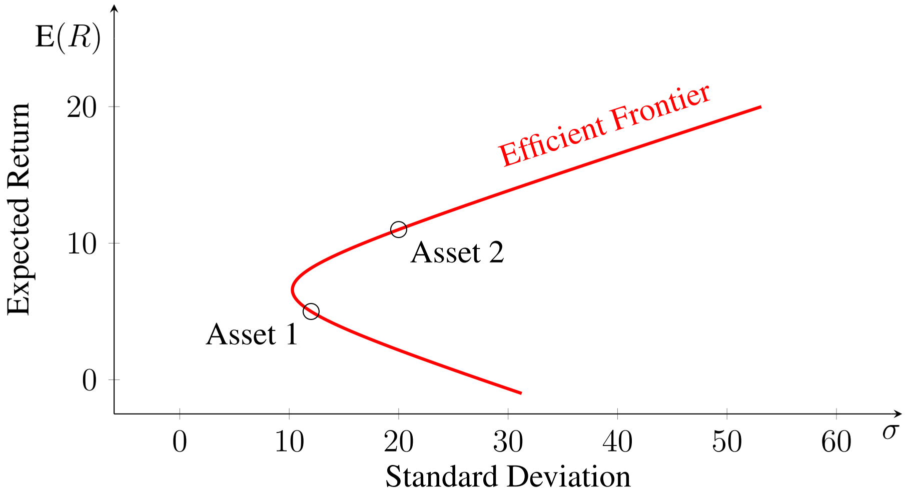

Figure 15.128: **Efficient Frontier**

Now let us formalize the optimization in the way that was done in the days when people had to further develop the algorithms themselves...

Given Z the aforementioned economic function:

$$Z = \Phi \mathrm{E}(R_P) - \mathrm{V}(R_P) \tag{15.3.653}$$

which should be maximized under the constraint $\sum_{i=1}^{n} X_i = 1$ and where Φ is a parameter that represents the degree of risk aversion of investors (in the standardize the relation units...).

The problem of maximization under constraints to determine the maximum of the economic function Z is defined by:

$$Z = \Phi \sum_{i=1}^{n} X_i \mathrm{E}(R_i) - \sum_{i=1}^{n}\sum_{j=1}^{n} X_i X_j \mathrm{cov}(R_i, R_j) + \lambda \left(1 - \sum_{i=1}^{n} X_i\right) \tag{15.3.654}$$

This function of $n+1$ variables $(X_1, X_2, \ldots, X_n, \lambda)$ is maximized if its derivative (partial derivative) from each of these variables is zero, which is to put the following system:

$$\begin{cases} \dfrac{\partial Z}{\partial X_1} = \Phi \mathrm{E}(R_1) - 2X_1\mathrm{cov}(R_1, R_1) - 2X_2\mathrm{cov}(R_1, R_2) - \ldots - 2X_n cov(R_1, R_n) - \lambda = 0 \\ \dfrac{\partial Z}{\partial X_2} = \Phi \mathrm{E}(R_2) - 2X_2\mathrm{cov}(R_2, R_1) - 2X_2\mathrm{cov}(R_2, R_2) - \ldots - 2X_n\mathrm{cov}(R_2, R_n) - \lambda = 0 \\ \ldots \\ \dfrac{\partial Z}{\partial X_n} = \Phi \mathrm{E}(R_n) - 2X_1\mathrm{cov}(R_n, R_1) - 2X_2\mathrm{cov}(R_n, R_2) - \ldots - 2X_n\mathrm{cov}(R_n, R_n) - \lambda = 0 \\ \dfrac{\partial Z}{\partial \lambda} = 1 - X_1 - X_2 - \ldots - X_n = 0 \end{cases} \tag{15.3.655}$$

Let us put:

$$\text{cov}(R_i,R_j)=\sigma_{ij} \tag{15.3.656}$$

Then we can write:

$$\begin{cases} 2X_1\sigma_{11}+2X_2\sigma_{12}+\ldots+2X_n\sigma_{1n}+\lambda=\Phi\text{E}(R_1) \\ 2X_2\sigma_{21}+2X_2\sigma_{22}+\ldots+2X_n\sigma_{2n}+\lambda=\Phi\text{E}(R_2) \\ \ldots \\ 2X_1\sigma_{n1}+2X_2\sigma_{n2}+\ldots+2X_n\sigma_{nn}+\lambda=\Phi\text{E}(R_n) \\ X_1+X_2+\ldots+X_n=1 \end{cases} \tag{15.3.657}$$

or in matrix form:

$$\begin{bmatrix} 2\sigma_{11} & 2\sigma_{12} & \ldots & 2\sigma_{1n} & 1 \\ 2\sigma_{21} & 2\sigma_{22} & \ldots & 2\sigma_{2n} & 1 \\ \ldots & & \ldots & \ldots & 1 \\ 2\sigma_{n1} & 2\sigma_{n2} & \ldots & 2\sigma_{nn} & 1 \\ 1 & 1 & \ldots & 1 & 0 \end{bmatrix} \begin{pmatrix} X_1 \\ X_2 \\ \ldots \\ X_n \\ \lambda \end{pmatrix} = \begin{pmatrix} \Phi\text{E}(R_1) \\ \Phi\text{E}(R_2) \\ \ldots \\ \Phi\text{E}(R_n) \\ 1 \end{pmatrix} \tag{15.3.658}$$

And we will put now:

$$A=\begin{bmatrix} 2\sigma_{11} & 2\sigma_{12} & \ldots & 2\sigma_{1n} & 1 \\ 2\sigma_{21} & 2\sigma_{22} & \ldots & 2\sigma_{2n} & 1 \\ \ldots & & \ldots & \ldots & 1 \\ 2\sigma_{n1} & 2\sigma_{n2} & \ldots & 2\sigma_{nn} & 1 \\ 1 & 1 & \ldots & 1 & 0 \end{bmatrix} \qquad B=\begin{pmatrix} \Phi\text{E}(R_1) \\ \Phi\text{E}(R_2) \\ \ldots \\ \Phi\text{E}(R_n) \\ 1 \end{pmatrix} \qquad X=\begin{pmatrix} X_1 \\ X_2 \\ \ldots \\ X_n \\ \lambda \end{pmatrix} \tag{15.3.659}$$

In this case, the system of equations to solve can be summarized in matrix form as:

$$AX=B \tag{15.3.660}$$

Therefore:

$$X=A^{-1}B \tag{15.3.661}$$

Determining the weight of each of the n assets that enter into the composition of a portfolio thus requires inversion of a square matrix of $n+1$ rows and $n+1$ columns having $(n^2-n)/2$ covariances (the diagonal having variances only and the matrix being symmetrical!). What is relatively long to calculate for large portfolios.

However, even once the weighting of assets is completed, the problem itself is not completely finished. Indeed, we can find the efficient frontier but the customer (investor) will impose a logic constraint relatively to the zero risk level of its portfolio and of the ratio return/maximum risk.

Given the heavy calculations required for the inversion of the matrix A, William F. has proposed a simplified model that we will see after a practical example of the Markowitz model.

✍**Example:**

Let us consider three assets entering a portfolio composition at the same time in equal proportions and n of their return observations (without missing values) R_{ij} entered in Microsoft® Excel® 14.0.7173 (the component j can be seen as a time period):

	A	B	C	D
1	Obs.	Asset 1	Asset 2	Asset 3
2	1	-0.15	0.29	0.38
3	2	0.05	0.18	0.63
4	3	-0.43	0.24	0.46
5	4	0.79	0.25	0.36
6	5	0.32	0.17	-0.57

Figure 15.129: Initial observed values of our portfolio assets

The goal will be now using the native tools of this spreadsheet software to determine the Markowitz portfolio efficiency frontier model and the C.M.L. (see definition and mathematical details further below) and the corresponding weight of assets (optimal weights) that minimizes the variance for a given expected mean of the return knowing the risk-free market rate R_f is equal to 0.22.

Below the table given above we will create in Microsoft® Excel® the list containing the proportions X_i of the assets (which we assume equidistributed at the beginning such that each weight is equal to $1/3$), we will display the average short return μ_i of each asset calculated using the estimator[a]:

$$\text{E}(R_i)=\hat{\mu}_i=\frac{\displaystyle\sum_{j=1}^{n}R_{ij}}{n}=\begin{cases}\texttt{=AVERAGE(B2:B6)}\\ \texttt{=AVERAGE(C2:C6)}\\ \texttt{=AVERAGE(D2:D6)}\end{cases}\tag{15.3.662}$$

and the variance σ_i^2 calculated for each asset of the estimator (we could also take the semivariance but this is another subject...):

$$\text{V}(R_i)=\hat{\sigma}_i^2=\frac{\displaystyle\sum_{j=1}^{n}(R_{ij}-\hat{\mu}_i)^2}{n-1}=\begin{cases}\texttt{=VAR(B2:B6)}\\ \texttt{=VAR(C2:C6)}\\ \texttt{=VAR(D2:D6)}\end{cases}\tag{15.3.663}$$

This gives us the following list in Microsoft® Excel® 14.07.7173:

	A	B	C	D
13		**Asset 1**	**Asset 2**	**Asset 3**
14	X_i	1/3	1/3	1/3
15	$\hat{\mu}_i$	0.116	0.226	0.252
16	$\hat{\sigma}_i^2$	0.21728	0.00253	0.22247

Figure 15.130: **Proportions and expected mean/variance estimators of 3 assets**

Thus explicitly:

	A	B	C	D
13		**Asset 1**	**Asset 2**	**Asset 3**
14	X_i	0.333333333333333	0.333333333333333	0.333333333333333
15	$\hat{\mu}_i$	=AVERAGE(B2:B6)	=AVERAGE(C2:C6)	=AVERAGE(D2:D6)
16	$\hat{\sigma}_i^2$	=VAR.S(B2:B6)	=VAR.S(C2:C6)	=VAR.S(D2:D6)

Figure 15.131: **Explicit Proportions and expected mean/variance estimators of 3 assets in Microsoft® Excel® 14.07.7173**

We must now calculate the average return of the portfolio as given by:

$$\text{E}(R_P)=\sum_{i=1}^{n} X_i R_i = X_1\hat{\mu}_1+X_2\hat{\mu}_2+X_3\hat{\mu}_3 \tag{15.3.664}$$

This relation is a bit long to enter in a spreadsheet software as it is, and will be even more if we have a much larger number of assets.

In our case, it is the sum of the products term by term of two cell ranges (X_i and $\hat{\mu}_i$) having the same dimensions (same number of rows and the same number of columns). We can then use the following function in the in Microsoft® Excel® 14.0.7173:

`=SOMMEPROD(B14:D14,B15:D15)`

For the portfolio the variance is a little bit more complicated since we have to calculate:

$$\begin{aligned}\text{V}(R_P)=\sigma^2(R_P)&=\sum_{i=1}^{n} X_i^2\text{V}(R_i)+2\sum_{i,j\mid i<j} X_iX_j\text{cov}(R_i,R_j)\\ &=\sum_{i=1}^{n} X_i^2\sigma_i^2+2\sum_{i,j\mid i<j} X_iX_j\text{cov}(R_i,R_j)\end{aligned} \tag{15.3.665}$$

The relation developed in our special case gives:

$$\begin{aligned}\sigma^2(R_P)=X_1^2\sigma_1^2+X_2^2\sigma_2^2+X_3^2\sigma_3^2+2X_1X_2\text{cov}(R_1,R_2)\\ +2X_1X_3\text{cov}(R_1,R_3)+2X_2X_3\text{cov}(R_2,R_3)\end{aligned} \tag{15.3.666}$$

The trick to apply this in a spreadsheet like Microsoft® Excel® is to use linear algebra and write this relationship in matrix form as we have proved it earlier above:

$$\sigma^2(R_P) = X^T c_{ij} X \tag{15.3.667}$$

Which is equivalent to write in Microsoft® Excel® 14.0.:

`=SUMPROD(MMULT(B14:D14,G14:I16),B14:D14)`

Either in explicit matrix form:

$$\sigma^2(R_P) = (X_1\; X_2\; X_3) \begin{bmatrix} \sigma_1^2 & \text{cov}(R_2,R_1) & \text{cov}(R_3,R_1) \\ \text{cov}(R_1,R_2) & \sigma_2^2 & \text{cov}(R_3,R_2) \\ \text{cov}(R_1,R_3) & \text{cov}(R_2,R_3) & \sigma_3^2 \end{bmatrix} \begin{pmatrix} X_1 \\ X_2 \\ X_3 \end{pmatrix} \tag{15.3.668}$$

Based on the above tables, it is simple in Microsoft® Excel® to obtain the covariance matrix (in practice it is often considered as difficult to get a robust estimate of the covariance matrix and there are various techniques for this purpose):

	F	G	H	I
13	$c_{i,j}$	Asset 1	Asset 2	Asset 3
14	Asset 1	0.21728	-0.00422	-0.06687
15	Asset 2	-0.00422	0.00253	0.01059
16	Asset 3	-0.06687	0.01059	0.22247

Figure 15.132: Covariance matrix of our 3 assets

Thus explicitly (the covariance matrix is symmetrical for recall... as seen in the section Statistics at page 604):

	F	G	H	I
13	$c_{i,j}$	Asset 1	Asset 2	Asset 3
14	Asset 1	=VAR.S(B2:B6)	=G15	=G16
15	Asset 2	=COVARIANCE.S(B2:B6,C2:C6)	=VAR.S(C2:C6)	=H16
16	Asset 3	=COVARIANCE.S(B2:B6,D2:D6)	=COVARIANCE.S(C2:C6,D2:D6)	=VAR.S(D2:D6)

Figure 15.133: Explicit Covariance matrix of our 3 assets in Microsoft® Excel® 14.07.7173

And for the expected mean and variance of the portfolio we have the following table:

	A	B
19		Portfolio
20	$E(R_p)$	0.1980
21	$\sigma^2(R_p)$	0.035698

Figure 15.134: Portfolio Mean and Variance estimators

thus applying the above relations:

	A	B
19		**Portfolio**
20	$E(R_p)$	=SUMPRODUCT(B14:D14,B15:D15)
21	$\sigma^2(R_p)$	=SUMPRODUCT(MMULT(B14:D14,G14:I16),B14:D14)

Figure 15.135: Explicit Portfolio Mean and Variance estimators in Microsoft® Excel® 14.07.7173

The problem now is to determine for a given fixed return of the portfolio (cell `B20`), the different proportions X_i of the asset that minimize the risk.

After having added the both cells `B24` (expected return of the portfolio) and `B25` (total number of proportions of assets):

	A	B
24	Expected return:	0.200
25	Sum of weights:	1.00

We must now solve the non-linear optimization problem:

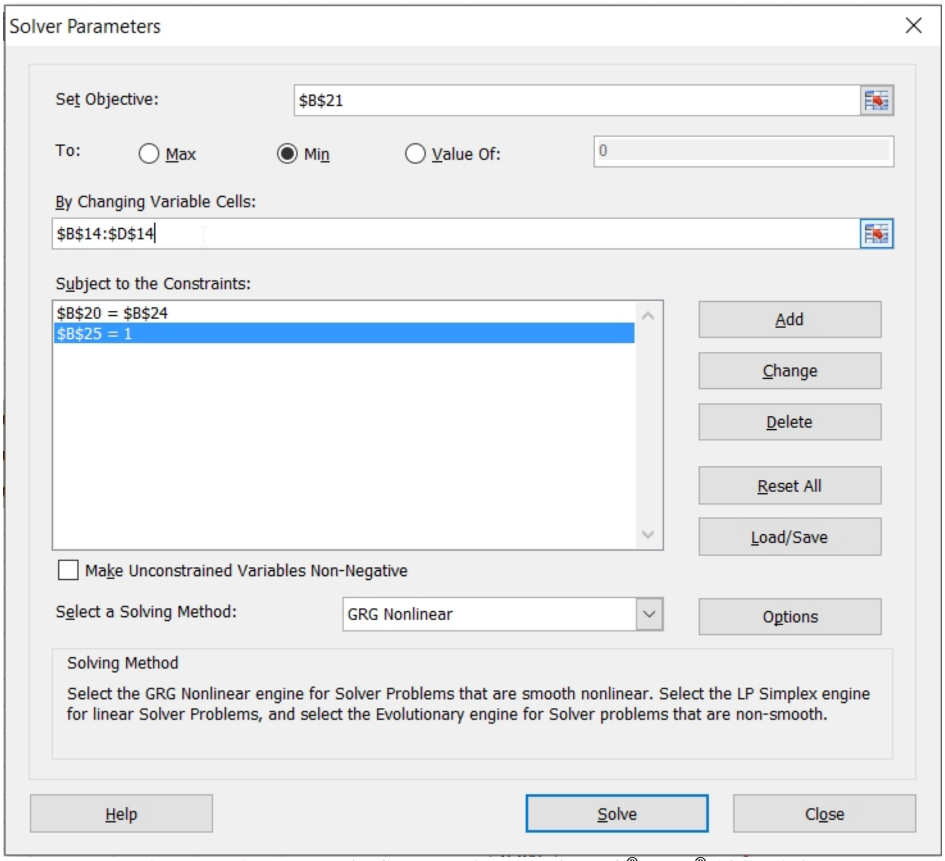
$$\begin{aligned} &\underset{\sigma^2(R_P)}{\text{minimize}} && \mathrm{E}(R_P)=0.2 \\ &\text{subject to} && \sum X_i = 1 \end{aligned} \tag{15.3.669}$$

A global view of our sheet gives so far:

	A	B	C	D	E	F	G	H	I
1	Obs.	Asset 1	Asset 2	Asset 3					
2	1	-0.15	0.29	0.38					
3	2	0.05	0.18	0.63					
4	3	-0.43	0.24	0.46					
5	4	0.79	0.25	0.36					
6	5	0.32	0.17	-0.57					
7									
8									
9									
10									
11									
12									
13		Asset 1	Asset 2	Asset 3		$c_{i,j}$	Asset 1	Asset 2	Asset 3
14	X_i	1/3	1/3	1/3		Asset 1	0.21728	-0.00422	-0.06687
15	$\hat{\mu}_i$	0.116	0.226	0.252		Asset 2	-0.00422	0.00253	0.01059
16	$\hat{\sigma}_i^2$	0.21728	0.00253	0.22247		Asset 3	-0.06687	0.01059	0.22247
17									
18									
19		Portfolio							
20	$E(R_p)$	0.1980							
21	$\sigma^2(R_p)$	0.035698							
22									
23									
24	Expected return:	0.200							
25	Sum of weights:	1.00							

Figure 15.136: Markowitz manual resolution configuration in Microsoft® Excel® 14.07.7173

And now we launch the solver:



Solver Parameters

Set Objective: `$B$21`

To: ○ Max ● Min ○ Value Of: 0

By Changing Variable Cells: `$B$14:$D$14`

Subject to the Constraints:

`$B$20 = $B$24`
`$B$25 = 1`

☐ Make Unconstrained Variables Non-Negative

Select a Solving Method: GRG Nonlinear

Solving Method

Select the GRG Nonlinear engine for Solver Problems that are smooth nonlinear. Select the LP Simplex engine for linear Solver Problems, and select the Evolutionary engine for Solver problems that are non-smooth.

Figure 15.137: Markowitz Solver settings in Microsoft® Excel® 14.07.7173

This gives us straight for solution (the same as the one given by R 3.0.2 as the reader can check it in the corresponding companion book):

	A	B	C	D
13		Asset 1	Asset 2	Asset 3
14	X_i	0.2331	0.7805	-0.0137
15	$\hat{\mu}_i$	0.116	0.226	0.252
16	$\hat{\sigma}_i^2$	0.21728	0.00253	0.22247
17				
18				
19		Portfolio		
20	$E(R_p)$	0.2000		
21	$\sigma^2(R_p)$	0.012057		

Now to determine the efficient Markowitz frontier we report manually (or with VBA) for different values of the target mean, the corresponding minimum variance. That gives us the following list:

	L	M	N	O	P
3	**Efficient Frontier**				
4	**Iteration**	**Variance**	**Return**	**Standard Deviation**	***Ratio de Sharpe***
5	1	0.010770	0.200	0.103778	0.000000
6	2	0.008214	0.205	0.090628	0.055170
7	3	0.005307	0.210	0.072850	0.137269
8	4	0.003338	0.215	0.057771	0.205903
9	5	0.002305	0.220	0.048008	0.416594
10	6	0.002209	0.225	0.046999	0.531922
11	7	0.003050	0.230	0.055227	0.543221
12	8	0.004828	0.235	0.069484	0.503726
13	9	0.007542	0.240	0.086847	0.460578
14	10	0.011194	0.245	0.105802	0.425324

Figure 15.138: Markowitz efficient frontier values samples

This gives us the following $\text{E}(R_P)=f(\sigma_{R_p})$ plot:

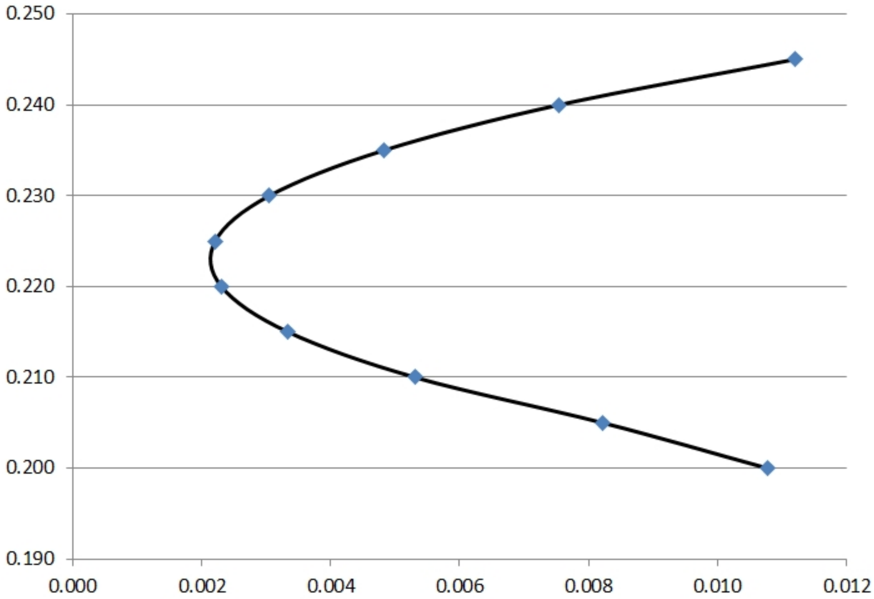


Figure 15.139: Markowitz efficient frontier plot in Microsoft® Excel® 14.07.7173

If the reader refers to our `R` companions book, the equivalent result for the efficient frontier (EWP: Equally Weighted Portfolio) is:

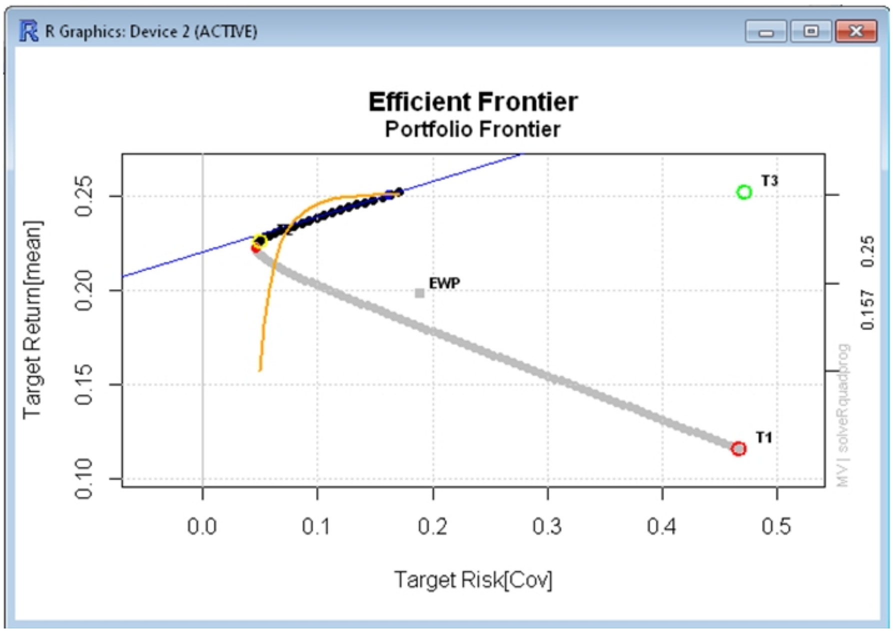

Figure 15.140: Markowitz efficient frontier plot in R 3.0.2

Or still with R always by following the step given in the companion book we can plot the evolution of the return and risk in function of the weights:

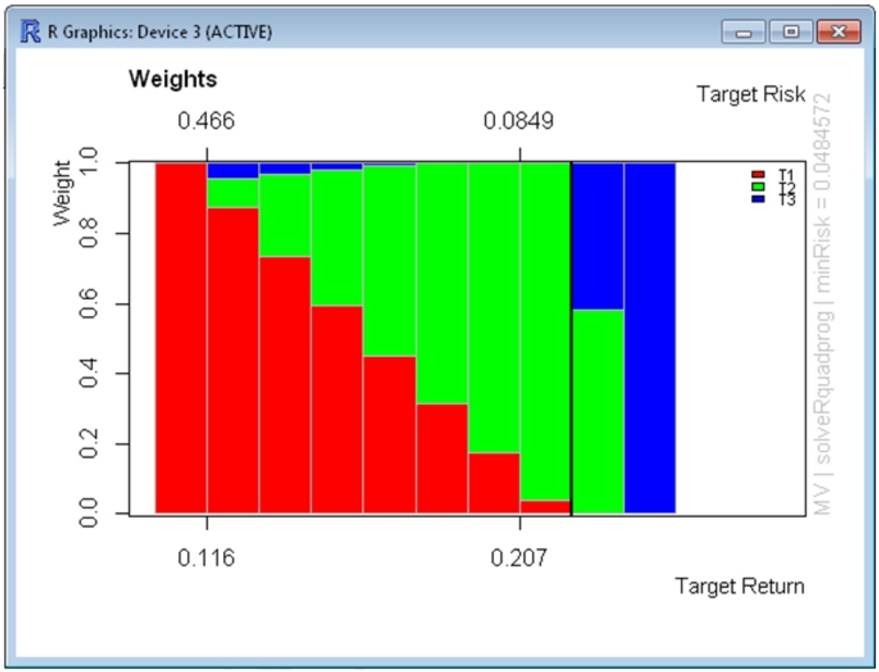

Figure 15.141: Markowitz asset weight plot in R 3.0.2

We will not this time give the results obtained with MATLAB® as the output of that latter are plotted in quite an awful way... (but the reader can see the corresponding companion book where there are given!).

---

[a] Obviously we know that this is not the best way as the arithmetic mean overestimated the real mean compared to geometric mean as $\mu_a > \mu_g$

So this is a nice little application example in a software accessible to almost everyone but that is relatively false in reality (but at least it is educational)!

However remember the 4 construction assumptions of this model that makes its use quite limited in practice...:

H1. The mean-variance optimization model is equivalent to model the assets of the portfolio by random variables for which these two moments exist. But in reality, nothing says that this is the case.

H2. The mean-variance optimization model assumes that only the mean and variance are important for an investor. But in reality we should take into account the skewness (or even the kurtosis) and maybe use the semi-variance instead of the variance.

H3. The model is build on a posteriori information without taking into account how the future could be. So an a priori information of the market should complete this model.

H4. The model is based on average return estimated for an allocation period that may change in the short-term. But a very small change in average return can have disproportionate impact on the proportions.

Also in practice we must be careful to one thing also.... Rebalancing a portfolio following an optimization calculation can be very expensive in transaction fees (a portfolio rebalancing computer model that doesn't take into account transaction fees is said to be a "frictionless portfolio model"). A case often cited in university is that of a US pension fund consisting of more than 2, 000 different types of assets whose rebalancing in October 12000 (holocene calendar) implied 40 portfolio managers, 500 million of assets for a total of 17.5 billion dollars!!! The legends says that the cost of this rebalancing in terms of transactions cost was not far from 120 million dollars...!

Remark

A big issue to the Markowitz model is the important sensitivity of the resulting portfolios if the parameters or inputs to the models undergo small changes. Multiple independent investigations has been able to provide strong evidence that two efficient frontiers whose parameters or inputs are extracted from the same distribution of returns but simply where the sampling period is different we get clearly statistically different efficient frontiers. R. O. Michaud et al. in their textbook *A practical guide to stock portfolio optimization and asset allocation* claim that « *In practice, the most important limitations of MV optimization are instability and ambiguity. [...] Small changes in input assumptions often imply large changes in the optimized portfolio. Consequently, portfolio optimality is often not well defined... The procedure overuses statistically estimated information and magnifies the impact of estimation errors. The result is that optimized portfolios are "error maximized" and often have little, if any, reliable investment value. Indeed, an equally weighted portfolio may often be substantially closer to true MV optimality than an optimized portfolio.* ». That's because of these limitations of the MV portfolio that they created a resampling portfolio method (see the practical example in our `R` companion book!).

Now based on exactly the same method we used in the section of Theoretical Computing with the Lagrange multipliers (see section Numerical Methods page 6670), we now introduce a risk free asset into the framework. Let R_f and w_f represent the return and weight of the risk free asset, respectively. Let $\vec{Z}$ represent the vector of excess return over the risk free rate. then using exactly the same reasoning we get:

$$\begin{aligned}&R_P=\vec{\mu}^T\vec{w}+\left(1-\vec{1}^T\vec{w}\right)R_f=R_f+\left(\vec{\mu}^T-R_f\vec{1}^T\right)\vec{w}=R_f+\vec{Z}^T\vec{w}\\&\sigma_P^2=\vec{w}^T\Sigma\vec{w}\end{aligned}\quad(15.3.670)$$

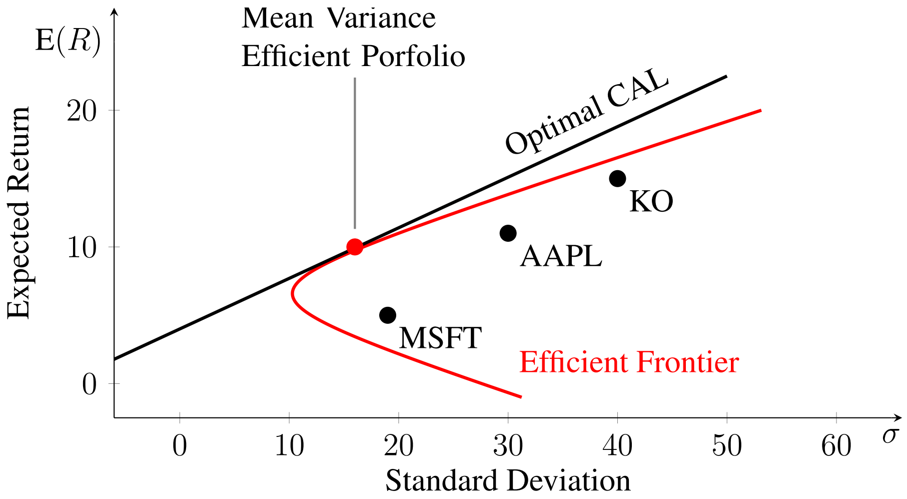

Figure 15.142: **Mean-Variance efficient portfolio**

The portfolio optimisation problem is then again to minimise the variance of the portfolio for a given level of return but there is no budget constraints as the presence of risk free assets allows unlimited borrowing and lending (we already put a factor $1/2$ as we know that an appearing factor of 2 will anyway cancel it later):

$$L(\vec{w},\lambda)=\frac{1}{2}\vec{w}^T\Sigma\vec{w}+\lambda\left(R_P-R_f-\vec{Z}^T\vec{w}\right)\quad(15.3.671)$$

Differentiating and setting the derivatives equal to zero, we get:

$$\begin{aligned}\frac{\partial L(\vec{w},\lambda)}{\partial\vec{w}}&=\Sigma\vec{w}-\lambda\vec{Z}=\vec{0}\\\frac{\partial L(\vec{w},\lambda)}{\partial\lambda}&=R_P-R_f-\vec{Z}^T\vec{w}=0\end{aligned}\quad(15.3.672)$$

We need to solve the two equations for the two unknowns, with $\vec{w}$ being the ultimate price. Solving the first equation for $\vec{w}$, we get:

$$\begin{aligned}&\Sigma\vec{w}-\lambda\vec{Z}=\vec{0}\\&\vec{w}=\lambda\Sigma^{-1}\vec{w}\end{aligned}\quad(15.3.673)$$

And substituting into the second equation:

$$\begin{aligned}&R_P-R_f-\vec{Z}^T\vec{w}=\vec{0}\\&\Rightarrow R_P-r_f-\lambda\vec{Z}^T\Sigma^{-1}\vec{Z}=0\\&\Rightarrow\lambda=\frac{R_P-R_f}{\vec{Z}^T\Sigma^{-1}\vec{Z}}\end{aligned}\quad(15.3.674)$$

Thus:

$$\vec{w}_{\text{MP}} = \lambda\Sigma^{-1}\vec{Z} = \frac{R_P - R_f}{\vec{Z}^T\Sigma^{-1}\vec{Z}}\Sigma^{-1}\vec{Z} = \frac{R_P - R_f}{\left(\vec{\mu}^T - R_f\vec{1}^T\right)^T\Sigma^{-1}\left(\vec{\mu}^T - R_f\vec{1}^T\right)}\Sigma^{-1}\left(\vec{\mu}^T - R_f\vec{1}^T\right) \tag{15.3.675}$$

This portfolio made of $\vec{w}_{\text{MP}}$ risked assets is named "market portfolio".

15.3.10.3.7.2 Overall maximum Sharpe portfolio

The use of the Markowitz model, as proposed in his 11959 (holocene calendar) book, raised many problems when it came to use algorithms for a basic list with a large number of values. These problems were of two orders:

1. The size of matrices required at that time a huge computer capacity and a fairly long period of calculation!
2. The use of the base model required that we know in its entirety the covariance matrix. The main problem about it is in the number of estimates to provide to build it and also the difficulty of making accurate and consistent estimates.

If we want the approach proposed by Markowitz can enter the field of application, we must obviously find a way to significantly simplify the procedure while losing as little as possible of the rigour of the method.

In 11963 (holocene calendar), William Sharpe proposed a solution whose essential characteristic consists in the assumption that the returns of the various values are only linked by their common relation with an underlying basic factor (stock index typically) which allows determining a coefficient named the "beta" (correlation like factor between the return of a security and that of a market portfolio).

This purely empirical hypothesis named "one index model" (or "unifactor model", "monofactorial model") has later take considerable importance because it was, as we shall see in subsequent developments, at the basis of the theory of pricing for some financial assets in an uncertain Universe.

Remark

Again, the developments that follow should look abstract but ... we'll see how to solve the previous above example with Microsoft® Excel® for the Markowitz model but applying the Sharpe's model and we will then even be able to visually compare the results of both methods.

The term "unifactor model" comes from the fact that the basic purpose of the Sharpe model is to define the performance of a financial investment in terms of its non-diversifiable risk, assimilated to that of the market risk (or "systematic risk") given by a number named the "beta" as previously mentioned.

Investors and managers distinguish three main kinds of risks:

1. The "specific risk" relative (implicit) to the asset himself (its variance) also named "unsystematic risk" or "idiosyncratic risk".
2. The "systematic/nondiversifiable risk" relatively to the economy / market in the broadest sense of the term (variance of the market reference portfolio).
3. The "global risk" which is somehow the sum of both (it's a little more subtle than a simple sum if fact...).

As you have probably guessed, the risk factor is difficult to quantify. The element that will help determine the variation is the performance of the asset compared to the change of market performance as a whole. Financial assets whose prices change frequently and whose volatility is high present therefore a high risk if the market is almost stable.

Here are for example distributions of two investment funds:

	TAA Model	Stocks B&H
Average Rolling Return	11.3%	10.6%
Standard Deviation	7.1%	17.4%
Sharpe Ratio (5%)	0.91	0.31
Max Drawdown	-3.8%	-39.2%
Percent Positive Years	98.3%	76.2%
Percent Years Beat S&P 500	47.0%	

Figure 15.143: Multi-Asset moving average strategy VS One index portfolio (source: Faber (12009), Butler|Philbrick & Associates (12010))

Here, is another example of return distributions of the second retirement fund (LPP) in Switzerland depending on the portfolio diversification strategy (the values after the abbreviation LPP represent the % of shares in the portfolio):

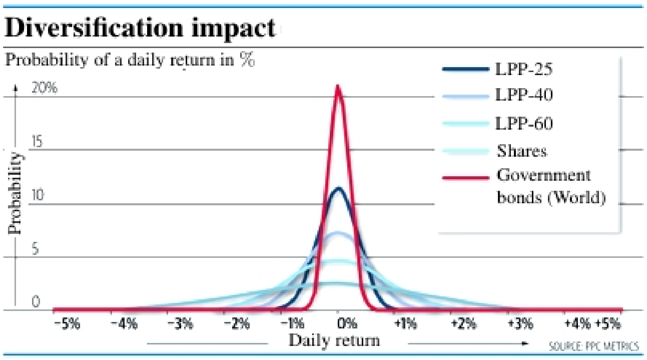

Figure 15.144: Swiss LPP various diversification returns

Definition (naive version #693): The "beta" measures the dependence (ratio) of the performance of a portfolio or of a financial asset relatively to the performance of a benchmark index and is the slope of a line named "security characteristic line" (SCL):

$$\beta = \frac{\text{expected variation of portfolio's}}{\text{variation of index level}} \tag{15.3.676}$$

This ratio is of course especially accurate when the past data are on the long run and that the sampling frequency is small. This ratio is also sometimes named "relative volatility".

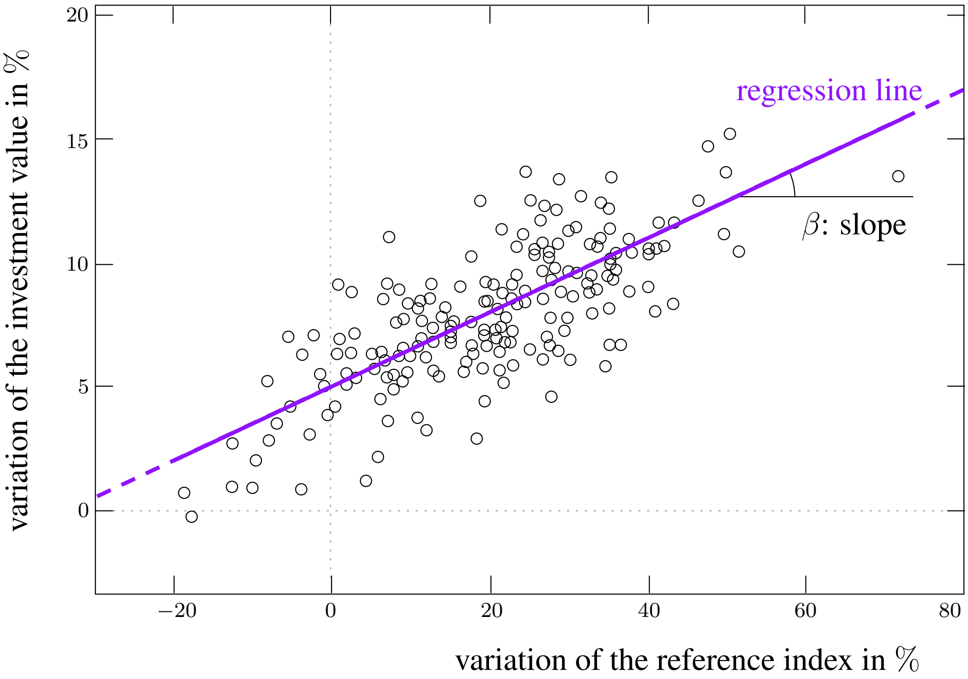

Figure 15.145: Idea of the linear regression behind the β coefficient

Remark

The benchmark index is chosen in the most relevant possible way with everything that this implies... If possible when the return of the reference index is zero, the change in value of the portfolio or asset should be zero.

Or a more realistic example (some informations visible in this screenshot will be discussed later):

Figure 15.146: **Linear regression principle of beta (and alpha) in Bloomberg$^{\text{TM}}$ Terminal**

Definitions (#15.3.694): The beta of a stock can be presented as either an Adjusted Beta or a Raw Beta:

D1. A "raw beta" is obtained from the linear regression of a stock's historical data. Raw beta, also known as "historical beta", is based on the observed relationship between the security's return and the returns of an index.

D2. The "adjusted beta" is an estimate of a security's future beta. Adjusted Beta is initially derived from historical data, but modified by the assumption that a security's true beta will move towards the market average, of 1, over time. The formula used to adjust the beta is according to Blume's Method (used by Bloomberg Terminal):

$$\beta_{\text{adj.}}=\frac{2}{3}\beta+\frac{1}{3} \qquad (15.3.677)$$

A simple analysis of the graph above (i.e. elementary functional analysis) therefore shows that a beta equal to 1 for a given asset means that an increase (respectively decrease) of 10% of the market reference index for a certain period will result in an increase (respectively decrease) of 10% on average performance of this asset. So the volatility of the asset is equal to that of the index.

A beta greater than 1 means that the evolution of the return of the financial asset is more volatile (or rather, was volatile, as this coefficient usually refers to a past period) than the return of the market reference index, while a beta less than 1 indicates the opposite. Thus, a fund with a beta of 1.15 is 15% more volatile than the index. Conversely, a fund with a beta of 0.70 is 30% less volatile than the index.

So to summarize:

- An investment with no risk (relatively to the benchmark) therefore displays a beta of 1.
- A beta of less than 1 indicates that if the market (benchmark) is down (bearish), the investment will likely to decline less than the market.
- A beta greater than 1 indicates that if the market (benchmark) is on the rise (bullish), the investment will likely follow a slower upward trend.

The concept of beta having been naively introduced, let us move now to the theory of the model that aims to simplify the Markowitz one using this famous coefficient!

First, by choice, we take the overall beta of a portfolio as being determined from the respective weighted betas of each of the asset or underlying betas that it is make up such that:

$$\boxed{\beta_P=\sum_{i=1} nX_i\beta_i} \tag{15.3.678}$$

with β_P being the beta of the overall portfolio, X_i the proportion of security i in portfolio P, β_i the beta of asset i and n is obviously the number of financial assets in the portfolio (the beta is then additive when weighted).

Sharpe suggested (in 11963 according to holocene calendar) that the return R_i of each asset i at time t is given by the linear regression (see section Numerical Methods page 6324) determining the "security characteristic line" view above (so it is a linear regression model with one explanatory factor but in practice there are obviously multiple linear or non-linear models):

$$\boxed{R_i=\alpha_i+\beta_i I+\varepsilon_i} \tag{15.3.679}$$

named also sometimes "single-factor benchmark of returns", where:

- I is the performance of a given reference economic index ... (stock index, index of gross national product, price levels or even portfolio market performance itself...) at time t and is the dependent variable of the univariate regression (in the terminology used in the section of Numerical Methods) considered as a random variable[25] (...).
- α_i,β_i are unbiased estimators (see section Statistics page 818) of the parameters specific to that value. The first term in finance is named "alpha coefficient" and is simply the intercept of the regression (the return of the assets when the performance of the benchmark is zero or when the market has zero returns often also named "residual return") and the second parameter is simply to recall the "beta" of the risky asset i. The alpha is not a source of risk, it is often ignored in the calculations.
- ε_i is a random variable assumed to be characterized by a zero mean, and variance equal to a constant (see section Numerical Methods page 6348) and the different ε_i are assumed uncorrelated between them (zero covariance).

---

[25] We know that is this case we should rather use the Deming regression seen also in the section of Numerical Methods

About the level of the index I, it will be characterized by the relation (to simplify later some developments):

$$I = \alpha_{n+1} + \upsilon_{n+1} \tag{15.3.680}$$

where α_{n+1} is an additional unbiased parameter to characterize index I and υ_{n+1} a random variable characterized by a zero mean and variance equal to a constant.

Notice first that (by adopting on the way the traditional notation for the performance of the market index) for an asset:

$$\begin{aligned} &R_i = \alpha + \beta_i I + \varepsilon = \alpha + \beta_i R_M + \varepsilon_i \\ &\Rightarrow \mathrm{V}(R_i) = \beta_i^2 \mathrm{V}(R_m) + \mathrm{V}(\varepsilon_i) \\ &\Rightarrow \underbrace{\sigma_i}_{\text{total risk}} = \sqrt{\underbrace{\beta_i^2\sigma_M^2}_{(\text{systematic risk})^2} + \underbrace{\sigma_\varepsilon^2}_{(\text{specific risk})^2}} \end{aligned} \tag{15.3.681}$$

This is easily generalized to a sum of weighted assets for a portfolio and where we get also as a standard deviation of the portfolio is the sum of two terms, i.e. systematic risk and specific risk (diversifiable):

$$\boxed{\sigma_P = \sqrt{\sum_i \sum_j w_i w_j \beta_i \beta_j \sigma_M^2 + \sum_i \sum_j w_i w_j \sigma_{\varepsilon_{ij}}}} \tag{15.3.682}$$

Of course if the number of assets approaches infinity then the weights approach zero and therefore the total risk also tends to zero and this is the trick of multi-asset portfolio management!!

Remark

The SML is sometimes confused with the "Capital Market Line" (CML). The SML is derived from the CML as it is a special case of it obviously! While the CML shows the rates of return for a specific portfolio, the SML represents the market's risk and return at a given time, and shows the expected returns of individual assets.

Optimal portfolio allocation lies on the Capital Allocation Line (CAL) such that it maximizes the utility of the investor. Thus investor's utility curve is tangent on that point to the CAL:

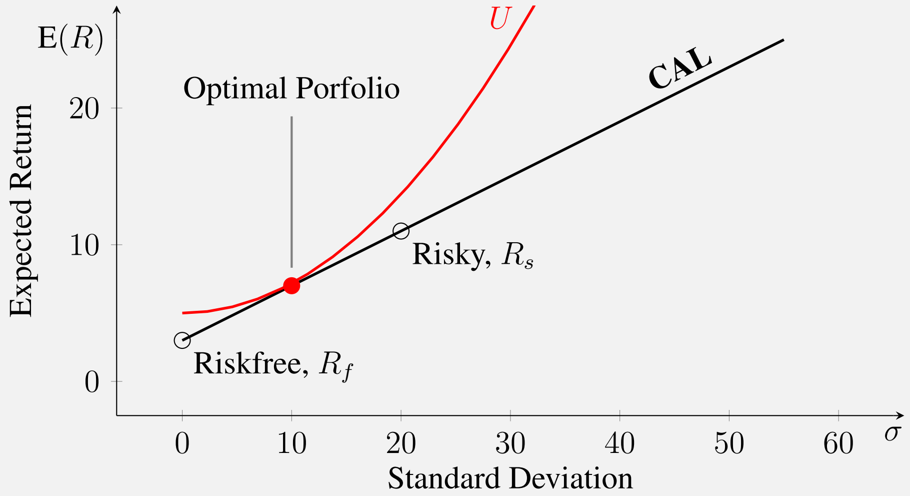

Figure 15.147: **Optimal portfolio allocation and Capital Allocation Line**

Notice that in econometrics the above relation is sometimes rewritten as:

$$\sigma_P^2=\underbrace{\left(\underbrace{\sum_{i=1}^n w_i^2\beta_i^2\sigma_M^2}_{\text{variance}}+\underbrace{\sum_{i=1}^n\sum_{\substack{j=1\\j\neq 1}}^n w_iw_j\beta_i\beta_j\sigma_M^2}_{\text{covariance}}\right)}_{\text{Market proportional}}+\underbrace{\left(\underbrace{\sum_{i=1}^n w_i^2\sigma_{\varepsilon_i}^2}_{\text{variance}}\right)+\sum_{i=1}^n\sum_{\substack{j=1\\j\neq 1}}^n w_iw_j\sigma_{\varepsilon_{ij}}}_{\text{Firm specific}} \quad (15.3.683)$$

The firm specific covariance is sometimes assumed zero. So we can write:

$$\sigma_P^2=\sum_{i=1}^n w_i^2(\beta_i^2\sigma_M^2+\sigma_{\varepsilon_i}^2)+\sum_{i=1}^n\sum_{\substack{j=1\\j\neq 1}}^n w_iw_j\beta_i\beta_j\sigma_M^2 \quad (15.3.684)$$

To summarize the main points, the simple linear regression model of financial asset yield is based on the following key assumptions:

H1. The return model is written in general (univariate case):

$$R_i=\alpha_i+\beta_iI+\varepsilon_i \quad (15.3.685)$$

assuming that we don't do any errors on the linear assumption of the model, nor the list of regressors (see other models below taking into account other factors).

H2. We assume that the perturbation ε satisfies the same assumption as the usual general linear models (Gaussian or others) as the zero mean, zero covariance, fixed variance over time which has to be said is a quite dangerous practice but useful assumption to be usable (and understandable) by practitioners of finance...

H3. For any sample of size n, we use the maximum likelihood estimators (see section Statistics page 818) for the mean and variance of returns on financial assets of the reference portfolio (index):

$$\hat{\sigma}_j=\sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(R_{ij}-\hat{\mu})^2}\qquad \hat{\mu}_j=\frac{1}{n}\sum_{i=1}^{n}R_{ij}\tag{15.3.686}$$

These assumptions now stated, we also use the results obtained in the section of Numerical Methods on the linear regression to get the beta. We have proved that there are several ways of doing a linear regression, one is to use the covariance and mean. By adopting the notation of econometrics, the slope of the regression (beta) can then be written:

$$\boxed{\beta_i=\frac{\text{cov}(R_i,R_I)}{\text{V}(R_I)}=\frac{\text{cov}(R_i,R_I)}{\sigma_I^2}}\tag{15.3.687}$$

giving the rigorous definition of the beta coefficient according to the Sharpe model where R_i is the return of the financial asset and R_I that of the market reference index (or market reference portfolio).

Now, considering the same assumption as in the Markowitz model, the return R_P of portfolio is defined again quite logically by:

$$R_P=\sum_{i=1}^{n}X_iR_i\tag{15.3.688}$$

where for recall X_i is the proportion of the asset i in the multi-asset portfolio P.

If the return are not explicitly known in practice, then we use the linear model:

$$R_P=\sum_{i=1}^{n}X_iR_i=\sum_{i=1}^{n}X_i(\alpha_i+\beta_iI+\varepsilon_i)=\sum_{i=1}^{n}X_i(\alpha_i+\varepsilon_i)+\sum_{i=1}^{n}X_i\beta_iI\tag{15.3.689}$$

Therefore by using the properties of the mean:

$$\text{E}(R_P)=\text{E}\left[\sum_{i=1}^{n}X_i(\alpha_i+\varepsilon_i)+\sum_{i=1}^{n}X_i\beta_iI\right]=\sum_{i=1}^{n}X_i\text{E}(\alpha_i)+\sum_{i=1}^{n}X_i\text{E}(\varepsilon_i)+\sum_{i=1}^{n}X_i\beta_i\text{E}(\alpha_{n+1}+\nu_{n+1})\tag{15.3.690}$$

Let us put to simplify the notation that:

$$X_{n+1}=\sum_{i=1}^{n}X_i\beta_i\tag{15.3.691}$$

In this case, by the two of the various hypothesis of the model ($\text{E}(\varepsilon_i)=0$ and $\text{E}(\nu_{n+1})=0$):

$$\text{E}(R_P)=\sum_{i=1}^{n}X_i\alpha_i+0+X_{n+1}\text{E}(\alpha_{n+1}+\nu_{n+1})=\sum_{i=1}^{n}X_i\alpha_i+0+X_{n+1}\alpha_{n+1}=\sum_{i=1}^{n+1}X_i\alpha_i\tag{15.3.692}$$

Finally:

$$\boxed{\mathrm{E}(R_P)=\sum_{i=1}^{n+1}X_i\alpha_i} \tag{15.3.693}$$

If the returns are explicitly given and therefore known, the expected mean is calculated with:

$$\boxed{\mathrm{E}(R_P)=\mathrm{E}\left(\sum_{i=1}^{n}X_iR_i\right)=\sum_{i=1}^{n}X_i\mathrm{E}(R_i)} \tag{15.3.694}$$

This relation is often named "weighted average return" or "weighted average yield".

As the customer (investor) will often seek to maximize the expected mean return while minimizing the variance (risk) it remains to determine the latter. Since now we assume explicitly known the returns of the financial assets and the market portfolio returns (index) we have:

$$\begin{aligned}\mathrm{V}(R_P)=\mathrm{V}\left[\sum_{i=1}^{n}X_iR_i\right]&=\sum_{i=1}^{n}X_i^2\mathrm{V}(R_i)+2\sum_{i,j|i<j}X_iX_j\mathrm{cov}(R_i,R_j)\\&=\sum_{i=1}^{n}X_i^2\mathrm{V}(R_i)+2\sum_{i,j|i<j}X_iX_j\mathrm{cov}(\alpha_i+\beta_iI,\alpha_j+\beta_jI)\end{aligned} \tag{15.3.695}$$

Hypothesis: If the index I is selected correctly, when $I=0$ we must have $R_i=0$ implying $\alpha_i=0$ (this is a strong assumption that leads to have an approximation!).

Therefore:

$$\begin{aligned}\mathrm{V}(R_P)&=\sum_{i=1}^{n}X_i^2\mathrm{V}(R_i)+2\sum_{i,j|i<j}X_iX_j\mathrm{cov}(\beta_jI,\beta_jI)\\&=\sum_{i=1}^{n}X_i^2\mathrm{V}(R_i)+2\sum_{i,j|i<j}X_iX_j\beta_i\beta_j\mathrm{cov}(I,I)\\&=\sum_{i=1}^{n}X_i^2\mathrm{V}(R_i)+2\sum_{i,j|i<j}X_iX_j\beta_i\beta_j\mathrm{V}(I)\end{aligned} \tag{15.3.696}$$

Finally:

$$\boxed{\mathrm{V}(R_P)=\sum_{i=1}^{n}X_i^2\sigma_i^2+2\sigma_I^2\sum_{i,j|i<j}X_iX_j\beta_i\beta_j} \tag{15.3.697}$$

So what gives for a portfolio with two assets:

$$\mathrm{V}(R_P)=\sum_{i=1}^{2}X_i^2\sigma_i^2+2\sigma_I^2\sum_{i,j|i<j}X_iX_j\beta_i\beta_j=X_1^2\sigma_1^2+X_2^2\sigma_2^2+2\sigma_I^2(X_1X_2\beta_1\beta_2) \tag{15.3.698}$$

We can condense the notation of the variance using as always the matrix formulation by first noting respectively the transposed vector and the vector-column of the weights of the portfolio by:

$$X^T=[X_1\,X_2\,\ldots\,X_n] \qquad X=\begin{pmatrix}X_1\\X_2\\\vdots\\X_n\end{pmatrix} \tag{15.3.699}$$

and by defining the array of betas:

$$B_{ij}=\begin{bmatrix}\dfrac{\sigma_1^2}{\sigma_I^2} & \beta_1\beta_2 & \ldots & \beta_1\beta_n\\ \beta_2\beta_1 & \dfrac{\sigma_2^2}{\sigma_I^2} & & \vdots\\ \vdots & & \ddots & \\ \beta_n\beta_1 & \ldots & & \dfrac{\sigma_n^2}{\sigma_I^2}\end{bmatrix} \tag{15.3.700}$$

Which finally gives us:

$$\boxed{\text{V}(R_P)=\sigma_I^2X^T(B_{ij}X)} \tag{15.3.701}$$

For a portfolio of two assets this last relationship is reduced to:

$$\begin{aligned}\text{V}(R_P)&=\sigma_I^2[X_1\,X_2]\left(\begin{bmatrix}\dfrac{\sigma_1^2}{\sigma_I^2} & \beta_1\beta_2\\ \beta_2\beta_1 & \dfrac{\sigma_2^2}{\sigma_I^2}\end{bmatrix}\right)=\sigma_I^2[X_1\,X_2]\begin{bmatrix}\dfrac{\sigma_1^2}{\sigma_I^2}X_1+\beta_1\beta_2X_2\\ \beta_2\beta_1X_1+\dfrac{\sigma_2^2}{\sigma_I^2}X_2\end{bmatrix}\\ &=\sigma_I^2\left(\frac{\sigma_1^2}{\sigma_I^2}X_1^2+\beta_1\beta_2X_2X_1+\beta_2\beta_1X_1X_2+\frac{\sigma_2^2}{\sigma_I^2}X_2^2\right)=\sigma_1^2X_1^2+\sigma_2^2X_2^2+2\sigma_I^2X_1X_2\beta_1\beta-2\end{aligned} \tag{15.3.702}$$

We thus find much the same as the algebraic form!

If we do not know explicitly the returns, the study of the variance is a little trickier. Then we must use the linear model such as:

$$\text{V}(R_P)=\text{V}\left[\sum_{i=1}^n X_i(\alpha_i+\varepsilon_i)+\sum_{i=1}^n X_i\beta_iI\right]=\sum_{i=1}^n X_i^2\text{V}(\alpha_i)+\sum_{i=1}^n X_i^2\text{V}(\varepsilon_i)+\sum_{i=1}^n X_i^2\beta_i^2\text{V}(\alpha_{n+1}+\nu_{n+1}) \tag{15.3.703}$$

And always under the assumption already specified above as that if the index I is properly chosen it implies $\alpha_i=0$.

Also, let us put:

$$Q_i=\text{V}(\varepsilon_i) \tag{15.3.704}$$

Moreover, we know that:

$$Q_{n+1}=\text{V}(\nu_{n+1}) \tag{15.3.705}$$

Therefore ignoring the variance of the intercept:

$$\text{V}(R_P)=\sum_{i=1}^{n} X_i^2 Q_i + X_{n+1}^2 Q_{n+1} \tag{15.3.706}$$

because:

$$\text{V}(\alpha_{n+1})=\text{V}(c^{te})=0 \tag{15.3.707}$$

Finally:

$$\text{V}(R_P)=\sum_{i=1}^{n+1} X_i^2 Q_i \tag{15.3.708}$$

In this context the problem remains to maximize the economic function Z:

$$Z=\Phi\text{E}(R_P)-V(R_P)+\lambda\left(1-\sum_{i=1}^{n} X_i\right) \tag{15.3.709}$$

at the difference that now it will be written:

$$Z=\Phi\sum_{i=1}^{n+1} X_i\alpha_i-\sum_{i=1}^{n+1} X_i^2 Q_i+\lambda\left(1-\sum_{i=1}^{n} X_i\right) \tag{15.3.710}$$

The calculation of each of partial derivatives then gives:

$$\begin{cases} \dfrac{\partial Z}{\partial X_1}=\Phi\alpha_1-2X_1Q_1-\lambda=0 \\ \dfrac{\partial Z}{\partial X_2}=\Phi\alpha_2-2X_2Q_2-\lambda=0 \\ \ldots \\ \dfrac{\partial Z}{\partial X_n}=\Phi\alpha_n-2X_nQ_n-\lambda=0 \\ \dfrac{\partial Z}{\partial X_{n+1}}=\Phi\alpha_{n+1}-2X_nQ_{n+1}-\lambda=0 \\ \dfrac{\partial Z}{\partial \lambda}=1-X_1-X_2-\ldots-X_n=0 \end{cases} \tag{15.3.711}$$

or in matrix form:

$$\begin{bmatrix} 2Q_1 & 0 & \ldots & 0 & 1 \\ 0 & 2Q_2 & \ldots & 0 & 1 \\ \ldots & & \ldots & & \\ 0 & 0 & \ldots & 2Q_{n+1} & 1 \\ 1 & 1 & \ldots & 1 & 0 \end{bmatrix} \begin{bmatrix} X_1 \\ X_2 \\ \ldots \\ X_{n+1} \\ \lambda \end{bmatrix} = \begin{bmatrix} \Phi\alpha_1 \\ \Phi\alpha_2 \\ \vdots \\ \Phi\alpha_{n+1} \\ 1 \end{bmatrix} \tag{15.3.712}$$

The resolution of this system then goes through the inversion of a matrix simpler than that of Markowitz model but still requires relatively restrictive assumptions.

Finally, notice that the finance practitioner often use the performance indicators weighted by the risk, the most internationally known being the "Sharpe ratio". It is determined by the ratio (to be more exact it is its expected mean) between the differential of the returns of an investment (assets) supposed without risk R_f (this difference being named by the practitioners "active return") and the performance of our portfolio and standard deviation of this portfolio at the market rates (we will rigorously determine the origin of this relation further in our study of the CAPM):

$$\boxed{S_P = \frac{R_P - R_f}{\sigma_P}} \tag{15.3.713}$$

This relation expresses the level of pure return by volatility unit (or per unit of risk). For simplicity, it is a (marginal) profitability indicator obtained per unit of risk taken in a multi-assent portfolio management strategy. It helps answer the question: the portfolio manager is he able to get a higher return to the reference investment but with more risk?

- If the Sharpe ratio is negative, the portfolio performed less than the benchmark and the situation is very bad.
- If the Sharpe ratio is between 0 and 0.5, the invested portfolio outperformed the benchmark in a way that is considered as too excessive risk taking. Or, the risk taken is too high for the achieved return performance.
- If the Sharpe ratio is greater than 0.5, the invested portfolio returns outperformed the benchmark by taking ad hoc risk. In other words, the outperformance is not done at the cost of too high risks.

The Sharpe Ratio can be developed to give a more explicit form relatively to what we have seen just before:

$$S_P = \frac{\displaystyle\sum_{i=1}^{n} X_i(\alpha_i + \beta_i I + \varepsilon_i) - \sum_{i=1}^{n} X_i(\alpha_i + \varepsilon_i)}{\sqrt{\mathrm{V}\left(X_i(\alpha_i + \beta_i I + \varepsilon_i)\right)}} = \frac{\displaystyle\sum_{i=1}^{n} \beta_i I}{\sqrt{\mathrm{V}\left(\alpha_i + \beta_i I + \varepsilon_i\right)}} \tag{15.3.714}$$

Let us also notice another common indicator that is the "tracking error" defined as the standard deviation of the difference in performance between the portfolio and the benchmark. The higher the tracking error, the more the investment looks like the benchmark in terms of risk:

$$\boxed{\text{TE} = \sqrt{\mathrm{V}(R_P - R_f)} = \sigma_{R_P - R_f} = \sqrt{\sigma_P^2 + \sigma_f^2 + 2R_{P,f}\sigma_P\sigma_f}} \tag{15.3.715}$$

Remark

Some practitioner prefer to use the "CALMAR ratio" instead of the Sharpe ratio for comparing investment performance. Conceptually, as we have just seen, the Sharpe Ratio divides the average return of an investment by the standard deviation of its returns. The standard deviation is taken as a measure of the investment's risk. A higher Sharpe Ratio suggests more returns at lower risk.

But the standard deviation includes variations above the average returns. Most people like those and only worry about the below average returns. The CALMAR ratio uses maximum drawdown (see our study of Time Series further below for the definition page 7907) instead of standard deviation as a measure of risk (but it's empirical because we could use also the semivariance and create a bunch of other indicators like the Omega ratio, Sterling ratio, MAR ratio, etc.). So the "CALMAR ratio" (acronym of: ***CAL**ifornia **M**anaged **A**ccounts **R**eports* where it was published for the first time) is an investment's average return (usually for a 3 year period, i.e. 36 months) divided by its maximum drawdown in the same period (analysed on batches of 36 months):

$$\text{CALMAR Ratio} = \frac{\text{Annualized ROR (last 3 years)}}{\text{Drawdown (last 36 months)}} = \frac{\left(\prod_{i=0}^{36}(1+R(i))\right)^{1/3}-1}{\max\left\{0, \max_{t\in(T-36,T)} R(T-36)-R(T)\right\}} \tag{15.3.716}$$

A higher CALMAR Ratio suggests more returns at lower risk.

It should be known that later versions of the Calmar ratio introduce the risk free rate into the numerator to create a Sharpe type ratio.

These models are relatively complex. This is why some years later, Sharpe and Lintner have created a new model that earned them the Nobel Prize in Economics and that we will study just after a practical example of what we just saw earlier above!

✍Example:

Let us consider three assets in equal proportions in an invested portfolio and n equal, non-missing, observations of their return R_{ij} entered in the spreadsheet software Microsoft® Excel® 14.0.7173 as visible below. These returns will be compared to a benchmark that I will be the performance of a benchmark market portfolio P_M:

	A	B	C	D	E
1	Obs.	P_M	Asset 1	Asset 2	Asset 3
2	1	0.45	-0.15	0.29	0.38
3	2	0.61	0.05	0.18	0.63
4	3	0.54	-0.43	0.24	0.46
5	4	0.29	0.79	0.25	0.36
6	5	0.12	0.32	0.17	-0.57

Figure 15.148: **Three assets with returns compared to a reference market portfolio**

The goal will be to determine the portfolio efficiency frontier with Sharpe's model.

In detail under graphical form let us first give the betas (return on assets based on the performance of the market portfolio / benchmark) with Microsoft® Excel® 14.0.7173 elementary tools:

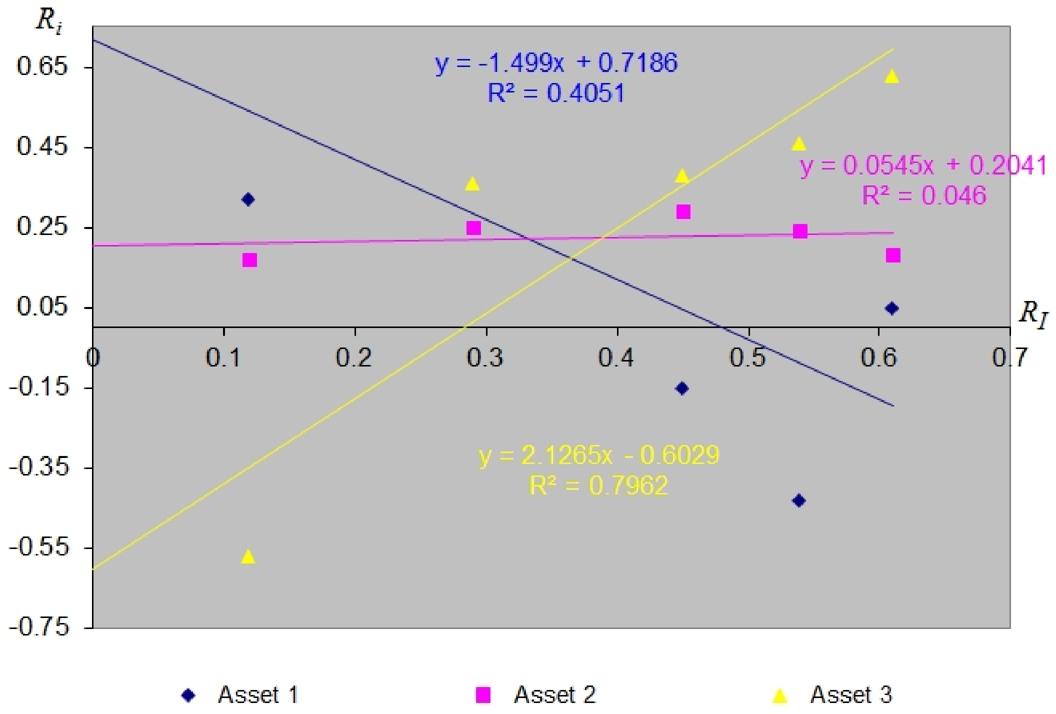

Figure 15.149: **Linear regression to calculate the betas of the assets returns**

and the following construction list for calculating the betas, variance and the expected mean return of the market portfolio and the different assets:

	A	B	C	D	E
1	Obs.	P_M	Asset 1	Asset 2	Asset 3
2	1	0.45	-0.15	0.29	0.38
3	2	0.61	0.05	0.18	0.63
4	3	0.54	-0.43	0.24	0.46
5	4	0.29	0.79	0.25	0.36
6	5	0.12	0.32	0.17	-0.57
7	Beta: β_i	1.000	-1.499	0.055	2.126
8	Mean: $\hat{\mu}_i$	0.402	0.116	0.226	0.252
9	Variance : $\hat{\sigma}_i^2$	0.039	0.217	0.003	0.222

Figure 15.150: **Key indicators of the benchmark portfolio and the 3 assets**

Explicitly:

	A	B	C	D	E
1	Obs.	P_M	Asset 1	Asset 2	Asset 3
2	1	0.45	-0.15	0.29	0.38
3	2	0.61	0.05	0.18	0.63
4	3	0.54	-0.43	0.24	0.46
5	4	0.29	0.79	0.25	0.36
6	5	0.12	0.32	0.17	-0.57
7	Beta:	=LINEST(B2:B6,$B2:$B6)	=LINEST(C2:C6,$B2:$B6)	=LINEST(D2:D6,$B2:$B6)	=LINEST(E2:E6,$B2:$B6)
8	Mean:	=AVERAGE(B2:B6)	=AVERAGE(C2:C6)	=AVERAGE(D2:D6)	=AVERAGE(E2:E6)
9	Variance :	=VAR(B2:B6)	=VAR(C2:C6)	=VAR(D2:D6)	=VAR(E2:E6)

Figure 15.151: Key indicators of the benchmark portfolio and the 3 assets with explicit formulas in Microsoft® Excel® 14.0.7173

The expected portfolio return consisting of the three assets is easy to calculate because we have their returns. So:

$$\mathrm{E}(R_P)=\sum_{i=1}^{n} X_i R_i = X_i\hat{\mu}_1+X_2\hat{\mu}_2+X_3\hat{\mu}_3 \tag{15.3.717}$$

This gives in Microsoft® Excel® 14.0.7174:

	A	B	C	D	E
11		Asset 1	Asset 2	Asset 3	Sum
12	X_i	1/3	1/3	1/3	1
13	$\hat{\mu}_i$	0.116	0.226	0.252	
14					
15		Portfolio			
16	$E(R_p)$	0.198			

Figure 15.152: Expected mean return of each asset and of the overall portfolio

Or explicitly:

	A	B	C	D	E
1	Obs.	P_M	Asset 1	Asset 2	Asset 3
2	1	0.45	-0.15	0.29	0.38
3	2	0.61	0.05	0.18	0.63
4	3	0.54	-0.43	0.24	0.46
5	4	0.29	0.79	0.25	0.36
6	5	0.12	0.32	0.17	-0.57
7	Beta: β_i	1.000	-1.499	0.055	2.126
8	Mean: $\hat{\mu}_i$	0.402	0.116	0.226	0.252
9	Variance : $\hat{\sigma}_i^2$	0.039	0.217	0.003	0.222
10					
11		Asset 1	Asset 2	Asset 3	Sum
12	X_i	1/3	1/3	1/3	1
13	$\hat{\mu}_i$	=C8	=D8	=E8	
14					
15		Portfolio			
16	$E(R_p)$	=SUMPRODUCT((B12:D12)*(B13:D13))			

Figure 15.153: Expected mean return of each asset and of the overall portfolio explicit formulas in Microsoft® Excel® 14.0.7174

Now we must calculate the variance using the relation proved in the theoretical part of the preceding paragraphs:

$$\mathrm{V}(R_P)=\sigma^2(R_P)=\sigma_I^2 X^T(B_{ij}X) \tag{15.3.718}$$

with for reminder in our special case:

$$B_{ij}=\begin{bmatrix} \dfrac{\sigma_1^2}{\sigma_I^2} & \beta_1\beta_2 & \beta_1\beta_3 \\ \beta_2\beta_1 & \dfrac{\sigma_2^2}{\sigma_I^2} & \beta_2\beta_3 \\ \beta_3\beta_1 & \beta_3\beta_2 & \dfrac{\sigma_3^2}{\sigma_I^2} \end{bmatrix} \tag{15.3.719}$$

with in our example with $\sigma_I^2=0.039$ (cell `B13`).

Or in an expanded form for our example:

$$\sigma^2(R_P)=X_1^2\sigma_1^2+X_2^2\sigma_2^2+X_3^2\sigma_3^2+2X_1X_2\sigma_I^2\beta_1\beta_2+2X_1X_3\sigma_I^2\beta_1\beta_3+2X_2X_3\sigma_I^2\beta_2\beta_3 \tag{15.3.720}$$

Which gives in Microsoft® Excel® for our array of betas B_{ij}:

	A	B	C	D
19				
20	B_{ij}	Asset 1	Asset 2	Asset 3
21	Asset 1	5.547102374	-0.0817033	-3.18757825
22	Asset 2	-0.081703338	0.06459025	0.115907
23	Asset 3	-3.187578249	0.115907	5.67960174

Figure 15.154: Matrix of betas B_{ij}

Or explicitly:

	A	B	C	D
19				
20	B_{ij}	Asset 1	Asset 2	Asset 3
21	Asset 1	=C9/B9	=C7*D7	=C7*E7
22	Asset 2	=C7*D7	=D9/B9	=D7*E7
23	Asset 3	=C7*E7	=D22	=E9/B9

Figure 15.155: Matrix of betas B_{ij} explicit formulas in Microsoft® Excel® 14.0.7174

And finally the couple mean/variance of the portfolio is given by (cells `E16` and `E17`):

	A	B	C	D	E
1	Obs.	P_M	Asset 1	Asset 2	Asset 3
2	1	0.45	-0.15	0.29	0.38
3	2	0.61	0.05	0.18	0.63
4	3	0.54	-0.43	0.24	0.46
5	4	0.29	0.79	0.25	0.36
6	5	0.12	0.32	0.17	-0.57
7	Beta: β_i	1.000	-1.499	0.055	2.126
8	Mean: $\hat{\mu}_i$	0.402	0.116	0.226	0.252
9	Variance : $\hat{\sigma}_i^2$	0.039	0.217	0.003	0.222
10					
11		Asset 1	Asset 2	Asset 3	Sum
12	X_i	1/3	1/3	1/3	1
13	$\hat{\mu}_i$	0.116	0.226	0.252	
14					
15		Portfolio			
16	$E(R_p)$	0.19800			
17	$\sigma^2(R_p)$	0.02169			
18					
19					
20	B_{ij}	Asset 1	Asset 2	Asset 3	
21	Asset 1	5.547102374	-0.0817033	-3.18757825	
22	Asset 2	-0.081703338	0.06459025	0.115907	
23	Asset 3	-3.187578249	0.115907	5.67960174	

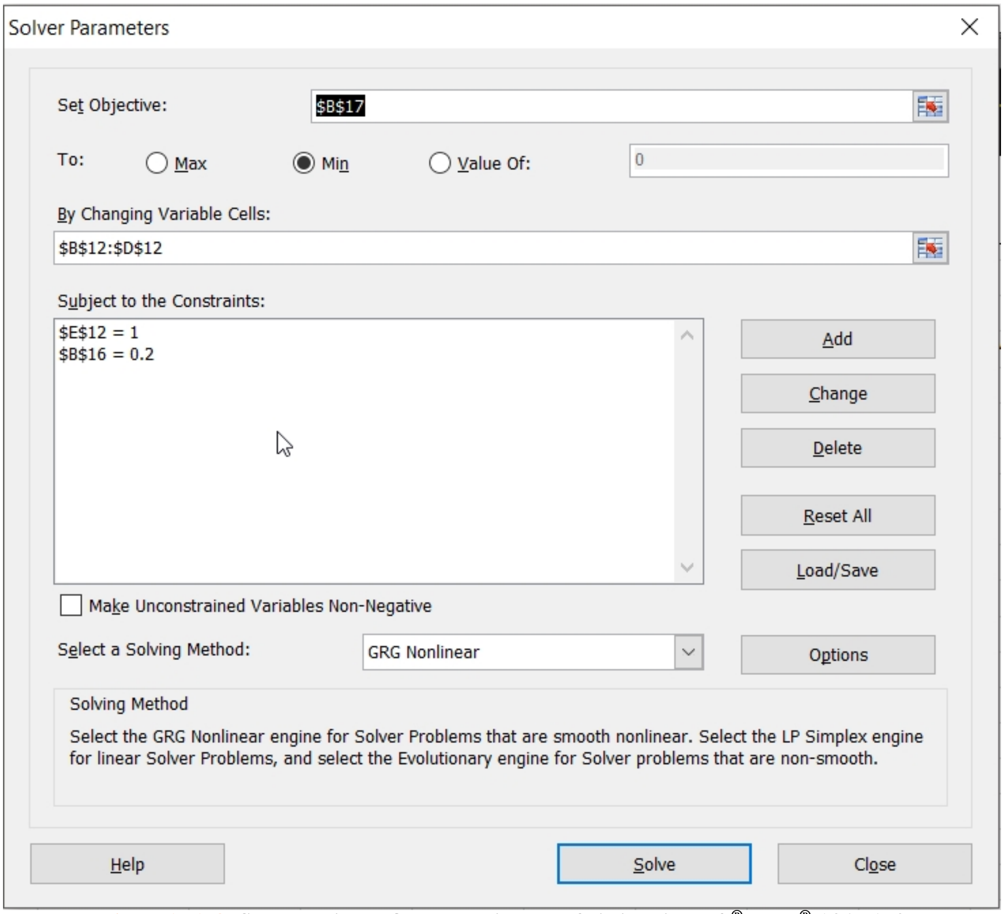
Figure 15.156: Couple mean / variance of the invested portfolio and global overview of all previous calculations

Explicitly of the part that interest us:

	A	B	C	D	E
14					
15		Portfolio			
16	$E(R_p)$	=SUMPRODUCT((B12:D12)*(B13:D13))			
17	$\sigma^2(R_p)$	=SUMPRODUCT(MMULT(B12:D12,B21:D23),B12:D12)*B9			

Figure 15.157: Couple mean / variance of the invested portfolio explicit formulas in Microsoft® Excel® 14.0.7174

Once this done, we proceed as for the Markowitz method. We use the solver to minimize the variance while imposing an expected mean return and a constraint as what the sum of weight of financial assets must be equal to unity:



Set Objective: $B$17

To: ○ Max ● Min ○ Value Of: 0

By Changing Variable Cells:
$B$12:$D$12

Subject to the Constraints:
$E$12 = 1
$B$16 = 0.2

☐ Make Unconstrained Variables Non-Negative

Select a Solving Method: GRG Nonlinear

Solving Method

Select the GRG Nonlinear engine for Solver Problems that are smooth nonlinear. Select the LP Simplex engine for linear Solver Problems, and select the Evolutionary engine for Solver problems that are non-smooth.

Figure 15.158: Solver setting to find the desired portfolio in Microsoft® Excel® 14.0.7174

That gives:

	A	B	C	D	E
10					
11		Asset 1	Asset 2	Asset 3	Sum
12	X_i	0.020522	0.869321	0.004575	1
13	$\hat{\mu}_i$	0.116	0.226	0.252	
14					
15		Portfolio			
16	$E(R_p)$	0.20000			
17	$\sigma^2(R_p)$	0.00191			

Figure 15.159: Desired portfolio results with Microsoft® Excel® 14.0.7174

To build the Sharpe efficient frontier we proceed in the same way as for the Markowitz efficient frontier:

	A	B	C
26	**Sharpe Efficient Frontier**		
27	**Iteration**	**Variance**	**Return**
28	1	0.0110	0.200
29	2	0.0076	0.205
30	3	0.0051	0.210
31	4	0.0034	0.215
32	5	0.0025	0.220
33	6	0.0024	0.225
34	7	0.0032	0.230
35	8	0.0047	0.235
36	9	0.0071	0.240
37	10	0.0103	0.245

Figure 15.160: Sharpe efficient frontier values samples

This gives us the following $\mathrm{E}(R_P)=f(\sigma_{R_p})$ plot (we have put the Sharpe and Markowitz efficient frontier together so that the reader can compare them):

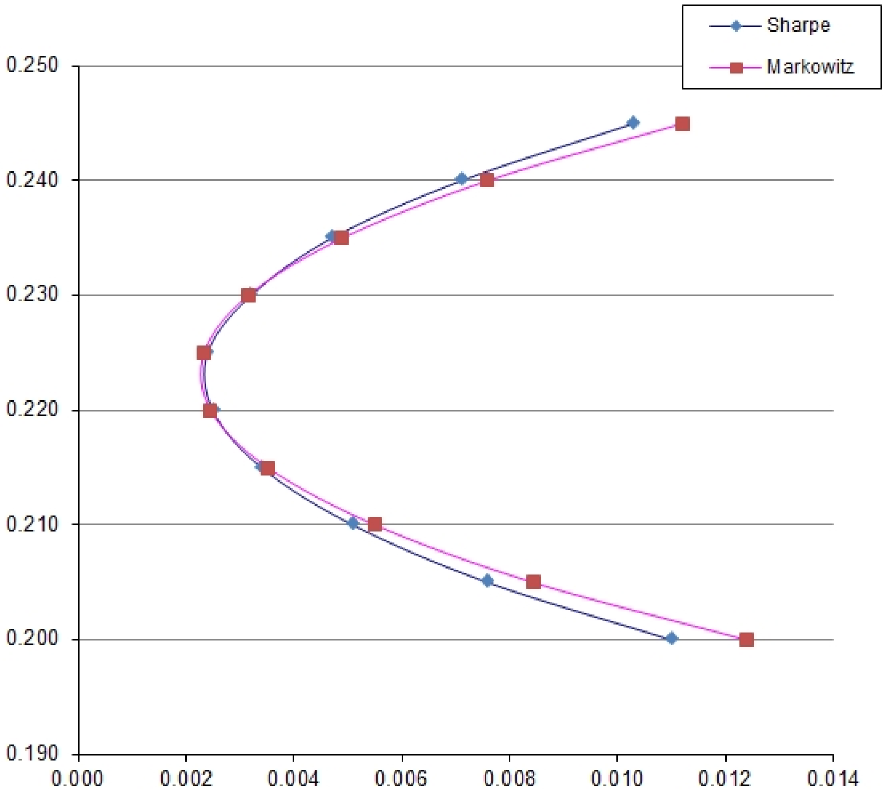


Figure 15.161: Sharpe & Markowitz efficient frontier plot in Microsoft® Excel® 14.07.7173

15.3.10.3.7.3 Equal Risk Contribution optimal weights portfolio

It seems that various numerical studies have shown that the Markowitz portfolio is very sensitive to small variations in assets values or simply to their correlation!

A proposed approach is then to use a portfolio whose contributions to the risk of different assets are equal. We are talking then about an "ERC (Equal Risk Contribution) portfolio" (that must not be confused with the equally weighted portfolio where $\omega_i = \omega_j$ for all i, j and not be confused with the "risk parity portfolio" that we will see further below!).

In order to determine the weights of each of the assets when the correlations are not identical between each other, it seems that there is no analytical solution so as far as we know (it is necessary to go through numerical methods). But let's see the idea with the special case of two assets and without short position (that is to say with non-negative weights).

The total variance of two assets is as we know given by:

$$\begin{aligned} \mathrm{V} &= w_1^2\sigma_1^2 + w_2^2\sigma_2^2 + 2w_1w_2\sigma_{12} = w_1^2\sigma_1^2 + w_2^2\sigma_2^2 + 2w_1w_2\rho\sigma_1\sigma_2 \\ &= w_1^2\sigma_1^2 + (1-w_1)^2\sigma_2^2 + 2w_1(1-w_1)\rho\sigma_1\sigma_2 \end{aligned} \tag{15.3.721}$$

Therefore it is trivial in this situation that the contribution to the risk of each asset is given by the vector:

$$\begin{pmatrix} w_1^2\sigma_1^2 + w_1(1-w_1)\rho\sigma_1\sigma_2 \\ (1-w_1)^2\sigma_2^2 + w_1(1-w_1)\rho\sigma_1\sigma_2 \end{pmatrix} \tag{15.3.722}$$

And so the contribution to risk in percent by:

$$\frac{1}{\sum_i \sigma_i}\begin{pmatrix} w_1^2\sigma_1^2 + w_1(1-w_1)\rho\sigma_1\sigma_2 \\ (1-w_1)^2\sigma_2^2 + w_1(1-w_1)\rho\sigma_1\sigma_2 \end{pmatrix} \tag{15.3.723}$$

In the case that interest us, finding the ERC portfolio involves finding w_1 such that both components of the vector are equal. That is to say:

$$w_1^2\sigma_1^2 + w_1(1-w_1)\rho\sigma_1\sigma_2 = (1-w_1)^2\sigma_2^2 + w_1(1-w_1)\rho\sigma_1\sigma_2 \tag{15.3.724}$$

What is simplified in:

$$w_1^2\sigma_1^2 = (1-w_1)^2\sigma_2^2 \tag{15.3.725}$$

Hence the polynomial of the second degree:

$$w_1^2(\sigma_2^2 - \sigma_1^2) - 2w_1\sigma_2^2 + \sigma_2^2 = 0 \tag{15.3.726}$$

The roots are given then obviously by:

$$\begin{aligned} w_1 &= \frac{2\sigma_2^2 \pm \sqrt{4\sigma_2^4 - 4(\sigma_2^2-\sigma_1^2)\sigma_2^2}}{2(\sigma_2^2-\sigma_1^2)} = \frac{\sigma_2^2 \pm \sqrt{\sigma_2^4 - (\sigma_2^2-\sigma_1^2)\sigma_2^2}}{(\sigma_2^2-\sigma_1^2)} \\ &= \frac{\sigma_2^2 \pm \sqrt{\sigma_2^4 - \sigma_2^4 + \sigma_1^2\sigma_2^2)}}{(\sigma_2^2-\sigma_1^2)} = \frac{\sigma_2^2 \pm \sigma_1\sigma_2}{(\sigma_2^2-\sigma_1^2)} \end{aligned} \tag{15.3.727}$$

and for w_2 just remember that it is just equal to $1-w_1$.

15.3.10.3.7.4 Error tracking optimal weights portfolio

Always in the context of a portfolio with two assets, the goal here is to find the weights that minimize the definition of the error tracking introduced earlier (see page 7724):

$$\text{TE}=\sqrt{\text{V}(R_p-R_f)}=\sigma_{R_p-R_f}=\sqrt{\sigma_p^2+\sigma_f^2-2R_{P,F}\sigma_P\sigma_F} \tag{15.3.728}$$

Or in other words, that minimize:

$$\begin{aligned}\text{TE}^2&=\sigma_p^2+\sigma_f^2-2R_{P,F}\sigma_P\sigma_F\\&=(w_1^2\sigma_1^2+w_2^2\sigma_2^2+2w_1w_2\sigma_1\sigma_2)+\sigma_f^2+2R_{P,F}\sqrt{w_1^2\sigma_1^2+w_2^2\sigma_2^2+2w_1w_2\sigma_1\sigma_2}\,\sigma_f\\&=(w_1^2\sigma_1^2+w_2^2\sigma_2^2+2w_1w_2\sigma_{12})+\sigma_f^2+2R_{P,F}\sqrt{w_1^2\sigma_1^2+w_2^2\sigma_2^2+2w_1w_2\sigma_{12}}\,\sigma_f\end{aligned} \tag{15.3.729}$$

For this we take the partial derivative with respect to one of the weights:

$$\frac{\partial\text{TE}^2}{\partial w_1}=2w_1\sigma_1^2+2\sigma_{12}-2R_{R,F}\frac{2w_1\sigma_1^2+2\sigma_{12}}{\sqrt{w_1^2\sigma_1^2+w_2^2\sigma_2^2+2w_1w_2\sigma_{12}}}\sigma_f=0 \tag{15.3.730}$$

Which is numerically easy to solve for a computer. By hand we did arrived at a satisfactory elegant result (do not hesitate to give us your development if you have a pedagogical elegant solution).

Once you have the result for w_1, to get w_2 just remember that it is just equal to $1-w_1$.

15.3.10.3.7.5 Sharpe optimal weights portfolio

Here we will study the case of minimizing the risk of a portfolio by maximizing the Sharpe ratio already introduced earlier above (see page 7723):

$$S_p=\frac{\text{E}(R_p)-R_f}{\sigma_p} \tag{15.3.731}$$

for a case of a portfolio of two assets (just to simplify...).

In order to simplify the calculations, let us use the excess returns of the two assets rather than their direct return:

$$R_1=r_1-R_f \qquad R_2=r_2-R_f \tag{15.3.732}$$

We then rewrite the Sharpe ratio:

$$\begin{aligned}S_p&=\frac{\text{E}(R_p)-R_f}{\sigma_p}=\frac{(w_1r_1+w_2r_2)-1\cdot R_f}{\sqrt{w_1^2\sigma_1^2+w_2^2\sigma_2^2+2w_1w_2\sigma_{12}}}\\&=\frac{(w_1r_1+w_2r_2)-(w_1+w_2)\cdot R_f}{\sqrt{w_1^2\sigma_1^2+w_2^2\sigma_2^2+2w_1w_2\sigma_{12}}}=\frac{w_1R_1+w_2R_2}{\sqrt{w_1^2\sigma_1^2+w_2^2\sigma_2^2+2w_1w_2\sigma_{12}}}\end{aligned} \tag{15.3.733}$$

We will now calculate the partial derivative with respect to w_1 and see when this one vanishes (obviously by symmetry the result will be the same for w_2):

$$\begin{aligned}\dfrac{\partial S_p}{\partial w_1}&=\dfrac{R_1}{\sqrt{w_1^2\sigma_1^2+w_2^2\sigma_2^2+2w_1w_2\sigma_{12}}}-\dfrac{1}{2}\dfrac{w_1R_1+w_2R_2}{(w_1^2\sigma_1^2+w_2^2\sigma_2^2+2w_1w_2\sigma_{12})^{3/2}}(2w_i\sigma_1^2+2w_2\sigma_{12})\\&=\dfrac{R_1}{\sqrt{w_1^2\sigma_1^2+w_2^2\sigma_2^2+2w_1w_2\sigma_{12}}}-\dfrac{(w_1R_1+w_2R_2)(w_1\sigma_1^2+w_2\sigma_{12})}{w_1^2\sigma_1^2+w_2^2\sigma_2^2+2w_1w_w\sigma_{12})^{3/2}}=0\end{aligned} \tag{15.3.734}$$

To simplify this we will do some algebraic manipulations. First we will multiply everything by:

$$\sqrt{w_1^2\sigma_1^2+w_2^2\sigma_2^2+2w_1w_2\sigma_{12}} \tag{15.3.735}$$

Which gives:

$$R_1-\dfrac{(w_1R_1+w_2R_2)(w_1\sigma_1^2+w_2\sigma_{12})}{w_1^2\sigma_1^2+w_2^2\sigma_2^2+2w_1w_2\sigma_{12}}=0 \tag{15.3.736}$$

We multiply on both sides of the equality by the denominator of the second term:

$$R_1(w_1^2\sigma_1^2+w_2^2\sigma_2^2+2w_1w_2\sigma_{12})-(w_1R_1+w_2R_2)(w_1\sigma_1^2+w_2\sigma_{12})=0 \tag{15.3.737}$$

Therefore:

$$\cancel{w_1^2R_1\sigma_1^2}+w_2^2R_1\sigma_2^2+2w_1w_2R_1\sigma_{12}-\cancel{w_1^2R_1\sigma_1^2}-w_1w_2R_1\sigma_{12}-w_1w_2R_2\sigma_1^2-w_2^2R_2\sigma_{12}=0 \tag{15.3.738}$$

and also:

$$\begin{aligned}w_2^2R_1\sigma_2^2+&(2w_1w_2R_1\sigma_{12}-w_1w_2R_1\sigma_{12})-w_1w_2R_2\sigma_1^2-w_2^2R_2\sigma_{12}\\&=w_2^2R_1\sigma_2^2+w_1w_2R_1\sigma_{12}-w_1w_2R_2\sigma_1^2-w_2^2R_2\sigma_{12}\\&=w_2R_1\sigma_2^2+w_1R_1\sigma_{12}-w_1R_2\sigma_1^2-w_2R_2\sigma_{12}=0\end{aligned} \tag{15.3.739}$$

We do a small substitution:

$$(1-w_1)R_1\sigma_2^2+w_1R_1\sigma_{12}-w_1R_2\sigma_1^2-(1-w_1)R_2\sigma_{12}=0 \tag{15.3.740}$$

Which gives:

$$w_1=\dfrac{R_1\sigma_2^2-R_2\sigma_{12}}{R_1\sigma_2^2+R_2\sigma_1^2-(R_1+R_2)\sigma_{12}} \tag{15.3.741}$$

and for w_2 just remember that it is just equal to $1-w_1$.

15.3.10.3.7.6 Maximum diversification optimal weights portfolio

The idea of this portfolio based on the principle of maximizing the "diversification ratio" is defined by:

$$\boxed{\text{DR}=\dfrac{\displaystyle\sum_i w_i\sigma_i}{\sigma_p}} \tag{15.3.742}$$

or in vector-matrix form:

$$\text{DR} = \frac{\vec{w}^T \cdot \text{diag}(\Sigma)}{\sqrt{\vec{w}^T \Sigma \vec{w}}} \qquad (15.3.743)$$

Indeed, since a diversified portfolio must have the smallest standard deviation portfolio (denominator tends to zero). So this ratio will have to be maximal, such that our optimization problem is then written:

$$\boxed{\begin{aligned} &\underset{\vec{\omega}}{\text{maximize}} && \text{DR} = \frac{\vec{w}^T \cdot \text{diag}(\Sigma)}{\sqrt{\vec{w}^T \Sigma \vec{w}}} \\ &\text{subject to} && \sum w_i = 1 \end{aligned}} \qquad (15.3.744)$$

If we write it down for two assets, then we have:

$$\text{DR} = \frac{w_1\sigma_1 + w_2\sigma_2}{\sqrt{w_1^2\sigma_1^2 + w_2^2\sigma_2^2 + 2w_1w_2\sigma_{12}}} \qquad (15.3.745)$$

Let us compare this expression with that obtained in our study of Sharpe's risk minimization portfolio seen previously:

$$S_p = \frac{w_1R_1 + w_2R_2}{\sqrt{w_1^2\sigma_1^2 + w_2^2\sigma_2^2 + 2w_1w_2\sigma_{12}}} \qquad (15.3.746)$$

So we have exactly the same thing except that we have to replace two variables. So by taking up the final result of Sharpe's minimum risk model which was for recall:

$$w_1 = \frac{R_1\sigma_2^2 - R_2\sigma_{12}}{R_1\sigma_2^2 + R_2\sigma_1^2 - (R_1 + R_2)\sigma_{12}} \qquad (15.3.747)$$

It then comes for the present case:

$$w_1 = \frac{\sigma_1\sigma_2^2 - \sigma_2\sigma_{12}}{\sigma_1\sigma_2^2 + \sigma_2\sigma_1^2 - (\sigma_1 + \sigma_2)\sigma_{12}} \qquad (15.3.748)$$

and for w_2 just remember that it is just equal to $1 - w_1$.

15.3.10.3.7.7 Treynor-Black optimal weights portfolio

The Treynor-Black (11973 according to holocene calendar) portfolio management model is closely linked to active portfolio management, which underlying idea is to outperform the benchmark portfolio's market by discretionary selection of the products, securities or sectors the most likely to grow faster than the market.

To introduce this model we will consider that we have a passive portfolio M that best replicates a market index (purchase of long-term assets selected on the basis of a known market index such as the CAC40, SP500, etc.) and an active portfolio A.

To simplify the calculations, let us use portfolio excess returns rather than their direct return:

$$\begin{aligned} R_A &= r_A - R_f \\ R_M &= r_M - R_f \end{aligned} \qquad (15.3.749)$$

According to the Treynor-Black model, the market portfolio has an α equal to zero because it is supposed to replicate the market without error. According to the Sharpe model (single index model), we can write:

$$R_A = \alpha_A + \beta_A(r_M - R_f) = \alpha_A + \beta_A r_M \tag{15.3.750}$$

We will also use the relationship demonstrated earlier above (see page 7718):

$$\sigma_A = \beta_A^2 r_M^2 + \sigma_\varepsilon^2 \tag{15.3.751}$$

and also (see page 7720):

$$\beta_A = \frac{\text{cov}(R_A, R_M)}{\text{V}(R_M)} = \frac{\sigma_{AM}}{\sigma_M^2} \Leftrightarrow \sigma_{AM} = \beta_A \sigma_M^2 \tag{15.3.752}$$

We will also use the relation proved just before for the optimum weight of a two-asset portfolio that maximizes the Sharpe ratio:

$$w_1 = \frac{R_1\sigma_2^2 - R_2\sigma_{12}}{R_1\sigma_2^2 + R_2\sigma_1^2 - (R_1 + R_2)\sigma_{12}} \tag{15.3.753}$$

This last relation is written in our context:

$$\begin{aligned}
w_A &= \frac{R_A\sigma_M^2 - R_M\sigma_{AM}}{R_A\sigma_M^2 + R_M\sigma_A^2 - (R_A + R_M)\sigma_{AM}}\\
&= \frac{(\alpha_A + \beta_A R_M)\sigma_M^2 - R_M\beta_A\sigma_M^2}{(\alpha_A + \beta_A R_M)\sigma_M^2 + R_M\sigma_A^2 - (\alpha_A + \beta_A R_M + R_M)\beta_A\sigma_M^2}\\
&= \frac{\alpha_A\sigma_M^2}{(\alpha_A + \beta_A R_M)\sigma_M^2 + R_M\sigma_A^2 - (\alpha_A + \beta_A R_M + R_M)\beta_A\sigma_M^2}\\
&= \frac{\alpha_A}{\alpha_A + \beta_A R_M + R_M\dfrac{\sigma_A^2}{\sigma_M^2} - \alpha_A\beta_A - \beta_A^2 R_M - \beta_A R_M}\\
&= \frac{\alpha_A}{\alpha_A + R_M\dfrac{\sigma_A^2}{\sigma_M^2} - \alpha_A\beta_A - \beta_A^2 R_M} = \frac{\alpha_A}{\alpha_A(1 - \beta_A) + R_M\frac{\sigma_A^2}{\sigma_M^2} - \beta_A^2 R_M}\\
&= \frac{\alpha_A}{\alpha_A(1 - \beta_A) + R_M\dfrac{\beta_A^2\sigma_M^2 + \sigma_\varepsilon^2}{\sigma_M^2} - \beta_A^2 R_M}\\
&= \frac{\alpha_A}{\alpha_A(1 - \beta_A) + \dfrac{R_M(\beta_A^2\sigma_M^2 + \sigma_\varepsilon^2) - \beta_A^2 R_M\sigma_M^2}{\sigma_M^2}} = \frac{\alpha_A}{\alpha_A(1 - \beta_A) + \dfrac{R_M\sigma_\varepsilon^2}{\sigma_M^2}}
\end{aligned} \tag{15.3.754}$$

Now we are going to assume that the beta of the active portfolio is equal to 1 because at the beginning of the construction of our portfolio A we will align it with the portfolio M. Then we have in this case:

$$w_A^0 = \frac{\alpha_A}{\dfrac{R_M\sigma_\varepsilon^2}{\sigma_M^2}} = \frac{\alpha_A}{\sigma_\varepsilon^2}\frac{\sigma_M^2}{R_M} = \frac{\dfrac{\alpha_A}{\sigma_\varepsilon^2}}{\dfrac{R_M}{\sigma_M^2}} \tag{15.3.755}$$

This is the expression we find in the textbooks as being the initial position in the active portfolio. The numerator is the contribution to the weight of the active portfolio while the denominator is the contribution of the market portfolio.

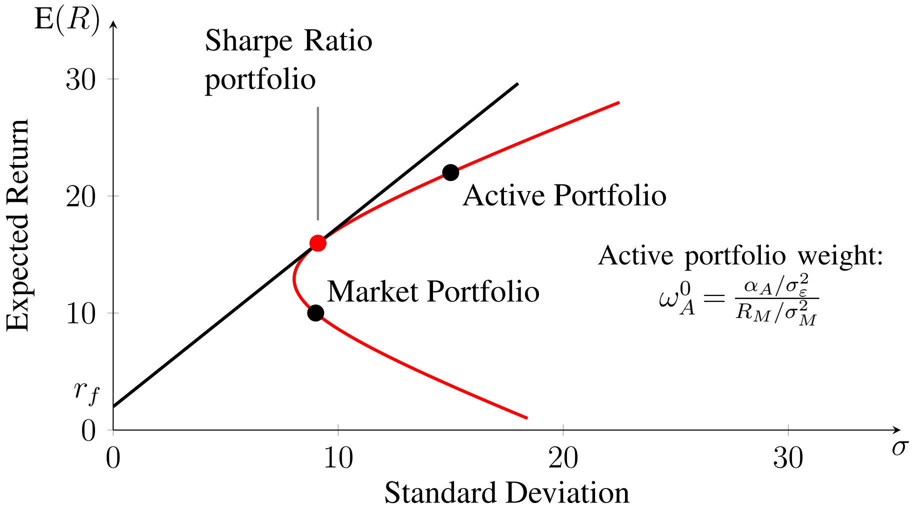

Figure 15.162: Treynor-Black Portfolio Selection

We then see that if the excess return of the passive portfolio's of the market is high this will decrease the weight of the active portfolio A. If the alpha of the active portfolio is high this will increase the weight of the active portfolio A.

Now let us go back to the unbalanced case where the beta of A is no longer equal to 1:

$$\begin{aligned} w_A^* &= \frac{\alpha_A}{\alpha_A(1-\beta_A)+\dfrac{R_M\sigma_\varepsilon^2}{\sigma_M^2}} = \frac{\alpha_A\sigma_M^2}{\alpha_A(1-\beta_A)\sigma_M^2+R_M\sigma_\varepsilon^2} \\ &= \frac{\dfrac{\alpha_A\sigma_M^2}{R_M\sigma_\varepsilon^2}}{\dfrac{\alpha_A(1-\beta_A)\sigma_M^2}{R_M\sigma_\varepsilon^2}+1} = \frac{\dfrac{\alpha_A\sigma_M^2}{R_M\sigma_\varepsilon^2}}{\dfrac{\alpha_A(1-\beta_A)\sigma_M^2}{R_M\sigma_\varepsilon^2}+1} = \frac{w_A^0}{w_A^0(1-\beta_A)+1} \end{aligned} \tag{15.3.756}$$

And do not forget that:

$$w_M^* = 1 - w_A^* \tag{15.3.757}$$

Let's not forget that in our active portfolio we have several assets. We can then write:

$$w_i^0 = \frac{\alpha_i}{\sigma_{\varepsilon,i}^2} \tag{15.3.758}$$

but the sum of the weights must be equal to 1. So we write:

$$w_i = \frac{\dfrac{\alpha_i}{\sigma_{\varepsilon,i}^2}}{\displaystyle\sum_i \frac{\alpha_i}{\sigma_{\varepsilon,i}^2}} \tag{15.3.759}$$

Since alpha can be negative, weights can be negative too (usually the active portfolio is composed of long and short positions).

Therefore we get:

$$w_i^* = w_A^* \frac{\dfrac{\alpha_i}{\sigma_{\varepsilon,i}^2}}{\sum\limits_i \dfrac{\alpha_i}{\sigma_{\varepsilon,i}^2}} \tag{15.3.760}$$

15.3.10.3.7.8 Risk Parity Portfolio

A risk parity portfolio denotes a class of portfolios whose assets verify the following equalities:

$$\omega_i \frac{\partial f(\vec{\omega})}{\partial \omega_i} = \omega_j \frac{\partial f(\vec{\omega})}{\partial \omega_j}, \forall i,j \tag{15.3.761}$$

where f is a positively homogeneous function of degree one that measures the total risk of the portfolio and $\vec{\omega}$ is the portfolio weight vector. In other words, the marginal risk contributions for every asset in a risk parity portfolio are equal. A common choice for f, for instance, is the standard deviation of the portfolio, which is usually named "volatility", i.e.:

$$\sigma_P = f(\vec{\omega}) = \sqrt{\vec{\omega}^T \Sigma \vec{\omega}} \tag{15.3.762}$$

where Σ is the covariance matrix of the assets.

With that particular choice of f, the risk parity requirements become:

$$\omega_i (\Sigma\vec{\omega})_i = \omega_j (\Sigma\vec{\omega})_j, \forall i,j \tag{15.3.763}$$

A natural extension of the risk parity portfolio is the so named "risk budget portfolio", in which the marginal risk contributions match preassigned quantities. Mathematically:

$$\omega_i (\Sigma\vec{\omega})_i = b_i \vec{\omega}^T \Sigma \vec{\omega}, \forall i \tag{15.3.764}$$

where $\vec{b} = (b_1, b_2, \ldots, b_N)$ (with $\mathbb{1}^T \vec{b} = 1$ and $\vec{b} \geq \vec{0}$) is the vector of desired marginal risk contributions.

In the case that Σ is diagonal and with the constraints $\mathbb{1}^T \vec{\omega} = 1$ and $\vec{w} \geq 0$, the risk budgeting portfolio is:

$$\boxed{\omega_i = \frac{\sqrt{b_i}/\sqrt{\Sigma_{ii}}}{\sum\limits_{k=1}^N \sqrt{b_k}/\sqrt{\Sigma_{kk}}} = \frac{\sqrt{b_i}/\sigma_i}{\sum\limits_{k=1}^N \sqrt{b_k}/\sigma_k}, \qquad i = 1 \ldots N} \tag{15.3.765}$$

That latter relation can be found in many textbooks with the case where b_i is not taken into account. Such tat:

$$\omega_i = \frac{1/\sigma_i}{\sum\limits_{k=1}^N 1/\sigma_k}, \qquad i = 1 \ldots N \tag{15.3.766}$$

and in that latter case we have the famous example with two assets:

$$\omega_1=\frac{\dfrac{1}{\sigma_1}}{\dfrac{1}{\sigma_1}+\dfrac{1}{\sigma_2}} \quad (15.3.767)$$

However, for non-diagonal Σ or with other additional constraints or objective function terms, a closed-form solution does not exist and some optimization procedures have to be constructed. The previous diagonal solution can always be used and is named "naive risk budgeting portfolio".

The design of risk parity portfolios as solved just above is of paramount importance both for academia and industry. However, practitioners would like the ability to include additional constraints and objective terms desired in practice, such as the mean return, box constraints, etc. In such cases, the risk-contribution constraints cannot be met exactly due to the trade-off among different objectives or additional constraints.

Let us explore, for instance, the effect of including the expected return as an additional objective in the optimization problem. The problem can be formulated as:

$$\boxed{\begin{array}{ll}\underset{\vec{\omega}}{\min} & \displaystyle\sum_{i=1}^{N}\left(\omega_i\left(\Sigma\vec{\omega}\right)_i-b_i\vec{\omega}^T\Sigma\vec{\omega}\right)^2-\lambda_\mu\vec{\omega}^T\vec{\mu}\\ \text{subject to} & \mathbb{1}^T\vec{\omega}=1,\vec{\omega}\geq\vec{0}\\ & \mathbb{1}^T\vec{b}=1,\vec{b}\geq\vec{0}\end{array}} \quad (15.3.768)$$

where:

$$R(\vec{\omega})=\sum_{i=1}^{N}\left(\omega_i\left(\Sigma\vec{\omega}\right)_i-b_i\vec{\omega}^T\Sigma\vec{\omega}\right)^2 \quad (15.3.769)$$

is the "risk concentration function" or "risk parity function, $\vec{\omega}^T\vec{\mu}$ is the expected return, and λ_μ is a trade-off parameter.

Remark

There are almost a dozens of variations of the empirical optimisation problem above for the Risk Parity portfolio. For people interested to see what are these different variations, you can refer to our `R` companion book.

15.3.10.3.8 Capital Asset Pricing Model (CAPM)

As we have seen before, Markowitz (11959 according to holocene calendar) developed the theory of optimal choice of a portfolio on the basis of the variance and the expected return. Later (11963 according to holocene calendar), Sharpe developed the theory of optimal choice of a portfolio on the basis of risk indices such as beta coefficients to simplify the heavy calculations (but since the computer are almost all powerful enough to run the Markowitz model without difficulties).

Sharpe, Lintner and Mossin (11965 according to holocene calendar) then studied the consequences of these theories to develop an extremely simple theory to evaluate the beta coefficients, expected returns and variances of financial assets portfolio from data statistics on the global market and the specificity of the composition of a portfolio.

This theory based again on the mean-variance problem is named the "Capital Asset Pricing Model" (CAPM) or "Capital Asset Pricing Model at Equilibrium" (CAPME). This is a frequently used model, both by practitioners than academics to evaluate the anticipated returns of equilibrium of any risky assets in the market.

Remark

In facts it is more a set of models named "linear attribution models", the SLM (Sharpe, Lintner and Mossin) CAPM is the most known and easiest one but there is also the Fama-French CAPM (three factors and five factors versions), the Fama-McBeth CAPM, the Carhart CAPM (four factors), the Scholes and William adjusted beta, the Dimson adjusted beta and surely a few other empirical one... that we will not introduce in this textbook because they are completely empirical and mathematically speaking not very beautiful and interesting.

To begin, let us recall that we have already seen in our study of the return that the short periodic rate of return (daily, weekly, monthly, yearly) of an asset is calculated as follows:

$$R_t=\frac{(P_t-P_{t-1})+C_t}{P_{t-1}} \tag{15.3.770}$$

with P_t that is the price of an asset at the period t, P_{t-1} the price of the same asset at the previous asset $t-1$ and finally C_t the cash flow paid by the asset during the period running from $t-1$ to t.

This is used as we know to calculate the "realized return" of an asset while in fact it is the "expected return" return that interest a particular investor.

Obviously we can first define some obvious return statistical indicators. One for example is the "mean daily return", denoted $\bar{R}$ that is just the arithmetic average of the R_t. We can therefore also define the "unbiased instantaneous return volatility", or also named "historical volatility", as:

$$\sigma_I=\sqrt{\frac{\sum\limits_{t=0}^{n}\left(R_t-\bar{R}\right)^2}{n-1}} \tag{15.3.771}$$

The mean daily return being often considered as equal to zero (what is obviously not valid in the field of hyperfrequency market trading!), we can find sometimes in the literature the following relation:

$$\sigma_I=\sqrt{\frac{\sum\limits_{t=0}^{n} R_t^2}{n-1}} \tag{15.3.772}$$

and named "realized volatility" (respectively "realized variance") or sometimes "reality variance".

Using the result of the Bachelier speculation model that we will see further below on page 7842 (under the assumption that the constraints of the model are verified) the projection of these two last relations over a period t' will be given by:

$$\sigma_R=\sigma_I\sqrt{t'} \tag{15.3.773}$$

and named in the case of yearly projection "annualized historical volatility" or respectively "annualized realized volatility".

At the time of taking the decision, the return that will achieve an investor by holding a given asset is uncertain this is why we speak of "expected returns": this is a return that we seek to evaluate and we hope to receive during the next investment period.

To calculate the expected return, as we have seen, it should be allocated to each possible value of the return a probability of realization, then calculate a weighted average of the possible values using the probabilities p_i as weights:

$$\text{E}(R_i)=\mu_i=p_1R_{i1}+p_2R_{i2}+\ldots+p_nR_{in}=\sum_{j=1}^{n} p_jR_{ij} \tag{15.3.774}$$

However, it is clear that in a given economy, investors will be tempted to hold more that one financial assets for obvious reasons and therefore seek to compose portfolios. The expected mean return of a portfolio may be calculated using the known relation:

$$\text{E}(R_P)=X_1\text{E}(R_1)+X_2\text{E}(R_2)+\ldots+X_n\text{E}(R_n)=\sum_{i=1}^{n} X_i\text{E}(R_i)=\sum_{i=1}^{n}\left(X_i\sum_{j=1}^{m} p_jR_{ij}\right) \tag{15.3.775}$$

where for recall n is the number of assets included in the portfolio, $\text{E}(R_i)$ the return of asset i in the portfolio and X_i the proportion of this asset i in the invested portfolio.

The expected return rate is however as we know insufficient to characterize an investment opportunity and we must also take into account the risk, i.e. the variability of the return on that investment over financial assets. The variance is, as we have already seen it, used as simple measurement of risk and given for a financial asset by:

$$\text{V}(R_i)=\sigma_i^2=p_1[R_{i1}-\text{E}(R_i)]^2+p_2[R_{i2}-\text{E}(R_i)]^2+\ldots+[R_{in}-\text{E}(R_i)]^2 \tag{15.3.776}$$

Therefore:

$$\text{V}(R_i)=\sigma_i^2=\sum_{j=1}^{n}(R_{ij}-\text{E}(R_i))^2 p_j \tag{15.3.777}$$

The calculation of the risk of a portfolio thus involves without surprise two important concepts: the variability of returns of each asset, measured by the variances of these, as well as the relationships between the various assets composing the portfolio.

The dependency between two assets is often measured, as we have already mentioned in our previous study of the Sharpe and Markowitz model, by the covariance or the correlation coefficient.

The covariance between two assets i and j is calculated as follows for recall:

$$\text{cov}(R_i,R_j)=p_1[R_{i1}-\text{E}(R_i)][R_{j1}-\text{E}(R_j)]+\ldots+p_n[R_{in}-\text{E}(R_i)][R_{jn}-\text{E}(R_j)] \tag{15.3.778}$$

As we know the probabilities are equally likely (and if we do not work on a sample otherwise we should have $n-1$ instead of n in the denominator for the product factor of the sum):

$$\text{cov}(R_i,R_j)=\frac{1}{n}\sum_{k=1}^{n}(R_{ik}-\text{E}(R_i))(R_{jk}-\text{E}(R_j)) \tag{15.3.779}$$

The covariance between the returns of two assets may be positive or negative and its value has no economic significance - in the sense of causality - as we know (see section Statistics page 614).

Remark

Let us once again recall that we have seen in the section Statistics that when the returns of two active assets vary in the same direction (respectively in opposite direction) their covariance will be positive (respectively negative).

The correlation coefficient between two assets i and j meanwhile is calculated as follows (see section Statistics page 614):

$$R_{ij}=\frac{\text{cov}(R_i,R_j)}{\sqrt{\text{V}(R_i)\text{V}(R_j)}}=\frac{c_{ij}}{\sigma_i\sigma_j} \tag{15.3.780}$$

Once the variance and covariance of the various assets calculated, we will be able to calculate the variance of the return of whole portfolio with n sets. This variance is given by the following relation as already proved in the section Statistics and the previous models above:

$$\text{V}(R_p)=\sum_{i=1}^{n}\sum_{j=1}^{n}X_iX_j\text{cov}(R_i,R_j)=\sum_{i=1}^{n}nX_i^2\sigma_i^2\sum_{i,j|i\neq j}X_iX_j\text{cov}(R_i,R_j) \tag{15.3.781}$$

or written differently:

$$\text{V}(R_p)=\sum_{i=1}^{n}X_i^2\text{V}(R_i)+2\sum_{i,j|i<j}X_iX_j\text{cov}(R_j,R_j) \tag{15.3.782}$$

The above relation of the variance of portfolio return clearly shows that even if the returns to different assets in the portfolio are completely uncorrelated, the variance of the latter can be further reduced by adding more assets.

To understand this, we notice that for n uncorrelated assets, the variance is reduced to (since the covariance is then zero):

$$\text{V}(R_P)=\sigma_P^2=\sum_{i=1}^{n} X_i^2\sigma_i^2 \tag{15.3.783}$$

Simplifying even more, if all variances are assumed equal and if all the assets are held in the same proportions $(1/n)$, we have obviously:

$$\sigma_P^2=\sum_{i=1}^{n}\left(\frac{1}{n}\right)^2\sigma_i^2=n\left(\frac{1}{n}\right)^2\sigma_i^2=\frac{1}{n}\sigma_i^2 \tag{15.3.784}$$

Thus, when n approaches infinity, the portfolio variance approaches zero. So if uncorrelated risks are combined portfolio, total risk can be eliminated by diversification, we speak then as we know of "diversifiable risk". In the cases where the risks are correlated, diversification eliminate only the risks specific to the assets while the market risk will continue to exist.

Notice that the risk reduction is greater when the various assets held are negatively correlated!!! In this situation, it is possible to combine risky assets to form a completely riskless portfolio!!!!

From the foregoing, it is clear that any investor wishing to build a portfolio will seek to hold a set of risky assets that will allow him to receive some return with minimum risk. In other words, he will seek to minimize the variance for an expected level of performance while respecting some budget constraints. We know that the expected return and the performance variance of a portfolio containing n risky assets are written as follows:

$$\begin{aligned}\text{E}(R_P)&=\sum_{i=1}^{n} X_i\text{E}(R_i)\\ \text{V}(R_P)&=\sum_{i=1}^{n}\sum_{i=j}^{n} X_iX_j\text{cov}_{ij}\end{aligned} \tag{15.3.785}$$

Moreover, we know that from these n assets that it is possible to construct an infinite number of portfolios by varying the weights X_i. But the most interesting portfolios for a particular investor portfolios are those that minimize the risk that he must endure to achieve a given level of performance. These portfolios are the result of the following minimization problem that is as we already know a non-linear optimization problem (see section Numerical Methods page 6662):

$$\begin{aligned}\underset{\text{V}(R_P)}{\text{minimize}}\quad & \text{E}(R_P)=c^{te}\\ \text{subject to}\quad & \sum X_i=1\end{aligned} \tag{15.3.786}$$

that we had already seen in our study of the Markowitz model.

It is therefore possible to create an infinite number of portfolios by varying the proportions invested in each asset. The next step is to select from among all available portfolios, a given portfolio. To do this, one must consider the individual preferences of the investor.

A rational investor should therefore consider only the portfolios lying on the efficient frontier for its investment choices. Its optimal portfolio will be at the point of tangency between the efficient frontier and its highest indifference curve that it would be capable of achieving.

Let us explicit that a little bit...! Consider for this the following MATLAB® plot:

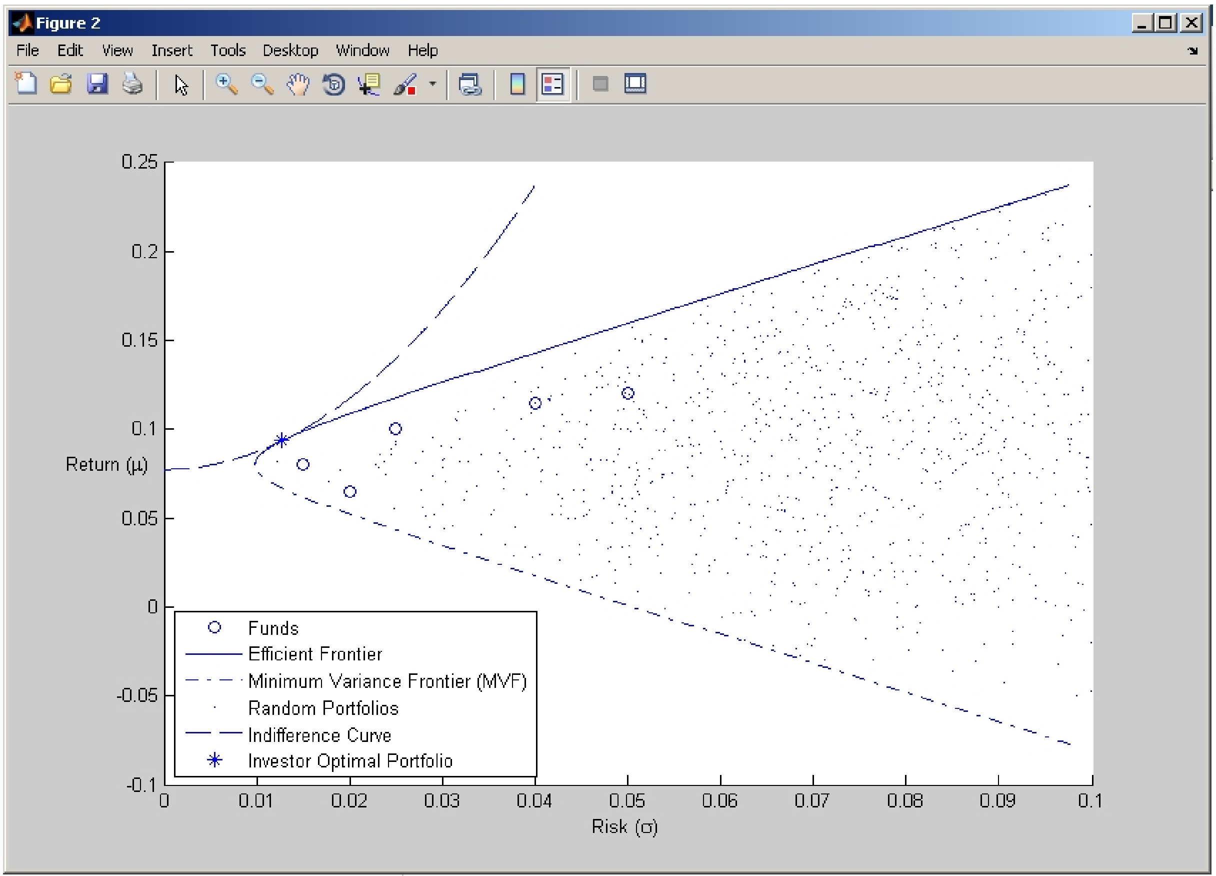

Figure 15.163: **Efficient frontier and indifference curve in MATLAB® 2013a**

The indifference curve above is quit obvious to understand: the average investor agree to take more risk as the expected returns increase and expect a zero risk when the return is the minimum of the mark risk free rate. This indifference curve is for most people obviously with a convex shape (the opposite would be quite hard to explain...).

By doing so, each investor maximizes his expected utility. In the presence of an economy containing only risky assets, the composition of the portfolio of risky assets varies from one individual to another.

To determine the correct (best) tangent to indifference curve and efficient frontier we can use an information partially available on the market: the risk free rate. Indeed, almost all investors have the possibility to invest in risk free financial assets. We will then seek for the portfolio that is the prolongation of the risk free investment and therefore corresponding to the tangent of a given indifference curve as visible in the figures above and below:

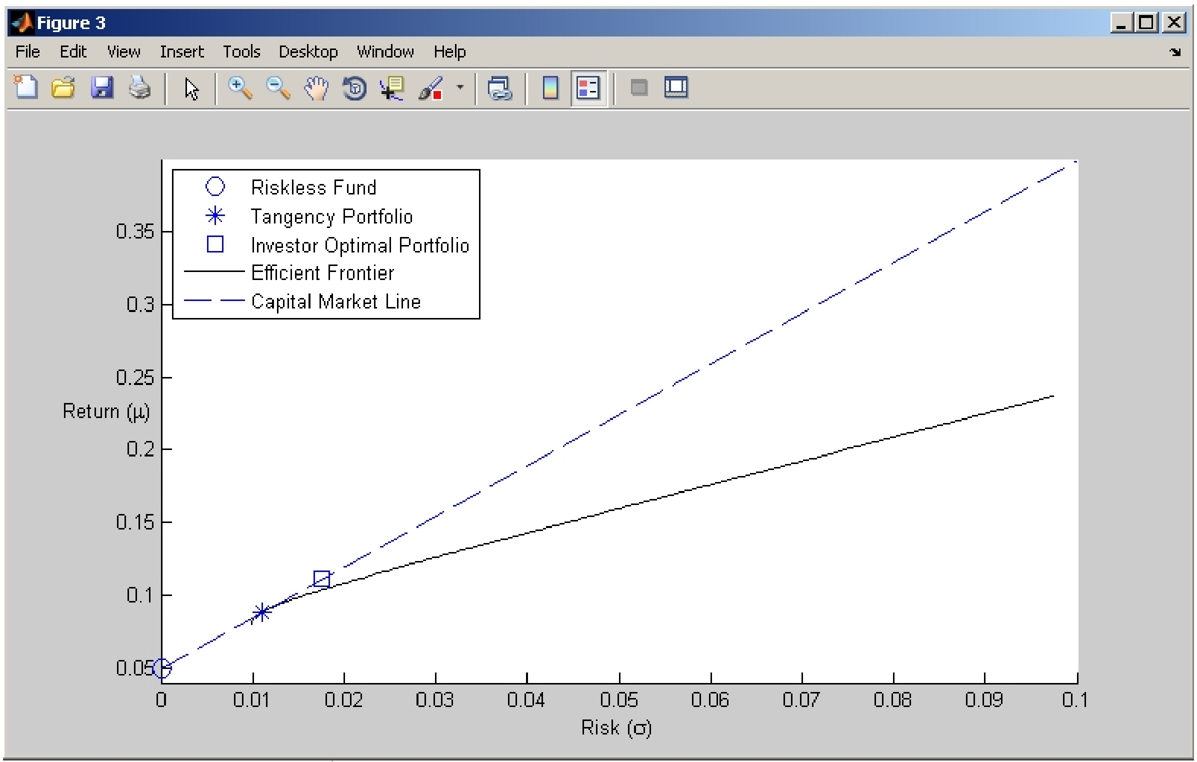

Figure 15.164: **Efficient frontier and SML in MATLAB® 2013a**

Then let us consider a portfolio that is a combination of risk-free assets (or risk free sub-portfolio) and the at risk asset (a market non-risk free portfolio). Then we have:

$$R_P = X_M R_M + (1 - X_M) R_f \tag{15.3.787}$$

where X_M is the fraction of the portfolio invested in the market portfolio (M) of return R_M and R_f is as always the risk-free rate return (or "certain return").

We then have (remember that the expected mean of a constant is equal to that constant as proved in the section Statistics):

$$\mathrm{E}(R_P) = X_M \mathrm{E}(R_M) + (1 - X_M)\mathrm{E}(R_f) = X_M \mathrm{E}(R_M) + (1 - X_M) R_f \tag{15.3.788}$$

and therefore:

$$\begin{aligned}\mathrm{V}(R_P) &= \mathrm{V}(X_M R_M + (1 - X_M) R_P)\\ &= \mathrm{E}\left[(X_M R_M + (1 - X_M) R_P - \mathrm{E}\left(X_M R_M + (1 - X_M) R_P\right))^2\right]\\ &= \mathrm{E}\left[(X_M R_M + (1 - X_M) R_P - X_M \mathrm{E}(R_M) - (1 - X_M) R_P)^2\right]\\ &= \mathrm{E}\left[(X_M R_M - X_M \mathrm{E}(R_M))^2\right] = \mathrm{E}\left[X^2 \left(R_M - \mathrm{E}(R_M)\right)^2\right]\\ &= X_M^2 \mathrm{E}\left[(R_M - \mathrm{E}(R_M))^2\right] = X_M^2 \mathrm{V}(R_M)\end{aligned} \tag{15.3.789}$$

Either in condensed form:

$$\sigma_P^2 = X_m^2 \sigma_M^2 \tag{15.3.790}$$

The derivative of expected return relatively to X_M gives us:

$$\frac{\partial \mathrm{E}(R_P)}{\partial X_M} = \mathrm{E}(R_M) - R_f \tag{15.3.791}$$

The derivative of the standard deviation relatively to X_M gives us (don't forget that the standard deviation of a constant is equal to zero!):

$$\frac{\partial\sigma(R_P)}{\partial X_M}=\sigma(R_M) \tag{15.3.792}$$

Putting these results together (ratio), we have:

$$\frac{\partial\mathrm{E}(R_P)}{\partial\sigma(R_P)}=\frac{\mathrm{E}(R_M)-R_f}{\sigma(R_M)} \tag{15.3.793}$$

and since:

$$\mathrm{E}(R_P)=X_M\mathrm{E}(R_M)+(1-X_M)R_f=X_M(\mathrm{E}(R_M)-R_f)+R_f \tag{15.3.794}$$

It comes then:

$$\mathrm{E}(R_P)=\frac{\sigma(R_P)}{\sigma(R_M)}(\mathrm{E}(R_M)-R_f)+R_f \tag{15.3.795}$$

And since the main target in finance is to represent graphically as for the Markowitz and Sharpe efficient frontier plot:

$$\mathrm{E}(R_P)=f(\sigma(R_P)) \tag{15.3.796}$$

So, it is traditional to write the prior-previous relation like an affine function:

$$\boxed{\mathrm{E}(R_P)=\frac{\mathrm{E}(R_M)-R_f}{\sigma(R_M)}\sigma(R_P)+R_f=(\mathrm{E}(R_M)-R_f)\frac{\sigma(R_P)}{\sigma(R_M)}+R_f} \tag{15.3.797}$$

This relation is the equation of a line named "capital market line" (C.M.L.). This line is a linear combination of the portfolios having risky assets with a free risk asset[26]. Therefore all efficient portfolios from the efficient frontier are dominated by those situated on that line for a same level of risk excepted in the case of the tangent portfolio hence it's name "super-efficient portfolio".

The intercept is obviously R_f and its slope is a variable function of the expected mean and standard deviation of the market portfolio and the factor find in front of the standard deviation of the R_P is the "Sharpe ratio" that we have already met multiple times so far:

$$S_P=\frac{R_P-R_f}{\sigma_P} \tag{15.3.798}$$

but without proving its origin... (but now the readers finally know where it comes from). Notice that in a well build portfolio we should have $S_P>0$ therefore the slope of the C.M.L. should be always positive!

The above equation is the central relation of the CAPM ("one-factor") model. Any portfolio measured on the market which is outside this line of this model is considered (at least in theory) as not being in balance.

---

[26] The capital market line (CML) represents portfolios that optimally combine risk and return. CML is a special case of the capital allocation line (CAL) defined earlier where the risk portfolio is the market portfolio.

By construction, this line equation therefore associates with each level of risk, the highest expected return at the intersection of the efficient frontier. Thus, given the performance of a risk-free asset it becomes easy from this equation to determine the point of tangency with the efficiency frontier of Markowitz or Sharpe to get the most efficient portfolio based on the risk-free performance and even without knowing the indifference curve!!

Let us now determine an equation for the expected return of any individual asset.

Consider a new portfolio of return R_P which is a combination of any unique asset A and the reference market portfolio, where X_A is the fraction of the portfolio invested in the asset A.

What we would like to do is to evaluate the slope of the curve of the combinations expected mean/standard deviation of the returns when we combine the market portfolio with the asset A.

We wish to evaluate the value of the slope of the tangent to the efficient frontier such that the weighting of the asset A is zero.

We have:

$$R_P = X_A R_A + (1-X_A) R_M \tag{15.3.799}$$

We get immediately:

$$\text{E}(R_P) = X_A \text{E}(R_A) + (1-X_A)\text{E}(R_M) \tag{15.3.800}$$

and (see section Statistics page 596 and page 597):

$$\sigma^2(R_P) = X_A^2\sigma^2(R_A) + (1-X_A)^2\sigma(R_M) + 2X_A(1-X_A)\text{cov}(R_A, R_M) \tag{15.3.801}$$

Let us derivate the expected return of the portfolio relatively to X_A, we get then for the expected mean:

$$\frac{\partial \text{E}(R_P)}{\partial X_A} = \text{E}(R_A) - \text{E}(R_M) \tag{15.3.802}$$

Doing same for the standard deviation, we get:

$$\frac{\partial \sigma(R_P)}{\partial X_A} = \frac{1}{2}\frac{2X_A\sigma^2(R_A) - 2(1-X_A)\sigma^2(R_M) + (2-4X_A)\text{cov}(R_A, R_M)}{\sqrt{X_A^2\sigma^2(R_A) + (1-X_A)^2\sigma(R_M) + 2X_A(1-X_A)\text{cov}(R_A, R_M)}} \tag{15.3.803}$$

The contribution of Sharpe and Lintner was that we must evaluate these derivatives at the point where $X_A = 0$ that is to say where the weighting of asset A in the new portfolio is zero.

In doing so, we get the following expression for the standard deviation of the new portfolio (of course, the expression for the expected return does not change):

$$\left.\frac{\partial \sigma(R_P)}{\partial X_A}\right|_{X_A=0} = \frac{1}{2}\frac{-2\sigma^2(R_M) + 2\text{cov}(R_A, R_M)}{\sqrt{\sigma^2(R_M)}} \tag{15.3.804}$$

which gives after simplification:

$$\left.\frac{\partial \sigma(R_P)}{\partial X_A}\right|_{X_A=0} = \frac{\text{cov}(R_A, R_M) - \sigma^2(R_M)}{\sigma(R_M)} \tag{15.3.805}$$

With the both derivatives above, we can obtain an expression for the curve of the combinations means/standard deviation for the new portfolio. Then we have:

$$\frac{\left.\dfrac{\partial \mathrm{E}(R_P)}{\partial X_A}\right|_{X_A=0}}{\left.\dfrac{\partial \sigma(R_P)}{\partial X_A}\right|_{X_A=0}}=\left.\frac{\partial \mathrm{E}(R_P)}{\partial \sigma(R_P)}\right|_{X_A=0}=\frac{\mathrm{E}(R_A)-\mathrm{E}(R_M)}{\dfrac{\mathrm{cov}(R_A,R_M)-\sigma^2(R_M)}{\sigma(R_M)}} \tag{15.3.806}$$

This slope must be equal to that of the C.M.L. By equalizing, we get:

$$\frac{\mathrm{E}(R_M)-R_f}{\sigma(R_M)}=\frac{\mathrm{E}(R_A)-\mathrm{E}(R_M)}{\dfrac{\mathrm{cov}(R_A,R_M)-\sigma^2(R_M)}{\sigma(R_M)}} \tag{15.3.807}$$

After a trivial simplification we get:

$$\frac{\mathrm{E}(R_M)-R_f}{\sigma^2(R_M)}=\frac{\mathrm{E}(R_A)-\mathrm{E}(R_M)}{\mathrm{cov}(R_A,R_M)-\sigma^2(R_M)} \tag{15.3.808}$$

And therefore after rearranging:

$$\begin{aligned}\mathrm{E}(R_A)&=\frac{\mathrm{E}(R_M)-R_f}{\sigma^2(R_M)}\left(\mathrm{cov}(R_A,R_M)-\sigma^2(R_M)\right)+\mathrm{E}(R_M)\\&=(\mathrm{E}(R_M)-R_f)\frac{\mathrm{cov}(R_A,R_M)}{\sigma^2(R_M)}-\mathrm{E}(R_M)+R_f+\mathrm{E}(R_M)\\&=(\mathrm{E}(R_M)-R_f)\frac{\mathrm{cov}(R_A,R_M)}{\sigma^2(R_M)}+R_f\end{aligned} \tag{15.3.809}$$

Hence:

$$\mathrm{E}(R_A)-R_f=(\mathrm{E}(R_M)-R_f)\frac{\mathrm{cov}(R_A,R_M)}{\sigma^2(R_M)} \tag{15.3.810}$$

By putting what we have already seen during our study of the Sharpe model, that is to say the non-diversifiable risk as beta factor:

$$\beta=(\mathrm{E}(R_M)-R_f)\frac{\mathrm{cov}(R_A,R_M)}{\sigma^2(R_M)} \tag{15.3.811}$$

So it is the volatility of the return of the non-risky asset compared to that to the market portfolio.

Then we have:

$$\mathrm{E}(R_A)-R_f=(\mathrm{E}(R_M)-R_f)\beta \tag{15.3.812}$$

This expression allows to express the excess return of risk-free asset as the product of the excess return of the market portfolio and the beta factor of the risk-free asset.

The excess return of an asset does not directly depend of its variance, which is often an intuitive measure of risk of an asset. What counts is its beta factor, which depends on its covariance with the market portfolio.

More typically, the last relation is used graphically as a straight line equation:

$$\boxed{\mathrm{E}(R_A)=f(\beta)=(\mathrm{E}(R_M)-R_f)\beta+R_f} \tag{15.3.813}$$

and written in many textbooks (or in the case of multiple assets), as:

$$\mathrm{E}(R_i)=f(\beta_i)=(\mathrm{E}(R_M)-R_f)\beta_i+R_f \tag{15.3.814}$$

This relation is named the "security market line" (SML), and more rarely "market asset line", it is extremely important in finance, as it therefore gives the mean expected return of an asset A in function of the beta, of the market return and the risk free rate. This model is say to be "monofactorial" in that it does distinguish only single explanatory factor of the risk of an asset (at the opposite of the Fama-French CAPM, Fama-McBeth CAPM or Carhart CAPM).

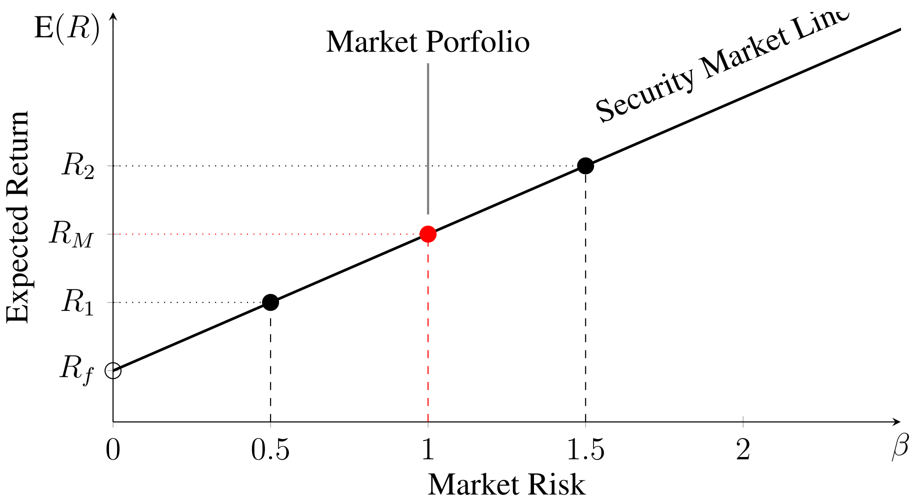

Figure 15.165: **Security Market Line**

There are obviously more complex models taking into account other additional factors such as the Fama-French model that use three explanatory variables of even five variables.

✍**Example:**

The risk free rate is 5% and the expected market return is 8%. An asset A is twice more sensible to market movement than the benchmark, verbatim when the index recorded an increase of 1%, the asset A increase of 2%. According to S.M.L, the expected return is therefore by applying:

$$\mathrm{E}(R_A)=(\mathrm{E}(R_M)-R_f)\beta+R_f=(8\%-5\%)\cdot 2+5\%=11\% \tag{15.3.815}$$

Remark

The reader will have easily noticed that in the above relation, if the beta is equal to unity, the expected return of asset A is then equal to the expected return of the market. The CAPM is then only a tool for determining excess return that we can expect wait when one invests in a portfolio or a company (company whose return is estimated on the basis of its dividend).

The latter relation can also be found in the literature under the following form (without the error term):

$$\mathrm{E}(R_A)=\lambda\beta+R_f \qquad (15.3.816)$$

with λ that is named the "premium per unit of risk" or just "risk premium" (excess of return required by investors when they put their money in the market benchmark portfolio rather than any other asset) and the ordinate is obviously the risk free interest rate (usually based on government bonds).

We have already met this relation (named "single-factor benchmark return") previously on page 7717 but in the following form:

$$R_i=\alpha_i+\beta_i I+\varepsilon_i \qquad (15.3.817)$$

Finally, let indicate that in theory (in the case of no arbitrage opportunity) we should have:

$$\mathrm{E}(R_A)-\left[\left(\mathrm{E}(R_M)-R_f\right)\beta+R_f\right]=0 \qquad (15.3.818)$$

but in practice with the numerical values of the market the result can be different from zero. This "anomaly" in the market is therefore named the "Jensen alpha":

$$\alpha_J=\mathrm{E}(R_A)-\left[\left(\mathrm{E}(R_M)-R_f\right)\beta+R_f\right] \qquad (15.3.819)$$

If Jensen's alpha is greater than 0, this obviously means that the portfolio asset beats its reference market portfolio. If it is less than 0, the asset portfolio underperformed the market portfolio.

The CAPM therefore stipulates that the expected rate of return (or that should require a rational investor having a risk aversion) of risky assets must be equal the rate of return of risk-free asset, plus a risk premium named sometimes "credit spread". In this case, the relation between systematic risk and expected return remains linear.

It may be interesting to clarify the mathematical assumptions on which were based the developments we have made so far! So these are the assumptions of the CAPM, some of which seem difficult to accept. However the reader should not forget that the validity of a model does not depend on the realism of its assumptions but on the conformity of its implications with reality!!

We have for recall stated explicitly or implicitly the following assumptions:

H1. Investors make up their portfolios being concerned exclusively by the expected return and the variance of these

H2. Investors are risk averse: they do not like risk

H3. There is no transaction cost (which is a joke in the case of delta-hedging[27]...)

H4. The assets are perfectly divisible

H5. Neither dividends nor capital gains are taxed

---

[27] most modern software can take transaction costs into account

H6. Many buyers and sellers are involved in the market and none of them can have influence on prices (perfect information)

H7. All investors can lend or borrow the amount they wish at the risk free rate and that latter is known by all

H8. The anticipation of the different investors are homogeneous

H9. The investment period is the same for all investors

Other more modern and complex models have been developed since obviously as we have already mention it multiple times! Taking into account for example the asymmetrical distribution of returns (non-normal) or based on the semivariance rather than the variance, base on a priori estimates of the market behaviour, or based not only on a single factor, etc.

✍**Example:**

For the example let us return to our example of the Markowitz model for which we had for recall for the assets:

	A	B	C	D
1	**Obs.**	**Asset 1**	**Asset 2**	**Asset 3**
2	1	-0.15	0.29	0.38
3	2	0.05	0.18	0.63
4	3	-0.43	0.24	0.46
5	4	0.79	0.25	0.36
6	5	0.32	0.17	-0.57

$R_{5,3}$

with some elementary indicators:

	A	B	C	D
13		**Asset 1**	**Asset 2**	**Asset 3**
14	X_i	1/3	1/3	1/3
15	$\hat{\mu}_i$	0.116	0.226	0.252
16	$\hat{\sigma}_i^2$	0.21728	0.00253	0.22247

And for the covariance matrix:

	F	G	H	I
13	$c_{i,j}$	**Asset 1**	**Asset 2**	**Asset 3**
14	**Asset 1**	0.21728	-0.00422	-0.06687
15	**Asset 2**	-0.00422	0.00253	0.01059
16	**Asset 3**	-0.06687	0.01059	0.22247

Now we will determine the capital market line for this example which is for recall the line formed by all portfolios composed of assets without risk, on one hand, and the market portfolio, on the other. By construction, it associates at each level of risk, the highest expected return.

To determine this line with Microsoft® Excel® we set first an initial rate of return without risk R_f that we arbitrarily take as worth 0.22 (in Switzerland in the year 12011 according to holocene calendar, the risk-free yield was estimated at 1% for example...) and to simplify the analysis with the spreadsheet software we will take the naive approach consisting by interpolating the efficiency frontier by the equation of a parabola such that:

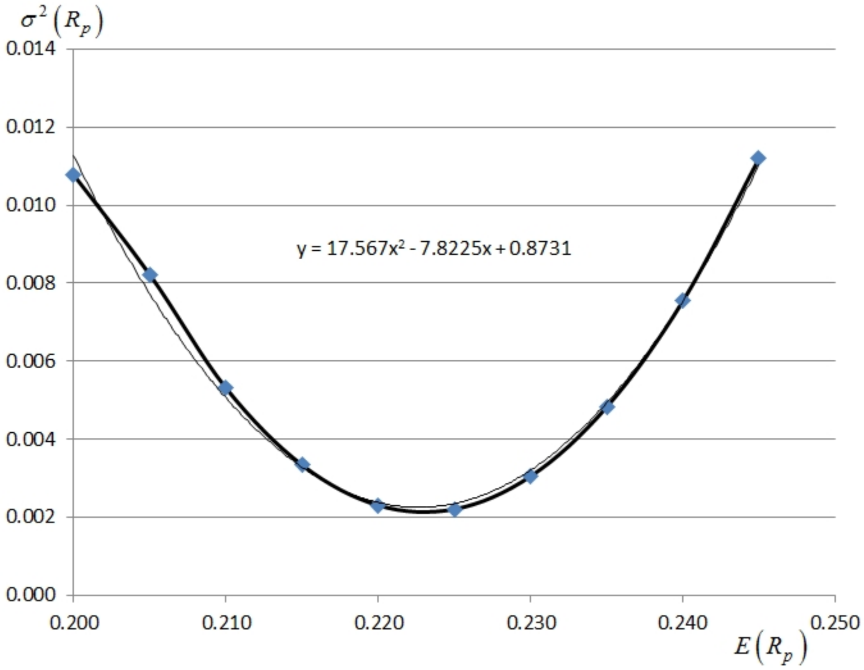

Figure 15.166: **Approximated parabola to Markowitz efficiency frontier in Microsoft® Excel® 14.0.7173**

So we have the approximate Markowitz equation curve:

$$y=17.567x^2-7.8225x+0.8731=ax^2+bx+c \qquad (15.3.820)$$

By the construction of the CML we can already draw approximately:

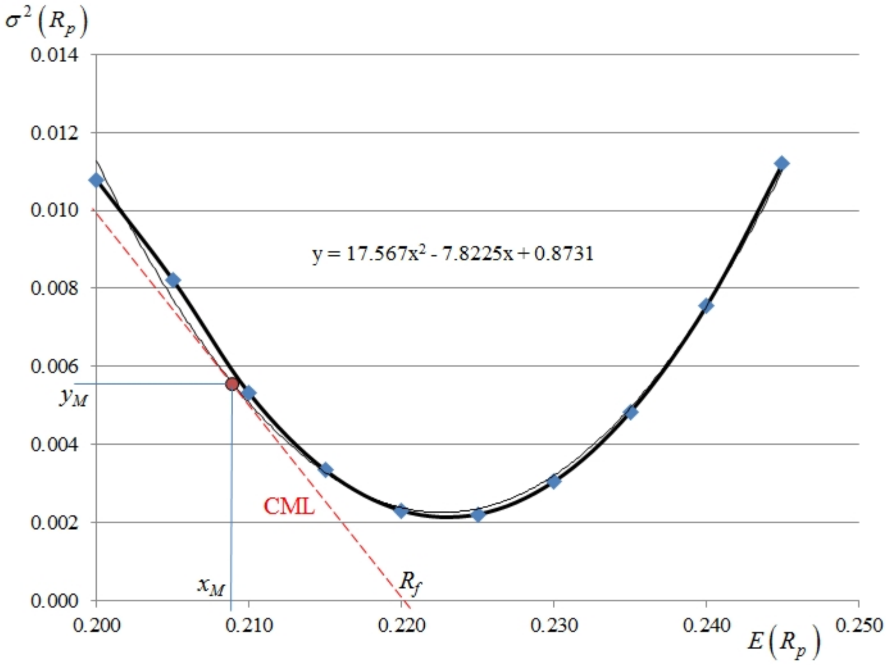

Figure 15.167: Approximated CML on Markowitz efficiency frontier in Microsoft® Excel® 14.0.7173

and let us write the CML equation by:

$$y' = a'x + b' \tag{15.3.821}$$

with the condition (see on the plot above):

$$a' = -\frac{b'}{0.22} \tag{15.3.822}$$

We then have two equations with two unknowns to solve this problem (the intersection of the line and parabola for the first equation and the equality of the slope of the line and the parabola at the intersection for the second equation):

$$\begin{aligned} &ax_M^2 + bx_M + c = a'x_M + b' \\ &2ax_M + b = a' \end{aligned} \tag{15.3.823}$$

The second equation gives us:

$$x_M = \frac{a' - b}{2a} = \frac{\dfrac{-b'}{0.22} - b}{2a} \tag{15.3.824}$$

Injected into the first equation:

$$a\left(\frac{\dfrac{-b'}{0.22} - b}{2a}\right)^2 + b\left(\frac{\dfrac{-b'}{0.22} - b}{2a}\right) + c = -\frac{b'}{0.22}\left(\frac{\dfrac{-b'}{0.22} - b}{2a}\right) + b' \tag{15.3.825}$$

If we solve this polynomial of the second degree we have two real solutions (Microsoft® Excel® can not determine the roots of this directly but with Maple™ 4.00b it's very simple):

$$b'_1 = -0.06822748631 \qquad b'_2 = 0.120763489 \tag{15.3.826}$$

Following a request from a user, here are the corresponding Maple™ lines:

```
>a:=18.795;b:=-8.3892;c:=0.9384;
>f:=a*(((-d/0.22)-b)/(2*a))^2+b*(((-d/0.22)-b)/(2*a))+c
=(-d/0.22)*(((-d/0.22)-b)/(2*a))+d;
>solve(f,d);
```

The second solution is to eliminate (we know it by trying to take it as a solution). So we have finally:

$$b'=-0.06822748631 \qquad a'=-\frac{b'}{0.22}=0.3101249378 \tag{15.3.827}$$

Which gives graphically (obviously the CML gives as expected the highest return for a given variance so it was impossible for the line to be left oriented):

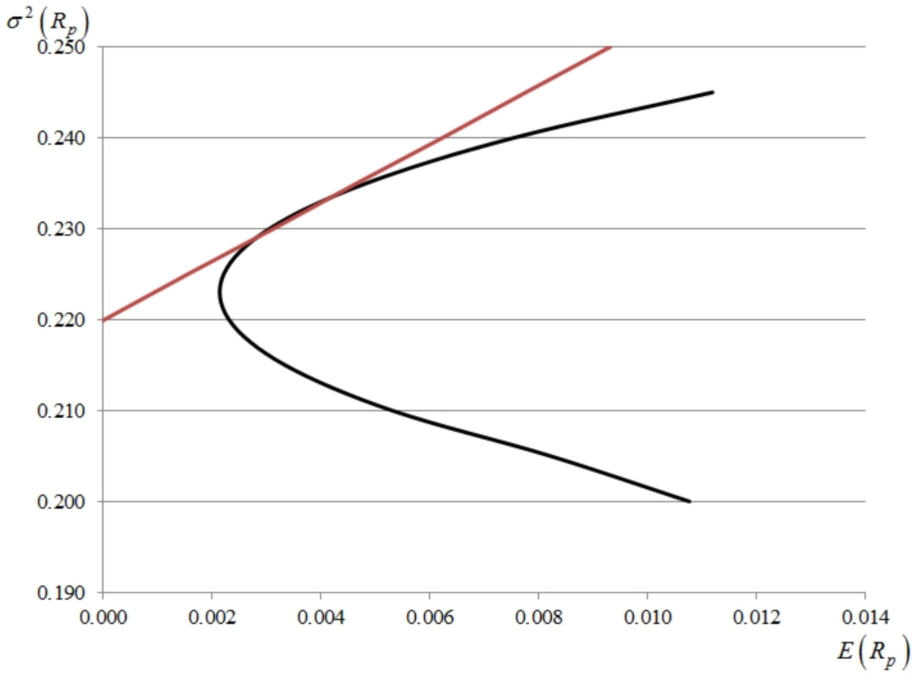

Figure 15.168: **Approximated parabola to Markowitz efficiency frontier with CAPM and traditional orientation Microsoft® Excel® 14.0.7173**

It also comes immediately:

$$x_M=\frac{\dfrac{-b}{0.22}-b}{2a}=0.2314265746 \tag{15.3.828}$$

Thus, by reusing the solver as above but with this new value for the expected mean we get for an optimal market portfolio with a risk-free asset having a return R_f of 0.22, an overall return of $0.2314276...$ the following asset weights:

$$X_1=-0.0399 \qquad X_2=1 \qquad X_x=0.0399 \tag{15.3.829}$$

with:

$$\sigma(R_P)=0.068 \tag{15.3.830}$$

So it is by construction the portfolio which, among all portfolios having only risky assets, maximizes performance while it behaves such as having a risk-free asset while minimizing the risk!!! Again, remember that this portfolio is named the "tangent portfolio".

If the reader refer to our MATLAB® companion book he can find the script that leads to the following results:

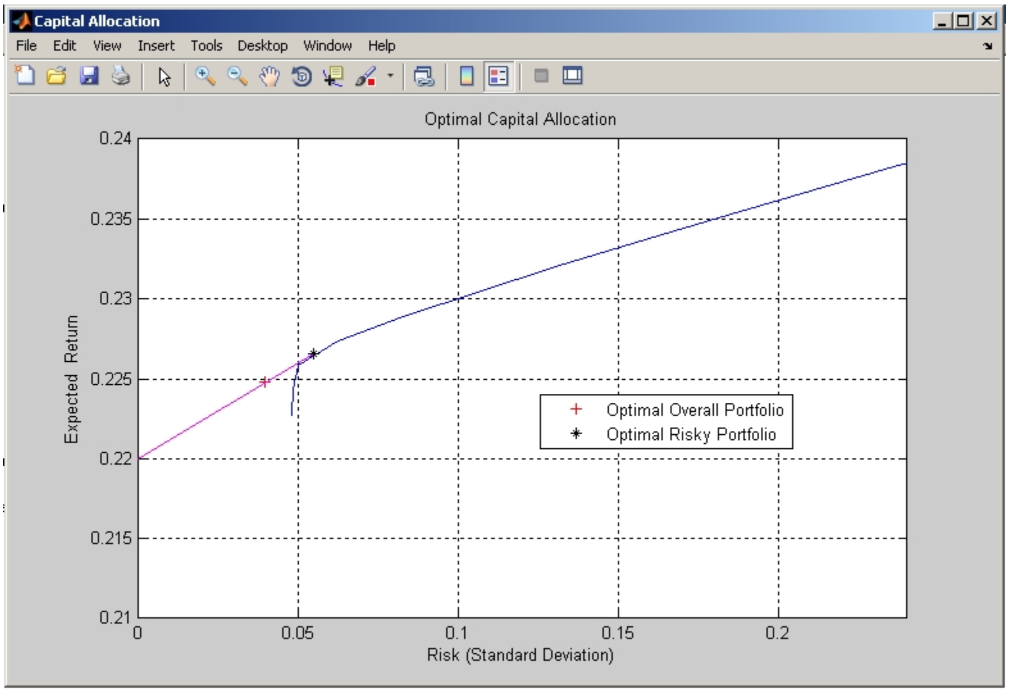

Figure 15.169: **Markowitz efficiency frontier with CAPM and CML in MATLAB® 2013a**

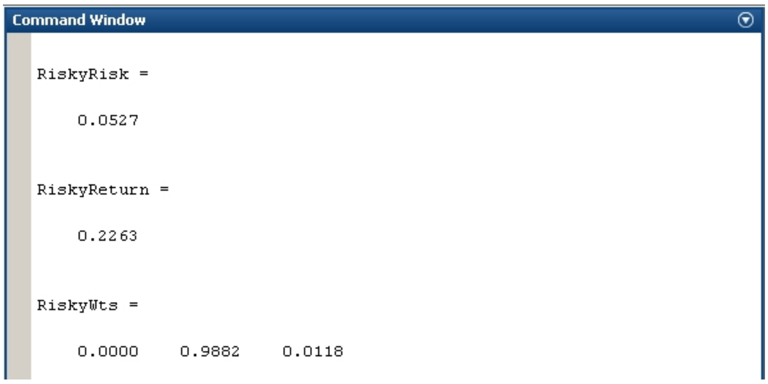
and the corresponding numerical values of interest:



```
RiskyRisk =

    0.0527

RiskyReturn =

    0.2263

RiskyWts =

    0.0000    0.9882    0.0118
```

Therefore we can see without surprise a significant difference between our rough Microsoft® Excel® approach and the results given by MATLAB®.

At this point the reader may have noticed that capital asset line and security market line represent assets on a risk and return map with the following correspondence:

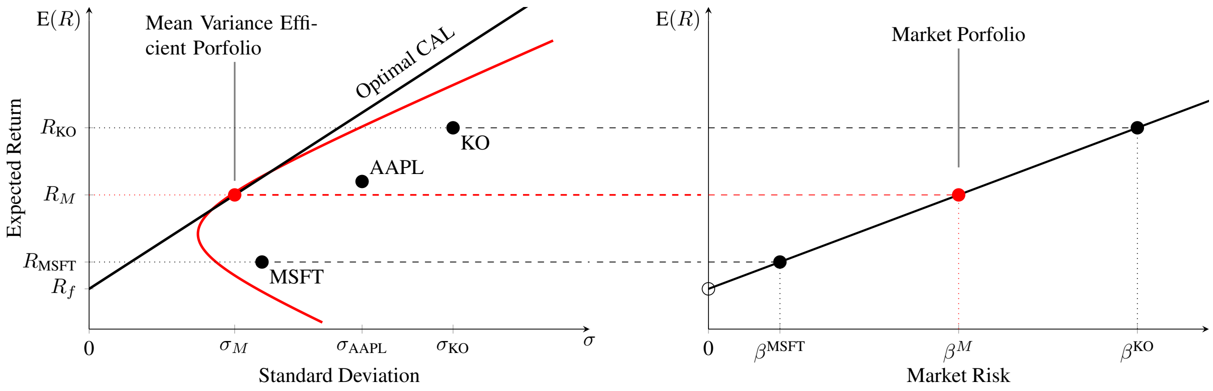


Figure 15.170: Security Market Line and Capital Market Line mapping

In practice we run a second stage regression that involves a single "cross-sectional regression" of the average (over time) of the stock returns on a constant and the β:

$$\bar{R}_i = \lambda_0 + \lambda_1 \beta_i + \varepsilon_i \tag{15.3.831}$$

where $\bar{R}_i$ is the return for stock i averaged over the 60 months. If the Sharpe-Lintner-Mossin CAPM is a valid model, two key predictions arise which can be tested using this second stage regression, that is: $\lambda_0 = R_f$ and $\lambda_1 = \text{E}(R_M) - R_f$.

It seems that it has been found that returns are systematically higher for small capitalisation stocks and are systematically higher for value stocks than the Sharpe-Lintner-Mossin CAPM would predict. That's why sometimes a different second-stage regression is run having for purpose to test this directly using a different augmented second stage regression:

$$\bar{R}_i = \alpha + \lambda_1 \beta_i + \lambda_2 \text{MV}_i + \lambda_3 \text{BTM}_i + \varepsilon_i \tag{15.3.832}$$

where MV_i is the market capitalisation for stock i and BTM_i is the ratio of its book value to its market value of equity. Again, if the Sharpe-Lintner-Mossin CAPM is a valid and complete model, then we should see that $\lambda_2 = 0$ and $\lambda_3 = 0$.

15.3.10.3.8.1 Hedging a future and commodity portfolio with the CAPM

We have seen during our introduction to Futures how to hedge a commodity portfolio based on a replication technique (see page 7657) or based on the modified duration (see page 7661).

But now let us see that we can also hedge using the betas of the Futures and their respective underlying commodity based on the CAPM model!

Remark

For information... the redactor of the following lines is not particularly a fan of the method that will follow since it is based on a lot of approximations but... as it is part of the CFA (Chief Financial Analyst) curriculum we will just close one eye...

First, following the CAPM model, let us say that for two assets that are a Commodity and a Future the following linear relation applies:

$$\begin{aligned} S &= \beta_{S,I}I+\alpha_{S,I}+\varepsilon_{S,I}\cong\beta_{S,I}I \\ F &= \beta_{F,I}I+\alpha_{S,I}+\varepsilon_{F,I}\cong\beta_{F,I}I \end{aligned} \quad (15.3.833)$$

and that we can write the following approximation (the residual return and the error term are considered negligible...):

$$\begin{aligned} \frac{\Delta S}{S} &\cong \beta_{S,I}\frac{\Delta I}{I}=\beta_S\frac{\Delta I}{I} \\ \frac{\Delta F}{F} &\cong \beta_{F,I}\frac{\Delta I}{I}=\beta_F\frac{\Delta I}{I} \end{aligned} \quad (15.3.834)$$

Then we have according to the relation see at page 7657:

$$\Delta V=\Delta S+N\Delta F\cong\beta_S S\frac{\Delta I}{I}+N\beta_F\frac{\Delta I}{I}=(\beta_S S+N\beta_F F)\frac{\Delta I}{I} \quad (15.3.835)$$

Note that the term in parentheses is in numerals, so we can not put something like this:

$$(\beta_S S+N\beta_F F)\frac{\Delta I}{I}=\beta_T\frac{\Delta I}{I} \quad (15.3.836)$$

Which would not be homogeneous!

So a very simple idea might be this: if the term in parentheses has a $N=0$ in the sense that we do not cover ourselves against any risk, then we must necessarily have (β_T is a synthetic "total" beta):

$$(\beta_S S+0\cdot\beta_F F)\frac{\Delta I}{I}=\beta_T S\frac{\Delta I}{I} \quad (15.3.837)$$

Reason why for what will follow we will focus on:

$$\beta_S S+N\beta_F F=\beta_T S \quad (15.3.838)$$

From which we can trivially draw two major relations:

- The first is that if we want to eliminate all risk then:

$$\beta_T = 0 \Rightarrow \beta_S S + N \beta_F F = 0 \tag{15.3.839}$$

and therefore we get one of the famous relation available in the CFA:

$$N^*_{\beta=0} = -\frac{\beta_S}{\beta_F}\frac{S}{F} \tag{15.3.840}$$

- The second is that if we want to achieve a given total synthetic beta, then we have:

$$N^*_{\beta_T} = \frac{\beta_T S - \beta_S S}{\beta_F F} = \frac{\beta_T - \beta_S}{\beta_F}\frac{S}{F} \tag{15.3.841}$$

which is sometimes denoted:

$$N^*_{\beta_T} = \frac{\$\beta_T - \$\beta_S}{\$\beta_F} \tag{15.3.842}$$

We see that we fall back on the previous relation if $\beta_T = 0$. Let us recall that if the sign of this last relation is positive we will have to take a long position (buyer of future), otherwise (negative) a short position (Future seller).

15.3.10.3.9 Black & Scholes option pricing models

It is to the genius of three famous mathematicians that the derivatives market (which it is usual to classify into three large families: Derivatives on securities, Derivatives on rates, Derivatives on currencies) owes its success, thanks to Black & Scholes equation established in the years 11970 according to holocene calendar (and published in 11973) that theoretically determines the exact premium (under several assumptions) that a customer must pay to acquire a Call or a Put and the strategy to be followed by the seller of these Options to hedge risk (to cite only the most well known example). Obviously this model works only if the temporal periods considered are relatively short (on the order of the week or a few months at best). Beyond the use of this particular theoretical model is quite a joke!

Remark

The dynamics of the Black & Scholes model had already been well dusted before by Louis Bachelier and Edward O. Thorpe, which is why we sometimes refer to the "Bachelor-Thorpe" model.

Fischer Black, Myron Scholes and Robert C. Merton are the ancestors of a generation of sophisticated derivative products, giving a lexicon of terms as exotic as Butterflies, Rainbows, Knock-in, Knock-Out, Barriers, Swaps, Calls, Puts, Sneakers, Swings, Caplets. This model is also considered this said as one of the main factors of the stock market crash of 11987 (holocene calendar) by some specialists ...

Evidently, however, there are many more sophisticated empirical models, such as:

- The Black & Scholes & Barenblatt model
- The Merton Jump Scattering model
- The Heston model
- and so on...

What we would like in what follows is to determine the theoretical value of the premium of an option from the following five data:

- The present value of the underlying financial asset of the option (determined by market speculation)
- The time remaining to the option before its maturity (chosen by the issuing company)
- The strike price fixed by the issuer subjectively or after modelling.
- The risk-free interest rate (assumed to be the expected rate of return of the underlying asset).
- The volatility (standard deviation) of the underlying price of the option (measured on the market).

The premium for the option thus determined should be unique and equitable for both parties. Indeed, the system of options would make it possible to charge an option price (premium) higher than the market forecasts and thus to generate a certain profit and from nothing, but the many players in the market will compete to be fair and attract the customers on their options rather than on those of the competitors.

The modelling of options prices (Black & Scholes) is based on the use of stochastic differential calculus. Thus, the Black & Scholes approach assumes that the evolution of the asset defines a geometric Brownian motion (in the sense that the possible movements of the price tend towards infinity) and that its output defines a Wiener process (a concept that we will define later on).

15.3.10.3.9.1 Put-Call parity equation

Before attacking somewhat arduous stochastic calculations, it is useful to establish beforehand a so-named "Put-Call parity equation" which will serve as a kind of conservation law to verify the validity of the results that we will establish further for the evaluation of options prices.

The goal will be to answer the following question: What amount of money M must we pay now to receive a guaranteed sum corresponding to the price "strike price" denoted K to a future time T?

To answer this question, let us recall that during our study of the calculation of interest we saw that in considering a capital C and a constant interest rate r we had in a case of continuous capitalization:

$$C=C_0e^{rt} \tag{15.3.843}$$

Therefore, if we but $C=K$ and $C_0=M$ we have then in a universe without risk, that is to say in delta-neutral (the case with risk will be the subject of the Black & Scholes that we will see later):

$$K=Me^{rt} \tag{15.3.844}$$

Therefore:

$$M=Ke^{-rt} \tag{15.3.845}$$

But this relationship is not quite right. Indeed, we must have $M=K$ that is guarantee at time $T=t$. Hence we are naturally led to put (this is a strictly increasing function!):

$$\boxed{M=Ke^{-r(T-t)}} \tag{15.3.846}$$

This small elementary reminder being made, we will now assume for what will follow that the Call and the Put possess the following properties:

P1. Same support that is valued S at time t (spot price).

P2. Same maturity T

P3. Same strike price K

And the following assumptions (which are the basis of the Black & Scholes model that we will describe below):

H1. There are no transaction costs (which is a joke in delta-hedging strategies...)

H2. Delta-hedging eliminates all risk (see further below the concept)

H3. The support is not a term instrument (it is possible to make short sales)

H4. The support does not pay dividends over the life of the option (i.e. between $[0,T]$).

H5. The options are European

H6. The risk-free market rate is assumed to be known in advance and considered as constant

H7. There is no arbitrage opportunities (but well in practice ... there is almost only this)

H8. The price of options does not affect the price of the underlying (mouarf!)

H9. Yields are not autocorrelated

By asking us again now the initial question: How much do we have to pay now for a portfolio in order to receive a guaranteed sum K (strike price) at a future time T?

Since the portfolio can be considered as a black box, there is nothing to prevent us by denoting by S the actual price of the underlying, P that of the Put and C that of the Call (see just below for an explanation of the origin of this equality):

$$\boxed{\Pi = S + P - C = Ke^{-r(T-t)}} \tag{15.3.847}$$

which is nothing else than the "Put-Call parity equation" or otherwise written if we put the beginning of time at zero, then:

$$S + P - C = Ke^{-rT} \tag{15.3.848}$$

Remark

Some practitioners then use the following relation, derived from the above one, to determine the risk free rate of the market:

$$r = -\frac{1}{T-t}\ln\left(\frac{K}{S_t + P_t - C_t}\right) \tag{15.3.849}$$

Strictly speaking, it would be better to write this last relation in the following form:

$$C_t - P_t = S_t - Ke^{-r(T-t)} \tag{15.3.850}$$

Whatever the rearrangement of the terms in this last equality, there must always be equality, otherwise there is an arbitrage opportunity. This relation also shows that the value of a European

Call with an exercise price K and maturity T can be deduced from that of a European Put with the same exercise price K and the same maturity T.

Let us see more in details where the Put-Call parity equation comes from the following request of a reader:

Theorem 15.7. The Put-Call parity equation arises from the absence of arbitrage opportunity.

Proof 15.7.1. Let us consider the frequent and natural configuration of a first economic agent with a portfolio P_A containing a European Call option (C) and an amount Ke^{-rT} invested in a risk-free investment. The initial value (we must put $t=0$) of this portfolio will therefore be:

$$P_A = C + Ke^{-rT} \tag{15.3.851}$$

Let us consider the second configuration naturally opposed to the first portfolio containing a European Put of price P and the underlying of price S. The initial value of this portfolio will therefore be:

$$P_B = P + S \tag{15.3.852}$$

We then have two scenarios:

S1. At maturity T, if the underlying has a value less than or equal to the strike price (i.e. $S_T \leq K$), the portfolio P_A will have for value K because the Call option will most likely not be exercised and therefore its financial value becomes zero but the risk-free asset (placed at the risk-free rate) will have a return equal K. The portfolio P_B will be equal to $(K-S_T)+S_T=K$ where the term in parentheses represents the gain generated by the Put.

S2. At maturity T, if the underlying has a value higher than the strike price (i.e. $S_T > K$), we are therefore in a situation contrary to that of the first scenario. The portfolio P_A will then have for value $(S_T-K)+K=S_T$. The portfolio P_B will be equal to $0+S_T=S_T$ because the sale will not be made and the Put option will be considered as having a zero value.

To summarize:

	If $S_T \leq K$	**If $S_T > K$**
P_A	$0+K=K$	$(S_T-K)+K=S_T$
P_B	$(K-S_T)+S_T=K$	$0+S_T=S_T$
Conclusion:	$P_A=P_B$	$P_A=P_B$

Table 15.52: **Summary of lack of absence of arbitrage opportunity**

So the two portfolios are always equal at maturity otherwise there is an arbitrage opportunity. What we can write (the index T for the price of the underlying at maturity is often omitted):

$$C + K = P + S \tag{15.3.853}$$

where the exponentials has vanished since $e^{-r(T-t)}$ for $T=t$ is equal to 1.

■ Q.E.D.

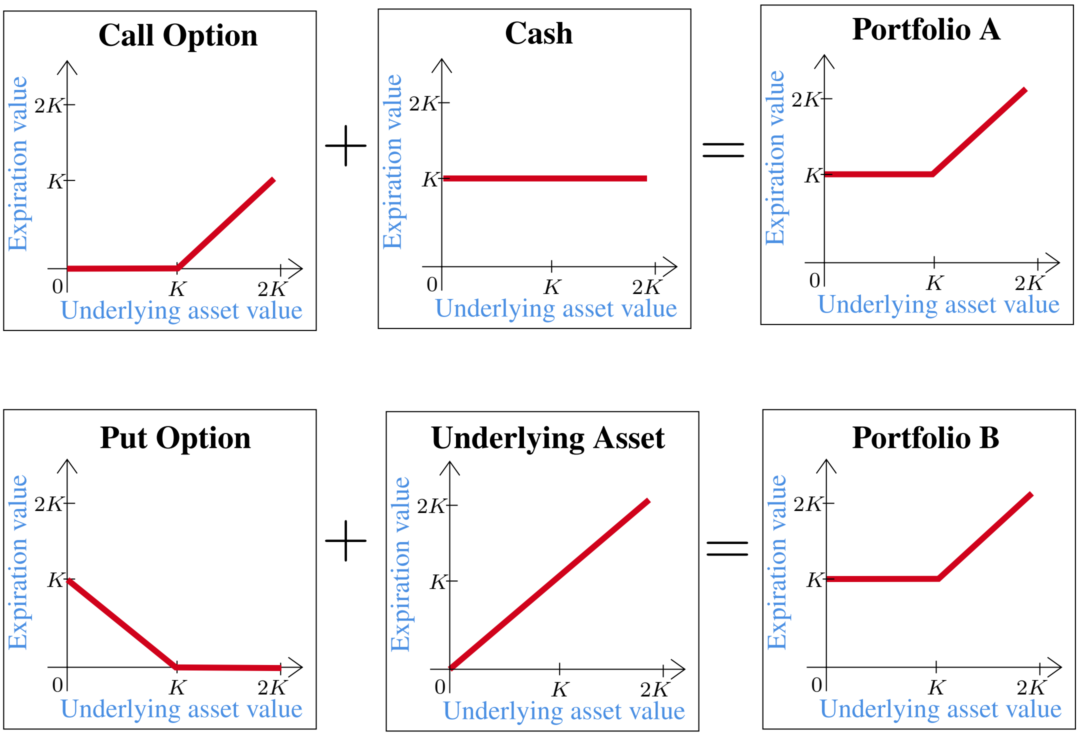

Figure 15.171: Put-Call parity equation illustrated

15.3.10.3.9.2 Efficient Market Hypothesis

The Black & Scholes model (and many other financial models) is based on the premise that the market is "efficient".

Definition (#15.3.695): An "efficient market" is a market where prices fully reflect all available information. Thus, if the market is efficient, it is not possible to make abnormal profits.

We can distinguish three types of efficient markets that depend on the type of information available:

1. The efficient market hypothesis in "weak form", which explicitly states that prices reflect all the information contained in the historical price series.
2. The efficient market hypothesis in "semi-strong form" establishes that prices reflect all available public information.
3. The "strong form" market assumption that all known public and private information is reflected in market prices.

Several studies have attempted to test the hypothesis of asset market efficiency. To test the weak form of the hypothesis, the analysis of the time series (see below) was used by specifically testing the hypothesis of a random walk (a "Brownian motion" - we will return to this later). More specifically, these tests have tried to check whether price increases are independent of past increases. If the random walk hypothesis is rejected, then the market is not efficient, since past price increases could help to anticipate future asset prices. The empirical evidence supports the efficient market hypothesis in weak form. In order to test the semi-strong form of the hypothesis, the rate of adjustment of market prices to the arrival of new information has been evaluated. The evidence for a rapid adjustment of market prices is dominant. The strong form of the market efficiency hypothesis is to test whether it is possible to take advantage of privileged information (information accessible to a small group of economic agents). Since non-public information can not be identified, a strong form test type considers reviewing the investment performance of individuals or groups who may have private information. Edwin J. Elton and Martin J. Gruber (11984 according to holocene calendar) report that the analysis of the performance of mutual funds, after deducting costs, supports the strong form of efficiency.

This implies the following assumptions (to summarize):

H1. The past history of the asset price is completely reflected in the present price which does not contain any other information about the asset.

H2. The market immediately incorporates any new information into the price of an asset.

The paradox of the Hypothesis of Market Efficiency is that if every investor truly believed that the market was perfectly efficient, then nobody would study companies, their balance sheets, and so on. It would suffice to buy the index. Indeed, efficient markets rely on individuals who are active on the market because they believe (and their believes are true when there is an opportunity arbitrage!) that this market is "inefficient" and that they can do better than the market!

This hypothesis is the source of much debate in the field ...

Remark

With the two assumptions previously stated, any unanticipated change in the asset price is named a "Markov process[a]".

---

[a] A Markov process is a process whose future evolution depends on its past only through its state at the present moment. The course of an action is probably not a Markov process (the "memory" of the process is probably longer - for example, a seasonal trend).

15.3.10.3.9.3 Wiener Process

Let Δz be the variation of the non-trend value of an asset over a small time interval denoted Δt.

Using the knowledge of the two major results of the Bachelier model, we therefore have for the variations of the value of the asset a positive expected mean dependent in a manner proportional to the square root of time according to:

$$\boxed{\Delta z=\varepsilon\sqrt{\Delta t}} \tag{15.3.854}$$

Where we put as hypothesis (acceptable ... because we work on small variations for recall!) that the coefficient of instability is a function:

$$\varepsilon \longrightarrow \mathcal{N}(0,1) \tag{15.3.855}$$

where $\mathcal{N}(0,1)$ is as we know the notation of the reduced Normal law as we have established it in the Statistics section.

Remark

Often in the field of economics, we denote it $W\mathcal{N}$ instead of $\mathcal{N}$ in tribute to Wiener.

That said, the antecedent relation is often denoted in a more generalized way as following:

$$\boxed{W_t=W_{t-1}+\varepsilon\sqrt{\Delta t}=W_{t-1}+\mathcal{N}(0,1)\sqrt{\Delta t}} \tag{15.3.856}$$

and defined as a "standard Brownian motion" with "white noise" (Normal marginal law), or "arithmetic Brownian motion", where the W is there in tribute to Wiener (such a process is also sometimes denoted GWN for "Gaussian White Noise" as we can obviously create white noises from other distributions)! It is interesting to notice that the Brownian motion is supposed indefinitely divisible (which means that the temporal period taken does not influence the law of probability which remains always the same ... it is a fractal property of the Brownian motion which has been studied by Benoît Mandelbrot too!).

Do not forget for a proof that we will do further below that we can deduce that:

$$W_t-W_{t-1}=\mathcal{N}(0,1)\sqrt{\Delta t}=\mathcal{N}(0,1)\sqrt{(t-1)-t}=\mathcal{N}(0,1) \tag{15.3.857}$$

It is possible to produce a plot of this Brownian motion with Microsoft® Excel® (here the version 11.8346) with in the column `A` the time with a typical equation step of 0.01 [s] (column which will be there only for the sake of comfort of reading and by tradition) and in cell `B2` the following formula:

```
=B1+NORMSINV(RAND())*SQRT(0.01)
```

where `B1` contains the value 0.

We then get the following variations of values for 4 columns of the same type:

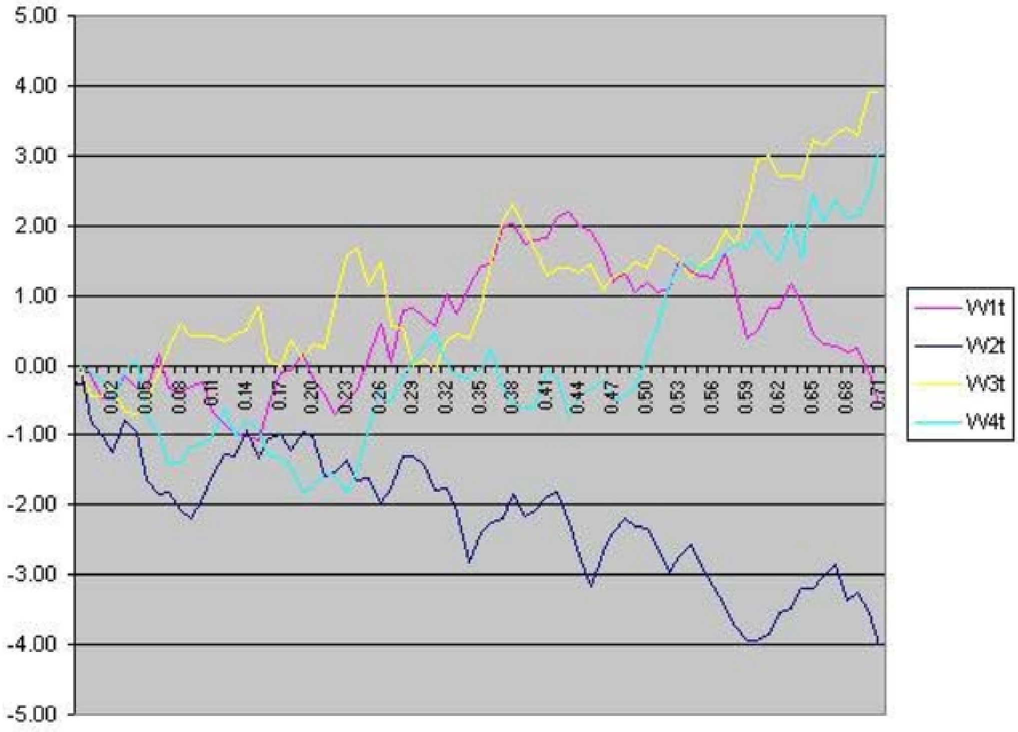

Figure 15.172: Example of 4 standard Brownian motions with Microsoft® Excel® 11.8346

Or in a much better quality using TikZ:

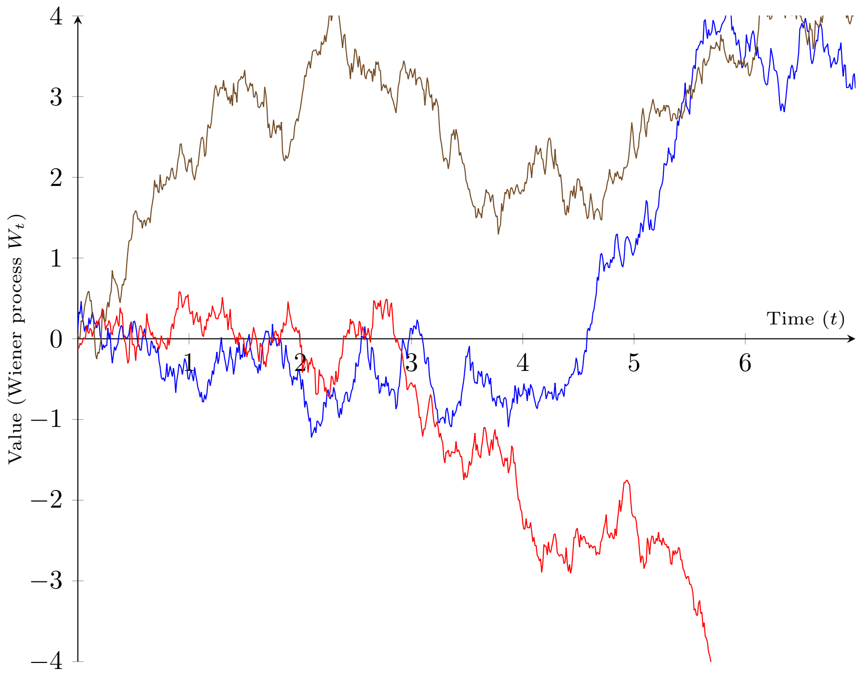

Figure 15.173: **Wiener process (normal random walk) with TikZ**

Standard Brownian movements have some remarkable properties as we can see: the trajectory tends to alternate above and below the abscissa axis. This comes from the fact that the Normal law considered has zero mean, in other words that there is no general tendency to increase or decrease the variations (to check it made at least $30,000$ points in Microsoft® Excel® and you will see...).

It is easily possible to characterize Δz with its mean:

$$\text{E}(\Delta z)=\text{E}\left(\varepsilon\sqrt{\Delta t}\right)=\sqrt{\Delta t}\cdot\text{E}(\varepsilon)=\sqrt{\Delta t}\cdot 0=0 \qquad (15.3.858)$$

Indeed, let us recall that for the Normal reduced centered law, we have:

$$\mu=\text{E}(x)=0 \qquad (15.3.859)$$

So we could expect this result of total absence of general trend (it was quasi-intuitive!).

We can also characterize Δz using its variance:

$$\text{V}(\Delta z)=\text{V}\left(\varepsilon\sqrt{\Delta t}\right)=\Delta t\cdot\text{V}(\varepsilon)=\Delta t\cdot 1=\Delta t \qquad (15.3.860)$$

hence:

$$\sigma_{\Delta z}=\sqrt{\Delta t} \qquad (15.3.861)$$

Indeed, let us recall that for the Normal reduced centered law, we have:

$$\sigma_x^2=\text{V}(x)=1 \qquad (15.3.862)$$

Finally (in fact this result immediately follows from the linearity property of the Normal law):

$$\Delta z\longrightarrow\mathcal{N}\left(0,\sqrt{\Delta t}\right) \qquad (15.3.863)$$

So when we have:

$$\begin{aligned}&\mathrm{E}(\Delta z)=0\\&\mathrm{E}(\Delta z^2)=\mathrm{E}(\varepsilon\Delta t)=\Delta t\mathrm{E}(\varepsilon)=\Delta t\end{aligned}\tag{15.3.864}$$

it is customary to speak of the "Gauss-Wiener process" or more simply of "Wiener process".

To summarize a little bit all this...:

1. We knew with Bachelier's model that the positive expected mean and the positive standard deviation of the value are proportional to the square root of time. We used these two results here.
2. We now know (under the well-defined hypothesis of a Normal type coefficient) that the variations have zero expected mean (trend) and a standard deviation proportional to the square root of the temporal variation.

The property which has just been established remains valid for a large time interval denoted T corresponding to n small intervals Δt! In other words:

$$T=n\cdot\Delta t\tag{15.3.865}$$

In this context, it is appropriate to replace large variations by Δx such that:

$$x(T)-x(0)\tag{15.3.866}$$

But without any trend, we have for the moment the equality:

$$x(T)-x(0)=\sum_{i=1}^{n}\Delta x_i=\sum_{i=1}^{n}\Delta z_i=\sum_{i=1}^{n}\varepsilon_i\sqrt{\Delta t}\tag{15.3.867}$$

As in the case of a change in the price over a short period of time, it is possible to characterize $x(T)-x(0)$ using its expected mean and its standard deviation:

$$\begin{aligned}&\mathrm{E}\big(x(T)-x(0)\big)=\mathrm{E}\left(\sum_{i=1}^{n}\varepsilon_i\sqrt{\Delta t}\right)=\sqrt{\Delta t}\mathrm{E}\left(\sum_{i=1}^{n}\varepsilon_i\right)=\sqrt{\Delta t}\sum_{i=1}^{n}\mathrm{E}(\varepsilon_i)=\sqrt{\Delta t}\cdot 0=0\\&\mathrm{V}\big(x(T)-x(0)\big)=\mathrm{V}\left(\sum_{i=1}^{n}\varepsilon_i\sqrt{\Delta t}\right)=\Delta t\mathrm{V}\left(\sum_{i=1}^{n}\varepsilon_i\right)=\Delta t\sum_{i=1}^{n}\mathrm{V}(\varepsilon_i)=\Delta t\sum_{i=1}^{n}1=n\cdot\Delta t=T\end{aligned}\tag{15.3.868}$$

which makes sense...

We then fall back, for a large time interval T:

$$x(T)-x(0)\longrightarrow\mathcal{N}(0,\sqrt{T})\tag{15.3.869}$$

Which we can also write in the following form using the properties proven in the section Statistics of the Normal law:

$$x(T)\longrightarrow\mathcal{N}(x(0),\sqrt{T})\tag{15.3.870}$$

Result we could reasonably expect with the aforementioned assumptions ...

This last result is written in the following explicit form in spreadsheets softwares:

$$\boxed{x(t)=x(0)+\mathcal{N}\sqrt{t}} \tag{15.3.871}$$

and we see that this is unrealistic because it would mean that any financial asset follows the same law (regardless of its volatility ...) and would have no general downward or upward trend. We will see how to improve this approach.

To close this approach, notice that if Δt tends to 0 (which amounts to considering a subdivision of time T into extremely small intervals), the course undergoes an infinitely large number of variations over period T. In other words, the process of evolution of the price of the asset is continuous, which leads to replace Δt by $\mathrm{d}t$, Δx by $\mathrm{d}x$ and Δz by $\mathrm{d}z$.

In this case, we get:

$$\mathrm{d}x \longrightarrow \mathcal{N}(0,\sqrt{\mathrm{d}t}) \tag{15.3.872}$$

which defines a "Wiener process" (we will come back to this when we will have established the stochastic differential equation).

But obviously this does not really conform to the reality as we have already mentioned ... We prefer then to add a constant shift in time which gives the Brownian motion that we will see now.

15.3.10.3.9.4 Generalized Brownian motion

In this case (generalization a little more realistic), the evolution of the course depends not only on a standard Brownian random process (second term below on the right of the equality), but also on a parameter of central tendency, or "drift" (first term below to the right of the equality):

$$\boxed{\mathrm{d}x = a \cdot \mathrm{d}t + b \cdot \mathrm{d}z} \tag{15.3.873}$$

With always:

$$\mathrm{d}z = \varepsilon\sqrt{\mathrm{d}t} \tag{15.3.874}$$

and:

$$\varepsilon \longrightarrow \mathcal{N}(0,1) \tag{15.3.875}$$

We thus have a "generalized Brownian motion", consisting of a standard Brownian motion ($\mathrm{d}z$ represented by a Normal law of zero expected mean and variance $\mathrm{d}t$ as we saw above) and a drift. In this scenario, a and b are imposed as constant contrary to the more general case that we shall see later.

The antecedent relation is often represented in the literature in the following differential form:

$$\mathrm{d}X_t = a\mathrm{d}t + b\mathrm{d}W_t = a\mathrm{d}t + b\mathrm{d}(\mathcal{N}(0,1)\sqrt{\mathrm{d}t}) \tag{15.3.876}$$

So graphically this gives, by adding this drift and taking a positive and non-zero value for a, a standard Brownian motion that will tend to alternate above and below the drift:

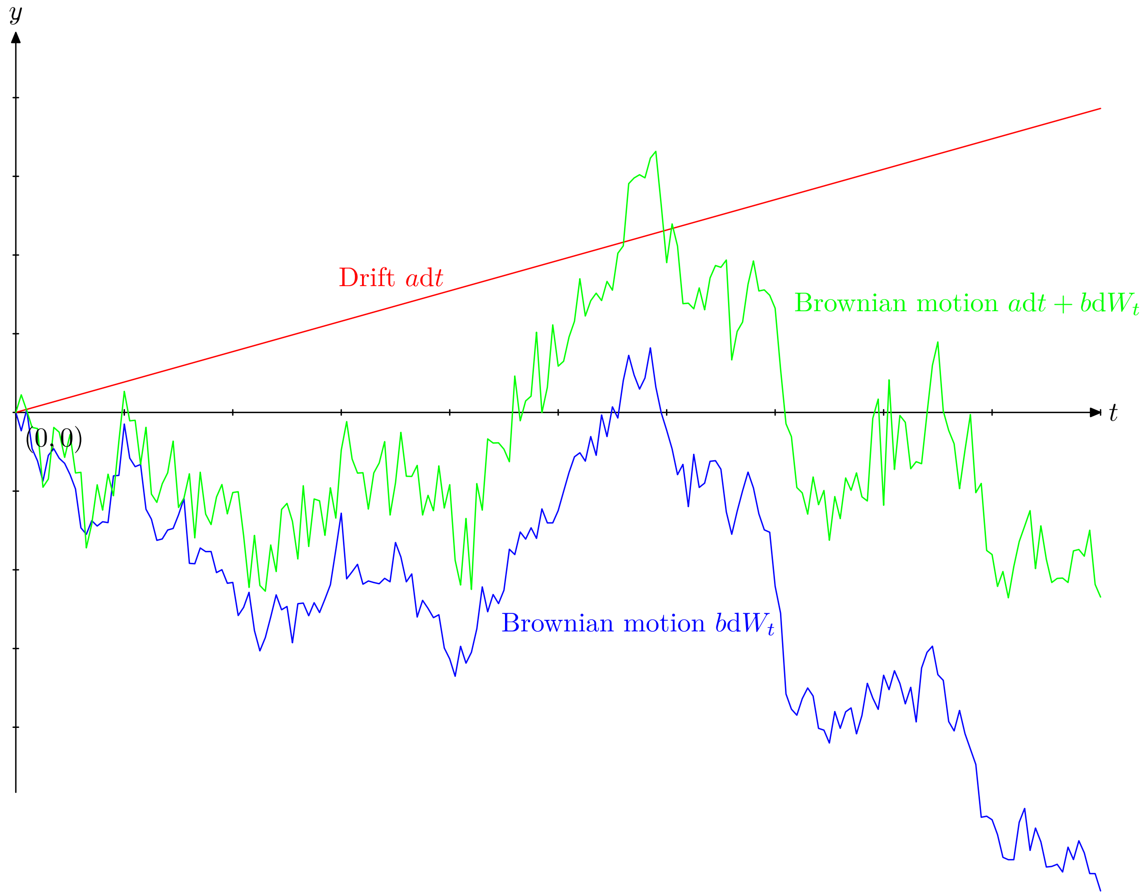

Figure 15.174: Example of standard Brownian motion with drift (and decomposition)

On a small time interval Δt, the process, in discrete time is obviously written:

$$\Delta x = a \cdot \Delta t + b \cdot \Delta z \tag{15.3.877}$$

In this case, we have:

$$\text{E}(\Delta x) = \text{E}(a\Delta t + b\Delta z) = a \cdot \Delta t + b \cdot \text{E}(\Delta z) \tag{15.3.878}$$

since only Δz has a random component.

Therefore:

$$\begin{aligned} \text{E}(\Delta x) &= a \cdot \Delta t + b \cdot \text{E}(\Delta z) = a \cdot \Delta t + b \cdot \text{E}(\varepsilon\sqrt{\Delta t}) = a\Delta t + b\sqrt{\Delta t} \cdot \text{E}(\varepsilon) = a\Delta t + 0 = a\Delta t \\ \text{V}(\Delta x) &= \text{V}(a \cdot \Delta t + b \cdot \Delta z) = 0 + b^2 \cdot \text{V}(\varepsilon\sqrt{\Delta t}) = b^2\Delta t \cdot \text{V}(\varepsilon) = b^2 \cdot \Delta t \end{aligned} \tag{15.3.879}$$

Finally:

$$\Delta x = \mathcal{N}(a\Delta t, b\sqrt{\Delta t}) \tag{15.3.880}$$

The result:

$$\text{V}(\Delta x) = \text{V}\left(\mathcal{N}(a\Delta t, b\sqrt{\Delta t}\right) = b^2\Delta t \tag{15.3.881}$$

is often named the "quadratic variation" of the generalized Brownian motion. The quadratic variation of the standard Brownian motion ($a=0$,$b=1$) being often denoted:

$$\mathrm{V}(B_t)=t \tag{15.3.882}$$

By subdividing a period T into n time intervals Δt (i.e. $T=n\Delta t$), the price change becomes over this period T:

$$x(T)-x(0)=\sum_{i=1}^{n}\Delta x_i \tag{15.3.883}$$

Since then:

$$\begin{gathered}\mathrm{E}(x(T)-x(0))=\mathrm{E}\left(\sum_{i=1}^{n}\Delta x_i\right)=\sum_{i=1}^{n}\mathrm{E}(\Delta x_i)=n\cdot a\cdot\Delta t=a\cdot T\\ \mathrm{V}(x(T)-x(0))=\mathrm{V}\left(\sum_{i=1}^{n}\Delta x_i\right)=\sum_{i=1}^{n}\mathrm{V}(\Delta x_i)=\sum_{i=1}^{n}\mathrm{V}(b\sqrt{\Delta t})=b^2\Delta t\sum_{i=1}^{n}1=n\cdot b^2\Delta t=b^2T\end{gathered} \tag{15.3.884}$$

Finally:

$$x(T)-x(0)=\mathcal{N}\left(a\cdot T,b\cdot\sqrt{T}\right) \tag{15.3.885}$$

Therefore:

$$x(T)=x(0)+\mathcal{N}\left(a\cdot T,b\cdot\sqrt{T}\right) \tag{15.3.886}$$

or also:

$$x(T)=\mathcal{N}\left(x(0)+a\cdot T,b\cdot\sqrt{T}\right) \tag{15.3.887}$$

It is then easy to understand why we say that the Normal law governs the random variable obtained by stopping a Brownian process at a given instant: it is an instantaneous picture of the Brownian motion simple or generalized!

By choosing:

$$a=x(0)\cdot\mu \qquad b=\sigma x(0) \tag{15.3.888}$$

We then have the prior-previous relation which is traditionally written in the following explicit form in spreadsheets softwares:

$$\boxed{x(t)=x(0)+\mu\cdot x(0)\cdot t+\mathcal{N}(0,1)\sigma x(0)\sqrt{t}} \tag{15.3.889}$$

where μ is the average return in $\%$ of the financial asset and σ the volatility of the return in $\%$. Or written otherwise:

$$x(t)=\mathcal{N}\left(x(0)+\mu x(0)t,\sigma x(0)\sqrt{t}\right) \tag{15.3.890}$$

In practice, the risk-free rate is chosen to represent the underlying returns because we assume that we always work in a neutral risk probability (absence of arbitrage opportunity).

It is then interesting for the financial analyst to visualize the expected mean as a function of t and the value $x(t)$ corresponds to a cumulative probability of 2.5% and 97.5% on a plot to have an idea of the evolution of the confidence interval at 95% of its $x(0)$. This is very easy to get in a spreadsheet software like Microsoft® Excel® and we can typically falls by playing with several types of charts on the same type of plot as shown below for a portfolio of 500 million USD with 5% yield and standard deviation of 20%:

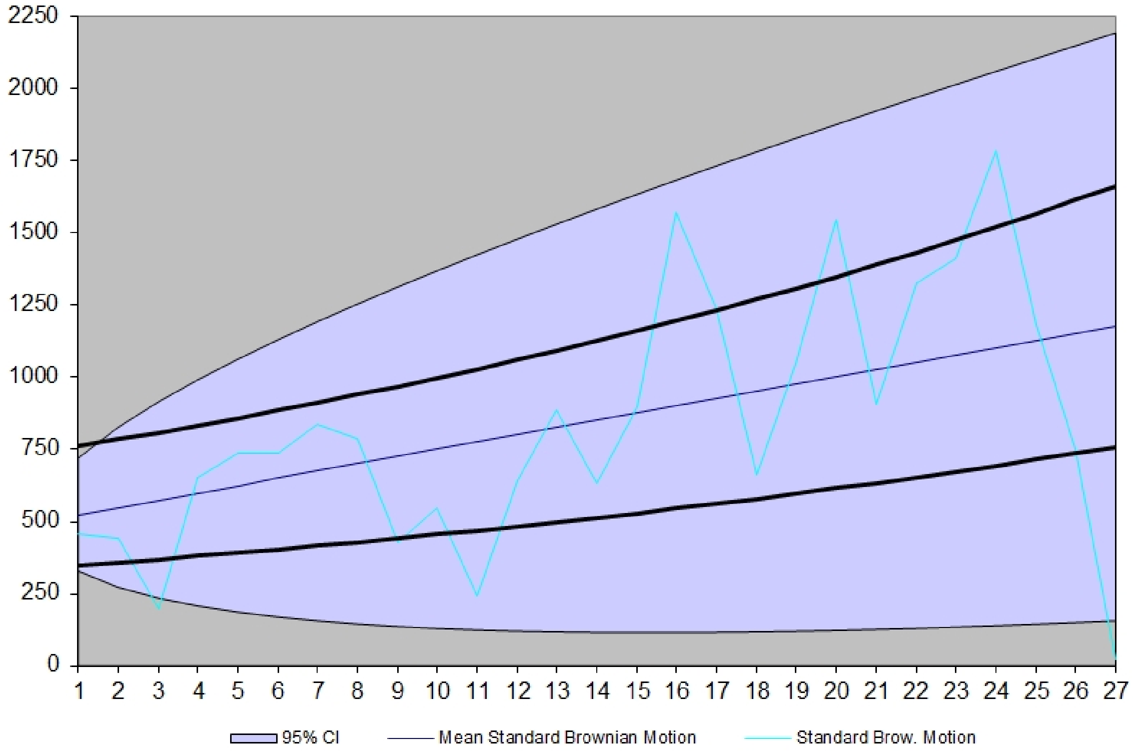

Figure 15.175: **Standard Brownian motion with confidence interval plot in Microsoft® Excel® 11.8346**

With the following table:

	A	B	C	D	E	F
1	Time	Mean Standard Brownian Motion	Standard Brow. Motion	Standard Deviation	Inf. 95% CI	Upp. 95% CI
2	0	500.00	500.00	0.00

Figure 15.177: **Data table corresponding to the previous plot in Microsoft® Excel® 11.8346 with explicit formulas**

Obviously, in practice it is possible to make this type of graph with any data comprising a linear drift and whose standard deviation is known.

15.3.10.3.9.5 Brownian bridge

Let us now consider a case of application of the Brownian motion which will be useful to us later! By revising the developments seen above, it comes immediately that:

$$x_t = x_{t-\Delta t} + \mu x_0 \Delta t + \mathcal{N}(0,1)\sigma x_0 \sqrt{\Delta t} \tag{15.3.891}$$

Indeed, let us check this by choosing:

$$\Delta t = 1 \tag{15.3.892}$$

We have:

$$x_t = x_{t-1} + \mu \cdot x_0 \cdot 1 + \mathcal{N}(0,1)\sigma x_0 \sqrt{1} = x_{t-1} + \mu x_0 + \mathcal{N}(0,1)\sigma x_0 \tag{15.3.893}$$

And therefore for $t = 1$:

$$x_1 = x_0 + \mu x_0 + \mathcal{N}(0,1)\sigma x_0 \tag{15.3.894}$$

And similarly for $t = 2$:

$$\begin{aligned} x_2 &= x_1 + \mu \cdot x_0 + \mathcal{N}(0,1)\sigma x_0 = \big(x_0 + \mu x_0 + \mathcal{N}(0,1)\sigma x_0\big) + \mu \cdot x_0 + \mathcal{N}(0,1)\sigma x_0 \\ &= x_0 + 2\mu \cdot x_0 + \underbrace{\big(\mathcal{N}(0,1) + \mathcal{N}(0,1)\big)}_{=\mathcal{N}(0,\sqrt{2})} \sigma x_0 = x_0 + 2\mu \cdot x_0 + \mathcal{N}(0,1)\sqrt{2\sigma x_0} \end{aligned} \tag{15.3.895}$$

This is indeed equivalent to:

$$x(t) = x(0) + \mu x(0)\Delta t + \mathcal{N}(0,1)\sigma x(0)\sqrt{\Delta t} \tag{15.3.896}$$

For $\Delta t = 2$:

$$W(t) = W_{t-\Delta t} + \mu W_0 \Delta t + \mathcal{N}(0,1)\sigma W_0 \sqrt{\Delta t} \tag{15.3.897}$$

Well, this being said, we would like to build a Brownian motion which starts at the time $t = 0$ from zero (which imposes $x(0) = 0$) fluctuates during a given period T and returns to zero as shown in the figure below:

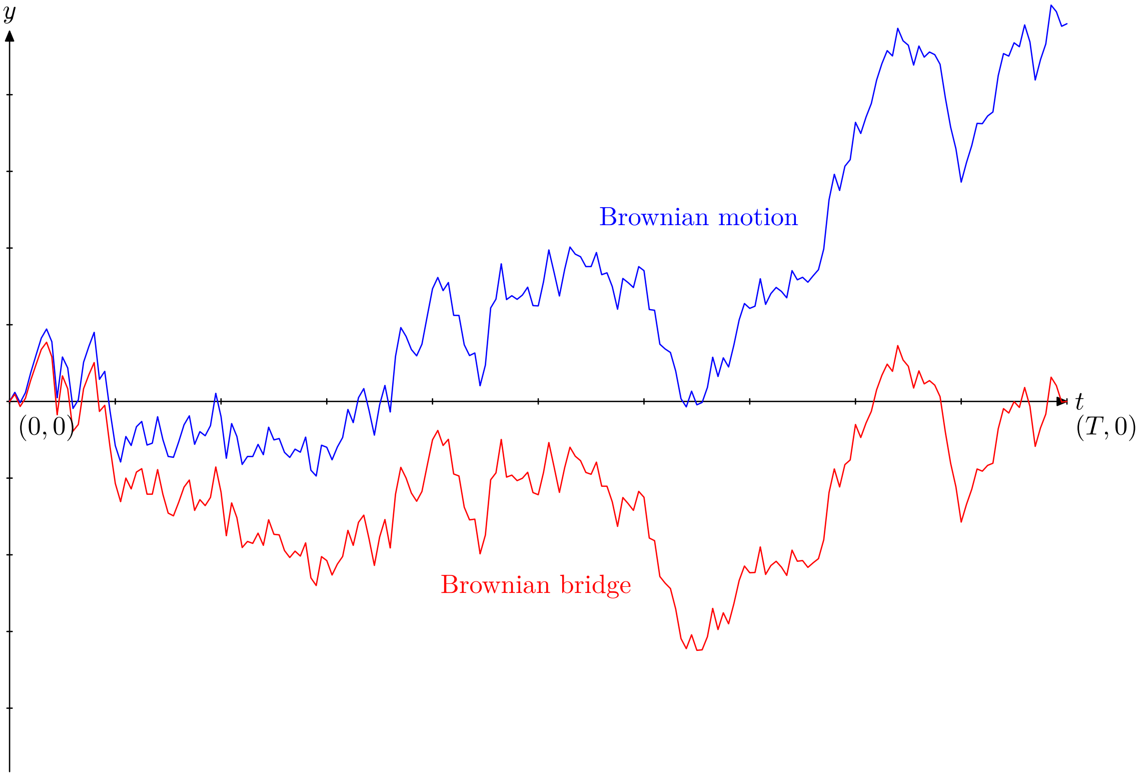

Figure 15.178: Brownian motion and Brownian bridge

As it is usual, let us choose the following notation:

$$W(t)=W_{t-\Delta t}+\mu W_0\Delta t+\mathcal{N}(0,1)W_0\sqrt{\Delta t} \tag{15.3.898}$$

If we want the Brownian motion to vanish at time T, it is sufficient to make a simple subtraction of the following type:

$$\text{BB}(t)=W(t)-W(T) \tag{15.3.899}$$

where BB means "Brownian bridge". If we stop here, we have indeed:

$$\text{BB}(t)=W(T)-W(T)=0 \tag{15.3.900}$$

But we have a problem with time $t=0$:

$$\text{BB}(0)=W(0)-W(T)\neq 0 \tag{15.3.901}$$

and to make sure that the difference is zero, the natural trick is to write:

$$\text{BB}(t)=W(t)-tW(T) \tag{15.3.902}$$

Thus, we have:

$$\text{BB}(0)=W(0)-0\cdot W(T)=0 \tag{15.3.903}$$

But then comes another problem. Indeed:

$$\text{BB}(T)=W(T)-T\cdot W(T)\neq 0 \tag{15.3.904}$$

So the final solution is to write:

$$\boxed{\mathrm{BB}(t)=W(t)-\frac{t}{T}\cdot W(T)} \quad (15.3.905)$$

and therefore:

$$\mathrm{BB}(t)=\mathrm{BB}(T)=0 \quad (15.3.906)$$

and we have:

$$\mathrm{E}(\mathrm{BB}(t))=\mathrm{E}\left(W(t)-\frac{t}{T}\cdot W(T)\right)=0 \quad (15.3.907)$$

The Brownian Bridge:

$$\mathrm{BB}(t)=W(t)-\frac{t}{T}\cdot W(T) \quad (15.3.908)$$

works for all the Wiener's processes, reason why we will sometimes see in the literature sometimes bridges with:

$$W_t=W_{t-\Delta t}+\mu W_0\Delta t+\mathcal{N}(0,1)\sigma W_0\sqrt{\Delta t} \quad (15.3.909)$$

or for example with:

$$W_t=W_{t-\Delta t}+\mu\Delta t+\mathcal{N}(0,1)\sigma\sqrt{\Delta t} \quad (15.3.910)$$

which is only one special case of the preceding with $W_0=1$.

✍**Example:**

To simulate such a process in Microsoft® Excel® 11.8346 for example we build:

	A	B	C
1	Average	0.05

Figure 15.179: **Explicit formulas in Microsoft® Excel® 11.8346 to build a Brownian bridge**

as the time interval is $\Delta t = 0.01$ then $T = 1/0.01 = 100$ and we get visually:

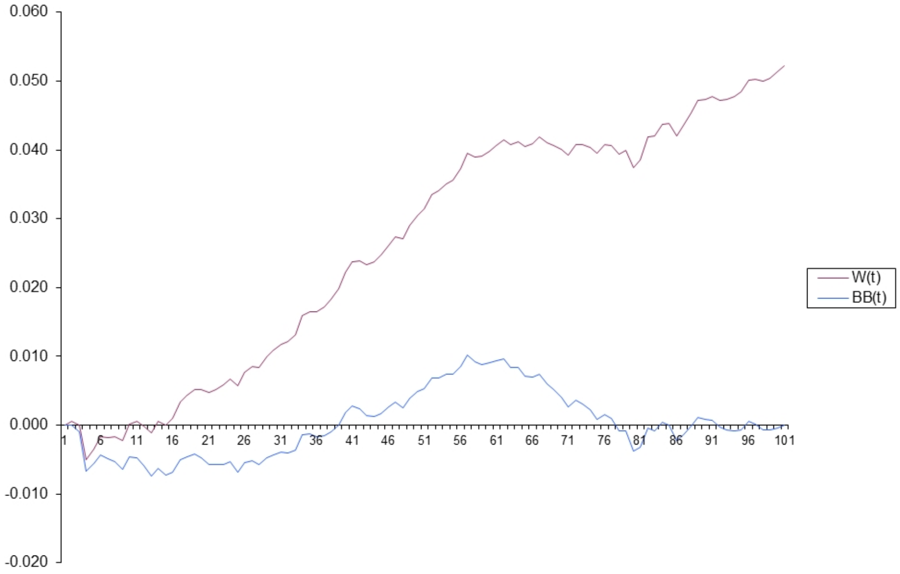

Figure 15.180: **Brownian bridge in Microsoft® Excel® 11.8346**

With everything seen so far, the reader should be able to understand the following plot showing a typical surface Call price curves with the special case of random Brownian bridge between the emission and maturity of the option:

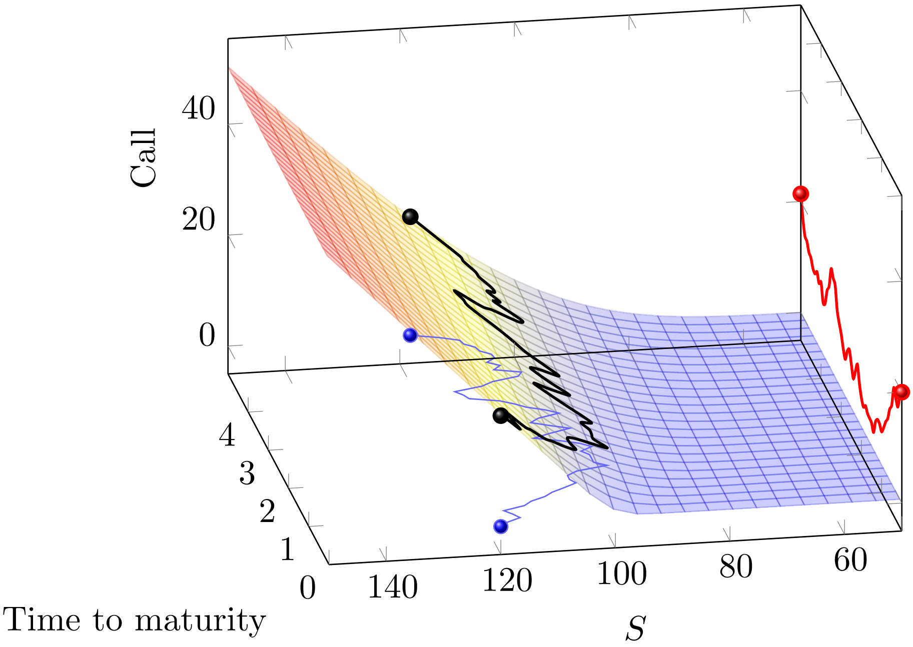

Figure 15.181: Surface Call price curves with a random Brownian bridge

15.3.10.3.9.6 Itō's process

Let us consider now a Brownian process corresponding to a variation of x in continuous time (practitioners speak also sometimes of "short-rate modelling") defined by:

$$dx = a(x,t)dt + b(x,t)dz \qquad (15.3.911)$$

a and b then being functions of the two variables x and t. This consideration is what we name an "Itō process", which is named after Kiyosi Itō. It is therefore a generalization of the previous case where a and b are no longer constant.

It is possible to calculate the expected mean and the variance of dx exactly in the same way as for the Wiener process and we obtain very easily by analogy:

$$\text{E}(dx) = 0 \qquad \text{E}(dx) = b^2(x,t)dt \qquad (15.3.912)$$

Therefore, we can write:

$$dx \longrightarrow \mathcal{N}\left(a(x,t)dt, b(x,t)\sqrt{dt}\right) \qquad (15.3.913)$$

Where $a(x,t)$ corresponds to the "instantaneous drift" and $b(x,t)$ to the "instantaneous variance".

Remark

It seems that the general case where a and b depend on time and of a parameter x (which, as we shall see later, corresponds to the strike price) is part of a model class which is named "Heat-Jarrow-Mortong models". In the case where only b would no longer be dependent on time, it seems that than it is named "Ho & Lee model". In reality there is a plethora of empirical models that adapt more or less well according to the situations and to study the whole, a life is no longer enough as for each model you can find a book between 200 and 400 pages...

The "geometric Brownian motion" which allows to theoretically define a possible prediction of the evolution of the yield of an asset is a special case of Itō processes (among so many other models ...) where we assume that:

$$a(x,t)=\mu\cdot x \qquad \text{and} \qquad b(x,t)=\sigma\cdot x \tag{15.3.914}$$

Remember that μ and σ are in percentage!

So the variance and the drift is independent of time! The advantage of assuming this is that unlike the Brownian arithmetic motion we will see that the yield then follows a log-normal law and therefore can not be negative. However, the two processes have two common weaknesses: the price of the associated asset can tend towards infinity in an infinite time (which is corrected the Vasicek process) and both consider volatility as constant in time...

Then we can write the expression of the geometric Brownian motion of the value of the asset as following:

$$\boxed{\mathrm{d}F=\mu x\mathrm{d}t+\sigma x\mathrm{d}z} \tag{15.3.915}$$

often represented in the literature also in the following form:

$$\mathrm{d}X_t=\mu X_t\mathrm{d}t+\sigma X_t\mathrm{d}W_t \tag{15.3.916}$$

Or even more explicitly:

$$\mathrm{d}X_t=(\mu X_t)\mathrm{d}t+(\sigma X_t)\mathrm{d}W_t=(\mu X_t)\mathrm{d}t+(\sigma X_t)\mathrm{d}\left(\mathcal{N}(0,1)\sqrt{\mathrm{d}t}\right) \tag{15.3.917}$$

Remark

The "Chan-Karolyi-Longstaff-Sanders model" is an attempt to generalize many stochastic process models used in finance:

$$\mathrm{d}X_t=(\alpha+\mu X_t)\mathrm{d}t+\sigma X_t^{\gamma}\mathrm{d}W_t \tag{15.3.918}$$

Here are some of the best known cases used in finance (the years are given based on holocene calendar):

Reference	Model
Merton (11973) / Bachelier / Brownian motion	$\mathrm{d}X_t = \mu \mathrm{d}t + \sigma \mathrm{d}W_t$
Geometric brownian motion	$\mathrm{d}X_t = \mu X_t \mathrm{d}t + \sigma X_t \mathrm{d}W_t$
Ornstein-Uhlenbeck (11930)	$\mathrm{d}X_t = -\theta X_t \mathrm{d}t + \sigma \mathrm{d}W_t$
Vasicek / Mean reverting (11977)	$\mathrm{d}X_t = k(\alpha + \mu X_t)\mathrm{d}t + \sigma \mathrm{d}W_t$
Cox-Ingersoll-Ross (11985)	$\mathrm{d}X_t = (\alpha - \mu X_t)\mathrm{d}t + \sigma \sqrt{X_t}\mathrm{d}W_t$
Dothan (11978)	$\mathrm{d}X_t = \sigma \mathrm{d}W_t$
Rendlemann-Bartter Geometric brownian motion (11905)	$\mathrm{d}X_t = \mu X_t \mathrm{d}t + \sigma X_t \mathrm{d}W_t$
Schwartz and Brennan (11980)	$\mathrm{d}X_t = (\alpha + \mu X_t)\mathrm{d}t + \sigma X_t \mathrm{d}W_t$
Cox and al. (11980)	$\mathrm{d}X_t = \sigma X_t^{3/2} \mathrm{d}W_t$
Variance with constant elasticity (CEV)	$\mathrm{d}X_t = \mu X_t \mathrm{d}t + \sigma X_t^{\gamma} \mathrm{d}W_t$
Chan-Karolyi-Longstaff-Sander (11992)	$\mathrm{d}X_t = (\alpha + \mu X_t)\mathrm{d}t + \sigma X_t^{\gamma} \mathrm{d}W_t$
Heston (11993)	$\mathrm{d}X_t = \mu X_t \mathrm{d}t + \sigma_t X_t \mathrm{d}W_t^X$ $\mathrm{d}\sigma_t = \kappa(\theta - \sigma_t)\mathrm{d}t + \xi \sqrt{\sigma_t}\mathrm{d}W_t^{\sigma}$
...	...

Table 15.53: **Some Chan-Karolyi-Longstaff-Sanders derived stochastic processes**

where the reader must remember that μ and σ are in percentage!

The k factor of the Vasiceck model is named the "mean-reversion speed" (typically used when the trader believe that in normal conditions, the average price of a stock, given a certain number of prior periods will lie between the bid price and the offer price and due to some heavy market forces it should revert back to the long term mean price level). All diffusion process above with a power seems to be commonly named "fractional diffusion processes".

Considering an asset returns and its variance as constants in time are choices based on the empirical observation of markets when assets are stocks. However, some more sophisticated models have asset returns and variances that depend on the asset value in time.

The financial interpretation of the relation:

$$\mathrm{d}F = \mu x \mathrm{d}t + \sigma x \mathrm{d}z \tag{15.3.919}$$

Becomes apparent when we divide the two members by x:

$$\boxed{\frac{\mathrm{d}S_t}{S_t} = \mu \mathrm{d}t + \sigma \mathrm{d}z} \tag{15.3.920}$$

Which corresponds to the rate of return of the asset over an infinitesimal period $\mathrm{d}t$.

The geometric Brownian motion is therefore a priori a good candidate to model the evolution of the price of certain financial assets from its rate of return.

In the specialized literature, the return is also sometimes denoted (justified notation) in the form of the following stochastic differential equation (S.D.E.):

$$\frac{\mathrm{d}S_t}{S_t} = (\mu - q)\mathrm{d}t + \sigma \mathrm{d}z \tag{15.3.921}$$

where S_t is obviously the price of the underlying named as we already know the "stock price" at time t, μ is named the "drift" (often assimilated to yield) and σ the "yield volatility". It is the notation and the vocabulary that we will adopt for the rest of the development. Let us notice that we see better than this assumes that the drift is independent of the value of the underlying (which is a verified observation for some assets).

In the case of a continuous dividend payment, given q the dividend rate, the dynamics of the price can be written intuitively:

$$\frac{\mathrm{d}\ln(S_t)}{\mathrm{d}S_t}=\frac{1}{S_t} \tag{15.3.922}$$

We can therefore also write (we continue with the case without dividends!):

$$\mathrm{d}\ln(S_t)=\mu\mathrm{d}t+\sigma\mathrm{d}z \tag{15.3.923}$$

In the case where $\sigma=0$ (Wiener process, i.e. the price of the underlying is perfectly known at a given time and without risks), we find ourselves with a differential equation (well known in the finance domain) that we can solve immediately:

$$\frac{\mathrm{d}\ln(S_t)}{\mathrm{d}S_t}=\mu\mathrm{d}t\Leftrightarrow\frac{\mathrm{d}S_t}{\mathrm{d}S_t}=\mu S_t\Rightarrow S_t=S_0e^{\mu(t-t_0)} \tag{15.3.924}$$

This is therefore an exponential (as the continuous interest we saw at the beginning of this section). This relation is valid only if the time interval is therefore very small and the return rate not too big!

We will now see thanks to the "Itō lemma" that it is possible (which is not the unique possibility!) to establish that such a process can define a log-normal law (see section Statistics page 734).

The Itō lemma is derived from the multivariable Taylor expansion (see section Sequences and Series page 1696) with 2 variables x and t and given by:

$$\Delta F=\frac{1}{1!}\frac{\partial F}{\partial t}\Delta t+\frac{1}{1!}\frac{\partial F}{\partial x}\Delta x+\frac{1}{2!}\frac{\partial^2 F}{\partial t^2}\Delta t^2+\frac{1}{2!}\frac{\partial^2 F}{\partial x^2}\Delta x^2+\ldots \tag{15.3.925}$$

with $F(0)=0$ at the origin of the Brownian motion.

Considering $\Delta t\ll\Delta x$, and taking the terms only up to the second order (formal perilous approximation but numerically not mandatory thanks to computing power of modern computers), we have:

$$\Delta F\cong\frac{1}{1!}\frac{\partial F}{\partial t}\Delta t+\frac{1}{1!}\frac{\partial F}{\partial x}\Delta x+\frac{1}{2!}\frac{\partial^2 F}{\partial x^2}\Delta x^2 \tag{15.3.926}$$

Let us now return to:

$$\Delta x=a\cdot\Delta t+b\cdot\Delta z=a\Delta t+b\varepsilon\sqrt{\Delta t} \tag{15.3.927}$$

Let us raise to the square (i.e. compute the quadratic variation), we get:

$$\Delta x^2=\left(a\Delta t+b\varepsilon\sqrt{\Delta t}\right)^2=a^2\Delta t^2+2\varepsilon ab\Delta t^{3/2}+b^2\varepsilon^2\Delta t\cong b^2\varepsilon^2\Delta t \tag{15.3.928}$$

But:

$$\mathrm{E}\left(b^2\varepsilon^2\Delta t\right)=b^2\Delta t\mathrm{E}\left(\varepsilon^2\right) \tag{15.3.929}$$

And as we have proved it in the Statistics section:

$$\mathrm{V}(X)=\mathrm{E}\left(X^2\right)-\mathrm{E}\left(X\right)^2\Leftrightarrow \mathrm{E}(X^2)=\mathrm{V}(X)+\mathrm{E}(X)^2 \tag{15.3.930}$$

Then we have:

$$\mathrm{E}\left(\varepsilon^2\right)=\mathrm{V}(\varepsilon)+\mathrm{E}(\varepsilon)^2=1+0=1 \tag{15.3.931}$$

Therefore:

$$\mathrm{E}(b^2\varepsilon^2\Delta t)=b^2\Delta t \tag{15.3.932}$$

By the way:

$$\mathrm{V}(b^2\varepsilon^2\Delta t)=b^4\Delta t^2\mathrm{V}(\varepsilon^2)=b^4\Delta t^2 \tag{15.3.933}$$

which both tend to 0 when Δt tends to 0.

We also have by considering a subdivision of time in extremely small intervals $\mathrm{d}t$ (approximation which will be useful to us a little later):

$$\lim_{\Delta t\rightarrow 0} b^2\varepsilon^2\Delta t\cong \lim_{\Delta t\rightarrow 0} b^2\Delta t=0 \tag{15.3.934}$$

which implies in that latter case:

$$b^2\varepsilon^2\Delta t\cong b^2\Delta t \tag{15.3.935}$$

Thus taking place in continuous time (thus a continuous model with extremely small time intervals), the application of the discrete Taylor development seen above:

$$\Delta F\cong\frac{1}{1!}\frac{\partial F}{\partial t}\Delta t+\frac{1}{1!}\frac{\partial F}{\partial x}\Delta x+\frac{1}{2!}\frac{\partial^2 F}{\partial x^2}\Delta x^2 \tag{15.3.936}$$

Can then be written:

$$\begin{aligned}\mathrm{d}F&\cong\frac{\partial F}{\partial t}\mathrm{d}t+\frac{\partial F}{\partial x}\mathrm{d}x+\frac{1}{2}\frac{\partial^2 F}{\partial x^2}b^2\mathrm{d}t=\frac{\partial F}{\partial t}\mathrm{d}t+\frac{\partial F}{\partial x}(a\mathrm{d}t+b\mathrm{d}z)+\frac{1}{2}\frac{\partial^2 F}{\partial x^2}b^2\mathrm{d}t\\&=\left(\frac{\partial F}{\partial t}+a\frac{\partial F}{\partial x}+\frac{1}{2}b^2\frac{\partial^2 F}{\partial x^2}\right)\mathrm{d}t+b\frac{\partial F}{\partial x}\mathrm{d}z\end{aligned} \tag{15.3.937}$$

Therefore:

$$\boxed{\mathrm{d}F\cong\left(\frac{\partial F}{\partial t}+a\frac{\partial F}{\partial x}+\frac{1}{2}b^2\frac{\partial^2 F}{\partial x^2}\right)\mathrm{d}t+b\frac{\partial F}{\partial x}\mathrm{d}z} \tag{15.3.938}$$

This final result is the "Itō's lemma" also named "Itō-Doeblin theorem".

Therefore as the reader can read it on Wikipedia: Itō's lemma is an identity used in Itō calculus to find the differential of a time-dependent function of a stochastic process. It serves as the stochastic calculus counterpart of the chain rule. It can be heuristically derived by forming the Taylor series expansion of the function up to its second derivatives and retaining terms up to first order in the time increment and second order in the Wiener process increment. The lemma is widely employed in mathematical finance, and its best known application is in the derivation of the Black–Scholes equation for option values.

Remarks

R1. Compare the form of the last equality with the relation: $\mathrm{d}x = a(x,t)\mathrm{d}t + b(x,t)\mathrm{d}z$

R2. The expression in parentheses above (factor of $\mathrm{d}t$) is sometimes referred to as the "Kolmogorov backward equation".

If we take:

$$F(x) = \ln(x) \tag{15.3.939}$$

Therefore:

$$\frac{\partial F}{\partial t} = 0 \qquad \frac{\partial F}{\partial x} = \frac{1}{x} \qquad \frac{\partial^2 F}{\partial x^2} = -\frac{1}{x^2} \tag{15.3.940}$$

In that case:

$$\mathrm{d}F \cong \left(0 + \frac{a}{x} - \frac{1}{2}b^2\frac{1}{x^2}\right)\mathrm{d}t + b\frac{1}{x}\mathrm{d}z \tag{15.3.941}$$

Returning to the geometric Brownian motion hypothesis, we know that we must consider that:

$$a = a(x,t) = \mu x \qquad \text{at} \qquad b = b(x,t) = \sigma x \tag{15.3.942}$$

Therefore we have:

$$\mathrm{d}F \cong \left(0 + \frac{\mu x}{x} - \frac{1}{2}\frac{\sigma^2 x^2}{x^2}\right)\mathrm{d}t + \sigma x\frac{1}{x}\mathrm{d}z \tag{15.3.943}$$

and we finally get the following stochastic differential equation with constant coefficients:

$$\mathrm{d}F \cong \left(\mu - \frac{\sigma^2}{2}\right)\mathrm{d}t + \sigma\mathrm{d}z \tag{15.3.944}$$

Either by taking the notation of the beginning in explicit form:

$$\mathrm{d}\ln(x) \cong \left(\mu - \frac{\sigma^2}{2}\right)\mathrm{d}t + \sigma\mathrm{d}z \tag{15.3.945}$$

Or in another even more explicit form:

$$\boxed{\mathrm{d}\ln(X_t) \cong \left(\mu - \frac{\sigma^2}{2}\right)\mathrm{d}t + \sigma\mathrm{d}W_t = \left(\mu - \frac{\sigma^2}{2}\right)\mathrm{d}t + \sigma\mathrm{d}\left(\mathcal{N}(0,1)\sqrt{\mathrm{d}t}\right)} \tag{15.3.946}$$

Sometimes named the "integral equation of price dynamics".

A trivial approach to the resolution of this integral is (we always consider in this model that volatility is independent of time... and abusively we replace the $\cong$ by a $=$ sign):

$$\int_t^{t+1} \mathrm{d}\ln(X_t) = \int_t^{t+1} \left(\mu - \frac{\sigma^2}{2}\right)\mathrm{d}t + \int_t^{t+1} \sigma \mathrm{d}W_t = \left(\mu - \frac{\sigma^2}{2}\right)\int_t^{t+1}\mathrm{d}t + \sigma\int_t^{t+1}\mathrm{d}W_t \tag{15.3.947}$$

Therefore:

$$\ln(X_{t+1}) - \ln(X_t) = \left(\mu - \frac{\sigma^2}{2}\right)\Big((t+1)-t\Big) + \sigma\Big(W_{t+1} - W_t\Big) \tag{15.3.948}$$

Hence:

$$\ln\left(\frac{X_{t+1}}{X_t}\right) = \mu - \frac{\sigma^2}{2} + \sigma\Big(W_{t+1} - W_t\Big) = \mu - \frac{\sigma^2}{2} + \sigma\mathcal{N}(0,1) \tag{15.3.949}$$

Remarks

R1. Remember that we started from the relation $\mathrm{d}F = \mu x \mathrm{d}t + \sigma x \mathrm{d}z$

R2. Brownian movements were successively discovered from the hypothesis of Normality in the 11960s (holocene calendar) and then from the stability hypothesis in the 11980s (holocene calendar). With these two hypotheses, mathematicians rank them in the special category of "2-stable Levy processes".

$\mathrm{d}F$ defines a geometrical Brownian motion with particular drift whose parameters that we can now measure (this is what we wanted to achieve). Therefore, the results we obtained for the Brownian motion can be recovered and allow us to write in the end:

$$\mathrm{d}F \longrightarrow \mathcal{N}\left(\left(\mu - \frac{\sigma^2}{2}\right)\mathrm{d}t, \sigma\sqrt{\mathrm{d}t}\right) \tag{15.3.950}$$

Which means that $\mathrm{d}F$ follows a log-normal law (see section Statistics page 734) of parameters:

$$\left(\mu - \frac{\sigma^2}{2}\right)\mathrm{d}t \qquad \text{and} \qquad \sigma\sqrt{\mathrm{d}t} \tag{15.3.951}$$

Or otherwise written:

$$\begin{aligned} \Delta F = \Delta\Big(\ln(X_t)\Big) &\to \mathcal{N}\left(\left(\mu - \frac{\sigma^2}{2}\right)\Delta t, \sigma\sqrt{\Delta t}\right) \\ \Rightarrow \ln(X_T) - \ln(X_0) &\to \mathcal{N}\left(\left(\mu - \frac{\sigma^2}{2}\right)T, \sigma\sqrt{T}\right) \\ \Rightarrow \ln(X_T) &\to \mathcal{N}\left(\ln(X_0) + \left(\mu - \frac{\sigma^2}{2}\right)T, \sigma\sqrt{T}\right) \end{aligned} \tag{15.3.952}$$

A small reminder with what was seen in the Statistics section but applied to finance of the log-normal law finance may be welcome! Consider the present value of a given asset (compound interest) whose rate varies for each period:

$$X_t = X_0 \prod_{i=1}^{N} \left(1 + t_i\%\right) \tag{15.3.953}$$

So if we take the logarithm:

$$\ln(X_t) = \ln(X_0) + \sum_{i=1}^{N} \ln(1 + t_i\%) \tag{15.3.954}$$

Thus, if the rate of return is a variable random and independent from period to period and identically distributed, then we have an expression which will give a Normal distribution according to the central limit theorem (see section Statistics page 938). Therefore, a random variable is log-normalized when its logarithm is Normally distributed!

✍**Examples:**

E1. Let us consider a stock with a current price of 40.-, with an assumed average geometric yield of 16% per year and an annual volatility of 20%. In 6 months ($T = 0.5$) we then have:

$$\ln(X_T) \longrightarrow \mathcal{N}(3.759, 0.141) \tag{15.3.955}$$

We can then build a 95% confidence interval (see section Statistics page 848):

$$3.759 - 1.96 \cdot 0.141 \leq \ln(X_t) \leq 3.759 + 1.96 \cdot 0.141 \tag{15.3.956}$$

And therefore:

$$\begin{gathered} e^{3.759 - 1.96 \cdot 0.141} \leq X_t \leq e^{3.759 + 1.96 \cdot 0.141} \\ 32.55 \leq X_t \leq 56.56 \end{gathered} \tag{15.3.957}$$

So there is 95% cumulative probability that in 6 months the value of the security is between 32.55.- and 56.56.-.

E2. Knowing that:

$$\ln\left(\frac{X_T}{X_0}\right) \rightarrow \mathcal{N}\left(\left(\mu - \frac{\sigma^2}{2}\right)T, \sigma\sqrt{T}\right) \tag{15.3.958}$$

and that at continuous rate:

$$X_T = X_0 e^{RT} \Leftrightarrow R = \frac{1}{T} \ln\left(\frac{X_t}{X_0}\right) \tag{15.3.959}$$

We then have for performance the possibility of applying the same type of calculations as before:

$$R \longrightarrow \mathcal{N}\left(\mu - \frac{\sigma^2}{2}, \frac{\sigma}{\sqrt{T}}\right) \tag{15.3.960}$$

Let's go a step further by integrating the differential element. So we have:

$$\frac{\mathrm{d}X_t}{X_t}=\left(\mu-\frac{\sigma^2}{2}\right)\mathrm{d}t+\sigma\mathrm{d}\left(\mathcal{N}(0,1)\sqrt{\mathrm{d}t}\right) \tag{15.3.961}$$

Let us integrate this last relation:

$$\int\frac{\mathrm{d}X_t}{X_t}=\int\left(\mu-\frac{\sigma^2}{2}\right)\mathrm{d}t+\int\sigma\mathrm{d}\left(\mathcal{N}(0,1)\sqrt{\mathrm{d}t}\right) \tag{15.3.962}$$

The first primitive is simple:

$$\int\frac{\mathrm{d}X_t}{X_t}=\ln(X_t)+c^{te} \tag{15.3.963}$$

The second primitive is also quite simple (no integration constant because at time zero the expectation of gain is zero):

$$\int\left(\mu-\frac{\sigma^2}{2}\right)\mathrm{d}t=\left(\mu-\frac{\sigma^2}{2}\right)\int\mathrm{d}t=\left(\mu-\frac{\sigma^2}{2}\right)t \tag{15.3.964}$$

The third primitive is equal to (no integration constant because at time zero the value of the gain is perfectly known as being equal to zero):

$$\int\sigma\mathrm{d}\left(\mathcal{N}(0,1)\sqrt{\mathrm{d}t}\right)=\sigma\mathcal{N}(0,1)\int\mathrm{d}\sqrt{\mathrm{d}t}=\sigma\mathcal{N}(0,1)\sqrt{t} \tag{15.3.965}$$

Caution to the abuse of notation here!!! In the root it is implicitly a $\mathrm{d}t$ (therefore the analysis time step!) and not simply a t. Remember that for the remaining developments below!!!

We therefore have:

$$\ln(X_t)=\left(\mu-\frac{\sigma^2}{2}\right)t+\sigma\mathcal{N}(0,1)\sqrt{t}-c^{te} \tag{15.3.966}$$

And finally (we put the "$-$" sign in the constant):

$$X_t=e^{\left(\mu-\frac{\sigma^2}{2}\right)t+\sigma\mathcal{N}(0,1)\sqrt{t}+c^{te}}=e^{c^{te}}e^{\left(\mu-\frac{\sigma^2}{2}\right)t+\sigma\mathcal{N}(0,1)\sqrt{t}} \tag{15.3.967}$$

To find the meaning of the first factor, it suffices to state the initial condition:

$$X_t(t=0)=X_0 \tag{15.3.968}$$

We then have immediately for the final expression of the geometric Brownian which is for recall a random variable:

$$\boxed{X_t=X_0e^{\left(\mu-\frac{\sigma^2}{2}\right)t+\sigma\mathcal{N}(0,1)\sqrt{t}}} \tag{15.3.969}$$

that was obtained by Paul Samuelson in 11965 (holocene calendar) and which is sometimes named the "Bachelier-Samuelson model" or "log-normal representation of the value of the asset" or "Itō's solution".

This last relation is often written in the following form:

$$X_t = X_0 e^{\left(\mu-\frac{\sigma^2}{2}\right)\Delta t+\sigma\mathcal{N}(0,1)\sqrt{\Delta t}} = X_0 e^{\left(\mu-\frac{\sigma^2}{2}\right)(T-t)+\sigma\mathcal{N}(0,1)\sqrt{T-t}} \tag{15.3.970}$$

Notice that if we write (due to the Jensen's inequality proven in the Statistics section page 576):

$$S_0\mathrm{E}\left(\max\left(e^{\left(\mu-\frac{\sigma^2}{2}\right)(T-t)+\sigma\mathcal{N}(0,1)\sqrt{T-t}}-K,0\right)\right) \tag{15.3.971}$$

this gives us the expectation mean of positive deviations from the strike price. And if we update this value in the idea that this sum of money can be invested in a risk-free return asset, we then get the Monte Carlo version of the evaluation of a Call type option:

$$C = S_0 e^{-r(T-t)}\mathrm{E}\left(\max\left(e^{\left(\mu-\frac{\sigma^2}{2}\right)(T-t)+\sigma\mathcal{N}(0,1)\sqrt{T-t}}-K,0\right)\right) \tag{15.3.972}$$

And in general the same form of relation written for a Put will be named the "fundamental relation of option pricing". In reality we must take care to the fact that here the word "fundamental" means that we must be careful, however, to choose the right stochastic process, which is why in the literature we have more often the following expression that generalizes the previous relationship:

$$\boxed{C,P = e^{-r(T-t)}\mathrm{E}\big(f(M_s)\big) = D(T,t,r)E\big(f(M_s)\big)} \tag{15.3.973}$$

where f is a function of a given stochastic process (since there are several functions depending on the type of underlying), and the function D is named a "discount factor". For this last relation, we find almost as many different writings as there are textbooks on the subject...

The above relation is also sometimes denoted:

$$e^{-rT}\tilde{\mathrm{E}}\big(f(S(T))\big) \tag{15.3.974}$$

where $\tilde{\mathrm{E}}$ means: *expectation under the risk-neutral stock price model*. What do we mean by this? By the risk-neutral stock price model, we mean a geometric Brownian motion with the same yield volatility σ as before but with the expected rate of return changed from μ to r. So that in the risk-neutral model, the expected stock price grows at the same rate as the risk-free investment.

This risk-neutral assumption behind the Black & Scholes model constitutes a great advantage in a trading environment. In the risk-neutral world, all cash flows can be discounted using the risk-free rate (r) whereas, in a real word, the discount rate should take into account the risk premium (for reminder the risk premium is the investment return an asset is expected to yield in excess of the risk-free rate of return), which is more delicate...

We can classify the dynamics of this function in three special cases:

- If $\mu > \dfrac{1}{2}\sigma^2$, $X_t \rightarrow +\infty$ when $t \rightarrow +\infty$
- If $\mu < \dfrac{1}{2}\sigma^2$, $X_t \rightarrow 0$ when $t \rightarrow +\infty$
- If $\mu = \dfrac{1}{2}\sigma^2$, X_t will randomly fluctuate between high and small values when $t \rightarrow +\infty$

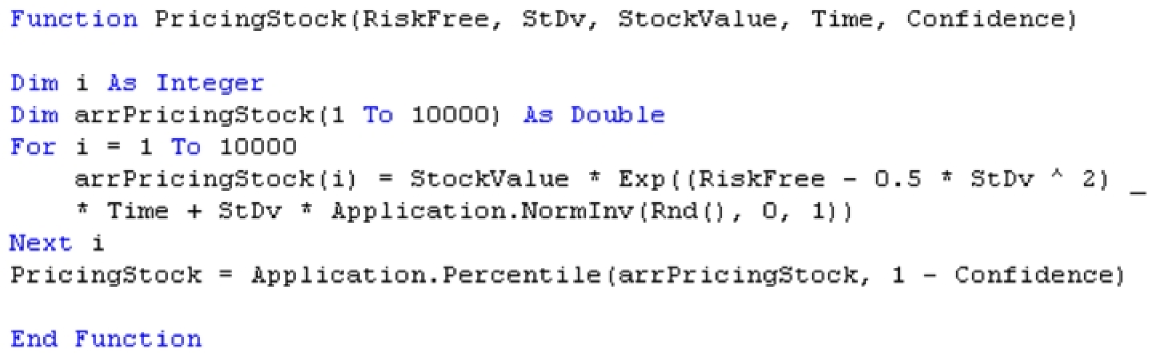
Following the request of a reader, although we have seen that the Brownian geometric motion was built higher from a log-Normal law of which we know the expected mean, let us do the inverse calculation, that is to say to calculate the expected mean of the Brownian geometric movement to evidently in the end fall back on our feet:

$$\begin{aligned}\mathrm{E}(X_t) &= \mathrm{E}\left(e^{\left(\mu-\frac{\sigma^2}{2}\right)t+\sigma\mathcal{N}(0,1)\sqrt{t}}\right) = X_0 e^{\left(\mu-\frac{\sigma^2}{2}\right)t}\mathrm{E}\left(e^{\sigma\mathcal{N}(0,1)\sqrt{t}}\right) \\ &= X_0 e^{\left(\mu-\frac{\sigma^2}{2}\right)t}\mathrm{E}\left(e^{\mathcal{N}(0,\sigma^2 t)}\right)\end{aligned} \tag{15.3.975}$$

So the term in parentheses follows by definition (or "by construction" if you prefer) a log-Normal law (see section Statistics page 734). The expected mean of the latter is then:

$$\mathrm{E}(X_t) = X_0 e^{\left(\mu-\frac{\sigma^2}{2}\right)t} e^{0+\frac{\sigma^2}{2}t} = X_0 e^{\left(\mu-\frac{\sigma^2}{2}\right)t} e^{\frac{\sigma^2}{2}t} = X_0 e^{\mu t} \tag{15.3.976}$$

To price an asset according to this model over a horizon, we can use the following Monte Carlo VBA function (the reader can also refer to our `R` or MATLAB® companion book for the same calculation):



```
Function PricingStock(RiskFree, StDv, StockValue, Time, Confidence)

Dim i As Integer
Dim arrPricingStock(1 To 10000) As Double
For i = 1 To 10000
    arrPricingStock(i) = StockValue * Exp((RiskFree - 0.5 * StDv ^ 2) _
    * Time + StDv * Application.NormInv(Rnd(), 0, 1))
Next i
PricingStock = Application.Percentile(arrPricingStock, 1 - Confidence)

End Function
```

We finally have a formulation (in the form of a probabilistic distribution function) of a temporal variation and of the intrinsic return of an asset that can be used for investment decision-making purposes on a forecast. But this model is still too smooth to model stock market crashes or bubbles (it is the same for recall with the standard Brownian motion) that can occur in the long term. This is why some more recent models that we will not study here add a Poisson process (discrete and with rare events by construction) to that of Wiener.

There are other models than the log-Normal but the latter is the most easy to understand and hence the most widespread. However, other more general methods must be encouraged!

To conclude this section, we summarize by a comparison the standard Brownian motion and the geometrical Brownian motion that govern the price dynamics when the parameters (instantaneous yield and volatility) are given in $\%$:

$$\begin{aligned}X_t &= X_0 + X_0\mu t + \mathcal{N}(0,1)\sigma X_0\sqrt{t} = X_0 + X_0\mu t + \sigma X_0 W_t = X_0(1+B_s)\\ X_t &= X_0 e^{\left(\mu-\frac{\sigma^2}{2}\right)t+\sigma\mathcal{N}(0,1)\sqrt{t}} = X_0 e^{\left(\mu-\frac{\sigma^2}{2}\right)t+\sigma W_t}\end{aligned} \tag{15.3.977}$$

and let us recall that the advantage of the geometrical Brownian motion is that it eliminates (thanks to the exponential) the negative values of the course which we could obtain with the standard Brownian motion of Bachelier.

It is then interesting for the financial analyst to visualize the expected mean as a function of T and the value $x(T)$ corresponding to a cumulative probability of 2.5% and 97.5% on a plot to have an idea of the evolution of the confidence interval at 95% of its $x(0)$. This is very easy to get in a spreadsheet software like Microsoft® Excel® and we can get by playing with several types of plots in the same chart on something like this (400 MUSD portfolio with 5% yield and 20% standard deviation):

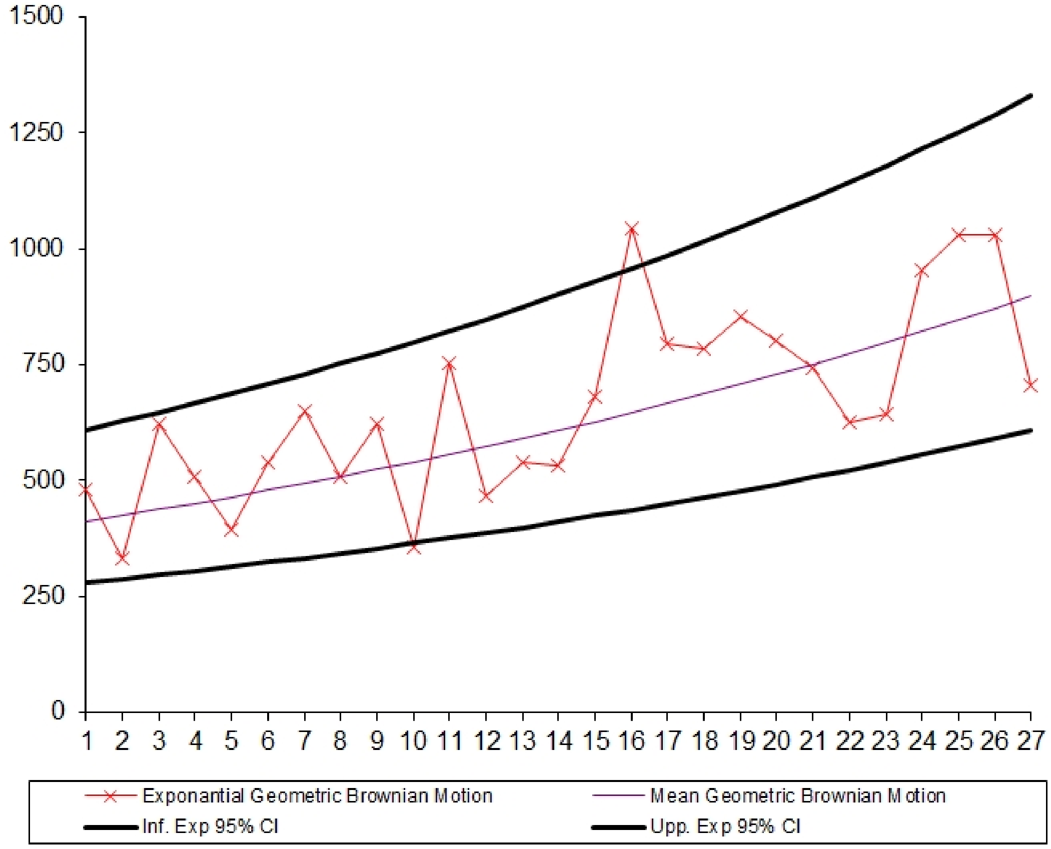


Figure 15.182: Geometric Brownian motion plot with 95% C.I. in Microsoft® Excel® 11.8346

With the following structure in Microsoft® Excel®:

	A	G	H	I	J

Figure 15.184: **Data table corresponding to the previous plot in Microsoft® Excel® 11.8346 with explicit formulas**

It is interesting to compare the evolution of this portfolio with the same parameters (volatility and yield) over the same period of time but with the standard brownian motion. This graphically gives:

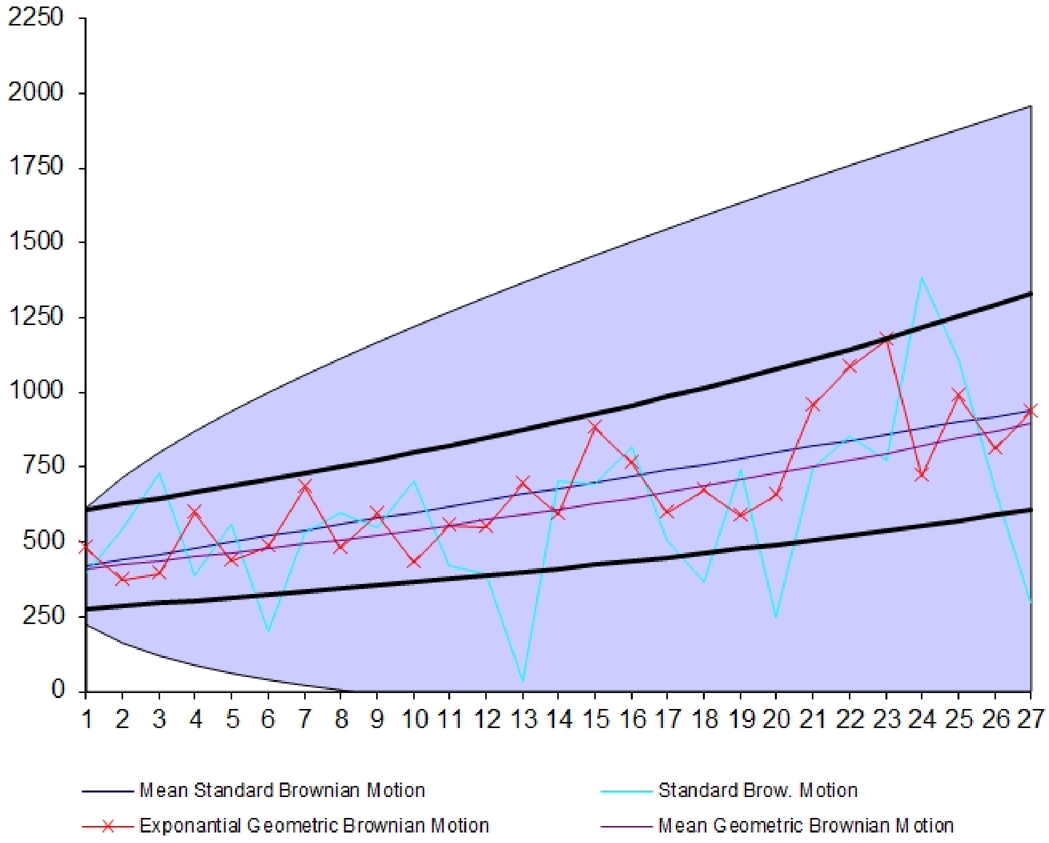

Figure 15.185: **Comparison of geometric and standard brownian motion**

Finally, the reader will notice that we can generalize the writing of the two Brownian process (taking the Napierian logarithm of the Brownian geometric process):

$$\begin{aligned}\ln(X_t) &= \ln\left(e^{\left(\mu-\frac{\sigma^2}{2}\right)t}+\sigma\mathcal{N}(0,1)\sqrt{t}\right)=\ln(X_0)+\ln\left(e^{\left(\mu-\frac{\sigma^2}{2}\right)t+\sigma\mathcal{N}(0,1)\sqrt{t}}\right)\\ &=\ln(X_0)+\left(\mu-\frac{\sigma^2}{2}\right)t+\sigma\mathcal{N}(0,1)\sqrt{t}\end{aligned} \quad (15.3.978)$$

by writing them in a form proposed by Benoît Mandelbrot in 11962 (holocene calendar):

$$X_t = X_0+\delta t+cL_t^{\alpha} \quad (15.3.979)$$

where δ and c are respectively the localization parameters (average return) and dispersion (non-Gaussian volatility) of the process, and where L_t^{α} designates the standard α-stable Lévy process.

The problem with this model is the loss of existence, for certain laws of probability that work very well, of the second moment (the variance) so important in terms of communication and images for professionals in the 11970s (holocene calendar) because it served them as the only measure of risk. The absence of finite variance was probably one of the most powerful causes of rejection (brain inertia not of customers but of board of directors...).

15.3.10.3.9.7 Itō's product and quotient rule

Before continuing on Black & Scholes pricing formula derivation, let us open a very small necessary parenthesis about Itō's approximation.

When we will study later how two assets are correlated to each other (during our proof of Margrabe formula further below), we will need what a majority of textbooks name "Itō's quotient rule" ! But to prove that latter, we will need first to derive "Itō's product rule" (even if in fact's it is just a again a simple Taylor approximation!). So let us see that!

Let $X^2=f(X)$. Then 2nd order Taylor development gives us (see section Sequences and Series page1698):

$$\mathrm{d}f(X)\cong f'(X)\mathrm{d}X+\frac{1}{2}f''(X)(\mathrm{d}X)^2=2X\mathrm{d}X+(\mathrm{d}X)^2 \tag{15.3.980}$$

But we also have (just a simple mathematical trick):

$$\mathrm{d}(XY)=\mathrm{d}\left(\frac{1}{2}((X+Y)^2-X^2-Y^2)\right)=\frac{1}{2}\left(\mathrm{d}(X+Y)^2-\mathrm{d}X^2-\mathrm{d}Y^2\right) \tag{15.3.981}$$

Now applying the Itō's lemma on each of the three terms above lead us to:

$$\begin{aligned}\mathrm{d}(X+Y)^2&\cong 2(X+Y)\mathrm{d}(X+Y)+(\mathrm{d}(X+Y))^2\\&=2\left(X\mathrm{d}X+X\mathrm{d}Y+Y\mathrm{d}Y+Y\mathrm{d}X\right)+(\mathrm{d}X)^2+2\mathrm{d}X\mathrm{d}Y+(\mathrm{d}Y)^2\big)\\\mathrm{d}X^2&\cong 2X\mathrm{d}X+(\mathrm{d}X)^2\\\mathrm{d}Y^2&\cong 2Y\mathrm{d}Y+(\mathrm{d}Y)^2\end{aligned} \tag{15.3.982}$$

Therefore:

$$\mathrm{d}(XY)\cong\frac{1}{2}(2X\mathrm{d}Y+2Y\mathrm{d}X+2\mathrm{d}X\mathrm{d}Y)=\mathrm{d}X\mathrm{d}Y+Y\mathrm{d}X+\mathrm{d}X\mathrm{d}Y \tag{15.3.983}$$

Let us now prove Itō's quotient rule given by:

$$\mathrm{d}\left(\frac{X}{Y}\right)=\frac{X}{Y}\left(\frac{\mathrm{d}X}{X}-\frac{\mathrm{d}Y}{Y}-\frac{\mathrm{d}X}{X}\frac{\mathrm{d}Y}{Y}+\left(\frac{\mathrm{d}Y}{Y}\right)^2\right) \tag{15.3.984}$$

We apply Itō's product rule to:

$$\mathrm{d}\left(X\frac{1}{Y}\right)\cong\frac{1}{Y}\mathrm{d}X+X\mathrm{d}\frac{1}{Y}+\mathrm{d}X\mathrm{d}\frac{1}{Y}=\frac{X}{Y}\left(\frac{\mathrm{d}X}{X}-\frac{\mathrm{d}Y}{Y}-\frac{\mathrm{d}X\mathrm{d}Y}{XY}\right) \tag{15.3.985}$$

Keep in mind that when we use the Taylor approximation:

$$\mathrm{d}f(Y)\cong f'(Y)\mathrm{d}Y+\frac{1}{2}f''(Y)(\mathrm{d}Y)^2 \tag{15.3.986}$$

So:

$$\mathrm{d}\left(Y^{-1}\right)\cong -Y^{-2}\mathrm{d}Y+2\frac{1}{2}Y^{-3}(\mathrm{d}Y)^2 \tag{15.3.987}$$

We put that back in $\mathrm{d}XY$ to get:

$$\mathrm{d}(XY)\cong\frac{1}{2}(2X\mathrm{d}Y+2Y\mathrm{d}X+2\mathrm{d}X\mathrm{d}Y)=\mathrm{d}X\mathrm{d}Y+Y\mathrm{d}X+\mathrm{d}X\mathrm{d}Y \tag{15.3.988}$$

Notice that actually in the huge majority of textbooks introducing these both rules, as for the Black & Scholes pricing relations, the $\cong$ is often abusively replaced by an $=$ sign...

15.3.10.3.9.8 Black & Scholes differential equation

We have obtained during the preceding developments the following differential equation for the random walk of the value of an asset under the constraint of a log-normal law and a Brownian motion:

$$\mathrm{d}F=\left(\frac{\partial F}{\partial t}+a\frac{\partial F}{\partial x}+\frac{1}{2}b^2\frac{\partial^2 F}{\partial x^2}\right)\mathrm{d}t+b\frac{\partial F}{\partial x}\mathrm{d}z=\left(\frac{\partial F}{\partial t}+\mu x\frac{\partial F}{\partial x}+\frac{1}{2}\sigma^2x^2\frac{\partial^2 F}{\partial x^2}\right)\mathrm{d}t+\sigma x\frac{\partial F}{\partial x}\mathrm{d}z \tag{15.3.989}$$

where for reminder μ and σ are expressed in percentage!

Either with the traditional notations in finance:

$$\mathrm{d}F=\left(\frac{\partial F}{\partial t}+a\frac{\partial F}{\partial S}+\frac{1}{2}b^2\frac{\partial^2 F}{\partial S^2}\right)\mathrm{d}t+b\frac{\partial F}{\partial S}\mathrm{d}z\underset{\substack{a=\mu x\\ b=\sigma x\\ x=S}}{=}\left(\frac{\partial F}{\partial t}+\mu S\frac{\partial F}{\partial S}+\frac{1}{2}\sigma^2S^2\frac{\partial^2 F}{\partial S^2}\right)\mathrm{d}t+\sigma S\frac{\partial F}{\partial S}\mathrm{d}z \tag{15.3.990}$$

If we now construct a neutral (not risky for recall) delta portfolio consisting of one option in short position and a number $-\Delta$ of underlying securities (often also denoted $-\Delta_t$ in the literature) in a long position (or conversely it does not matter).

The value of the portfolio Π is then expressed by:

$$\Pi=F-\Delta S \tag{15.3.991}$$

The idea of the equality above is the same as when we have a portfolio with a cash amount S of a security (i.e. the total cash amount of the securities in the securities portfolio) and we protect ourselves, for example, from a downward trend with the acquisition of a number of Put but with the difference that here the total cash amount of options that is set at F (i.e. the total cash amount of the options in the options portfolio) and that we look for the number of underlying to buy (hence the negative sign) in the case of a supposed bearish trend.

The time differential of the portfolio is then written (which assumes that we make instantaneous delta hedging without costs, what in practice is quite difficult to achieve...!):

$$\mathrm{d}\Pi=\mathrm{d}F-\Delta\mathrm{d}S \tag{15.3.992}$$

You will notice that we assume constant the quantity Δ during the time differential...

> Caution!!! Some authors choose, by convention, to invert the signs of the terms that are on the right of the equality of the two preceding relations. This does not change the final result of the solution of the differential equation but it must be known that this can be done since it is only a protection choice of bullish or bearish trend.

By combining the previous relations and (here we adopt the traditional notation used in the finance field) the equation of the risky asset given by:

$$\frac{\mathrm{d}S}{S}=\sigma\mathrm{d}z+\mu\mathrm{d}t \tag{15.3.993}$$

we get:

$$\mathrm{d}\Pi=\mathrm{d}F-\Delta\mathrm{d}S=\left[\left(\frac{\partial F}{\partial t}+\mu S\frac{\partial F}{\partial S}+\frac{1}{2}\sigma^2S^2\frac{\partial^2F}{\partial S^2}\right)\mathrm{d}t+\sigma S\frac{\partial F}{\partial S}\mathrm{d}z\right]-\Delta[S\sigma\mathrm{d}z+S\mu\mathrm{d}t] \tag{15.3.994}$$

where we have in the right-hand square brackets the geometrical Brownian motion.

This gives, after rearrangement of terms, the differential equation of the portfolio:

$$\mathrm{d}\Pi=\sigma S\left(\frac{\partial F}{\partial S}-\Delta\right)\mathrm{d}z+\left(\mu S\frac{\partial F}{\partial S}+\frac{1}{2}\sigma^2S^2\frac{\partial^2F}{\partial S^2}+\frac{\partial F}{\partial t}-\mu\Delta S\right)\mathrm{d}t \tag{15.3.995}$$

Consider now that Δ is bound by the speculative dependence relation (of which we take the integer value) which eliminates from the previous relation the randomly risky part of the portfolio (it is the $\mathrm{d}z$ generates the risk randomly for recall!) such that (we will see again this expression of the delta during our study of the "Greeks" further below):

$$\frac{\partial F}{\partial S}-\Delta=0\Leftrightarrow\Delta=\frac{\partial F}{\partial S} \tag{15.3.996}$$

We can then write the infinitesimal variation without risk of our portfolio:

$$\mathrm{d}\Pi=\left(\mu S\frac{\partial F}{\partial S}+\frac{1}{2}\sigma^2S^2\frac{\partial^2F}{\partial S^2}+\frac{\partial F}{\partial t}-\mu\Delta S\right)\mathrm{d}t \tag{15.3.997}$$

But, we also have for a portfolio placed in a risk-free investment (since we have just eliminated the random risk we can write it like this):

$$\mathrm{d}\Pi=r\Pi\mathrm{d}t \tag{15.3.998}$$

That is sometimes also written in the literature:

$$\mathrm{d}S_t^0=rS_t^0\mathrm{d}t \tag{15.3.999}$$

The attentive reader will have noticed that the two relations above:

$$\begin{gathered}\mathrm{d}\Pi=\left(\mu S\frac{\partial F}{\partial S}+\frac{1}{2}\sigma^2S^2\frac{\partial^2F}{\partial S^2}+\frac{\partial F}{\partial t}-\mu\Delta S\right)\mathrm{d}t\\ \mathrm{d}\Pi=r\Pi\mathrm{d}t\end{gathered} \tag{15.3.1000}$$

are therefore a situation of non-arbitrage.

Now substituting the four relations:

$$\Pi=F-\Delta S\qquad\Delta=\frac{\partial F}{\partial S}\qquad\mathrm{d}\Pi=r\Pi\mathrm{d}t\qquad r=\mu \tag{15.3.1001}$$

into:

$$\mathrm{d}\Pi=\left(\mu S\frac{\partial F}{\partial S}+\frac{1}{2}\sigma^2S^2\frac{\partial^2F}{\partial S^2}+\frac{\partial F}{\partial t}-\mu\Delta S\right)\mathrm{d}t \tag{15.3.1002}$$

We get:

$$\boxed{\frac{\partial F}{\partial t}+\frac{1}{2}\sigma^2 S^2\frac{\partial^2 F}{\partial S^2}+rS\frac{\partial F}{\partial S}-rF=0} \tag{15.3.1003}$$

which is nothing else than the "Black & Scholes linear parabolic partial differential equation (without second member) of the second order" (with non-constant coefficient S). This relation is therefore valid only under the assumption that the return r is the risk-free one on the market and therefore that the Brownian motion is a Brownian motion at neutral risk! Similarly, this last relation also assumes that the variance is independent of time!

Remark

The Black & Scholes PDE is in fact a special case of a more general PDE known in Quantum Field Theory and denoted:

$$\frac{\partial u}{\partial t}(x,t)+\mu(x,t)\frac{\partial u}{\partial x}(x,t)+\frac{1}{2}\sigma^2(x,t)\frac{\partial^2 u}{\partial x^2}(x,t)-V(x,t)u(x,t)+f(x,t)=0$$

where μ,σ,ψ,V,f are known functions, T is a parameter, and $u:\mathbb{R}\times[0,T]\rightarrow\mathbb{R}$ is the unknown. Then the Feynman-Kac formula tells us that the solution can be written as a conditional expectation:

$$u(x,t)=\mathrm{E}^Q\left[\int_t^T \exp\left(-\int_t^r V\left(X_\tau,\tau\right)\mathrm{d}\tau\right) f\left(X_r,r\right)dr+\exp\left(-\int_t^T V\left(X_\tau,\tau\right)\mathrm{d}\tau\right)\psi\left(X_T\right)\middle| X_t=x\right]$$

under the probability measure Q such that X is an Itô process driven by the equation:

$$\mathrm{d}X_t=\mu(X,t)\mathrm{d}t+\sigma(X,t)\mathrm{d}W_t^Q$$

with $W^Q(t)$ is a Wiener process (also named "Brownian motion") under Q, and the initial condition for $X(t)$ is $X(t)=x$.

The fact that the drift μ is equal to the risk-free return r also has a significant impact on the interpretation of this differential equation. This indeed assumes indirectly that two options with different drifts have their implied return which is equal and that is taken as the one without risk of the market !!! This is the reason why in finance if we have two options whose drift differs and the variance and maturity are identical, the Black & Scholes equation gives the same pricing by construction !!!

This last equation is more often written in the form relating to the implicit reference of a Call such as:

$$\frac{\partial C}{\partial t}+\frac{1}{2}\sigma^2 S^2\frac{\partial^2 C}{\partial S^2}+rS\frac{\partial C}{\partial S}-rC=0 \tag{15.3.1004}$$

Or in a slightly more condensed form (depending on the textbooks...):

$$\partial_t C+\frac{1}{2}\sigma^2 S^2\partial_s^2 C+rS\partial_S C-rC=0 \tag{15.3.1005}$$

and even more condensed... (but here it becomes frankly an abused notation...):

$$C_t+\frac{1}{2}\sigma^2 S^2 C_{SS}+rSC_S-rC=0 \tag{15.3.1006}$$

The reader will have noticed that the parameter μ (derivation) is absent from this equation! In other words, the value of an option is independent of the rate of change in the values of the underlying securities! The only parameter that affects the price of the option is the yield volatility σ of the underlying. A consequence of this is that two people with divergent opinions about the value of μ are still in agreement on the value of the option.

The objective is obviously to solve this differential equation in order to determine the return $F(S,t)$. This can not be solved in two lines...

Before working on this hard painful task some definitions and practical preconditions concerning certain parameters are useful and necessary (we will determine their explicit form after the resolution of the differential equation):

15.3.10.3.9.9 Self-financing portfolio on underlying

A "self-financing portfolio" strategy is a dynamic strategy of buying or selling securities and loans or borrowing from the bank, the value of which is not modified by the addition or withdrawal of cash (we could have introduced this subject at the beginning of this section but we thought it more appropriate to do so only now). In other words: a portfolio is self-financing if there is no exogenous infusion or withdrawal of money; the purchase of a new asset must be financed by the sale of an old one.

We will assume here for the example that we can only invest in a single security (risky investment), and in cash (supposedly non-risky investment), that is to say for that latter by placing or borrowing money at a bank.

We denote by S_t the price on the date t of the security, by r_t the interest rate for an investment between $[t, t+\mathrm{d}t]$ at the bank.

Given V_t the market value, or the net asset value, or even the "Mark to Market value (MtM)" of the portfolio at date t. After renegotiation, the number of shares δ_t in the portfolio is constant until the next management expiry date. For the sake of simplicity, we assume for the moment that the manager takes into account the value of the underlying price in his decision rule only at the time of renegotiation.

In a very short time, the change in value of the portfolio is due only to the change in the value of the underlying and to the interest paid by the bank on the cash, i.e., since the amount invested in the cash is:

$$V_t - \delta_t \cdot S_t \qquad (15.3.1007)$$

we have the "self-financing equation":

$$\boxed{\mathrm{d}V_t = \delta_t \cdot \mathrm{d}S_t + (V_t - \delta_t \cdot S_t) r_t \mathrm{d}t = V_t r_t \mathrm{d}t + \delta_t \cdot (\mathrm{d}S_t - r_t S_t \mathrm{d}t)} \qquad (15.3.1008)$$

Thus, for a Call seller (for example ...), the purpose is to find the initial cost V_0 and strategy δ_t that make it possible to get (the finance practitioner talk about "realizing the financial asset"):

$$(S_T - K)^+ \qquad (15.3.1009)$$

in all market scenarios. If there is such a hedging strategy, then we say that we are dealing with a "complete market".

15.3.10.3.9.10 Greeks and others...

In the reality these theoretical models are very beautiful to read (for the honour of the human spirit) but quite unrealistic. Reason why traders use (as in engineering) simple and comprehensible indicators named the "Greek" to make their sales or purchase decisions (or to make the information understandable by the Director Board...). However, with a little creativity, the same indicators can be used in many other fields (manufacturing, project management, chemistry, etc.).

Here is the list of the best known one (we will calculate their explicit expression for some models that we will develop further below):

Definitions (#15.3.696):

D1. The "delta" of an option, which is important to understand (or know), is given by:

$$\boxed{\Delta=\frac{\partial F}{\partial S}} \tag{15.3.1010}$$

and represents the rate of change in the value of the portfolio's options, depending on the values of the underlying securities S (mathematically, therefore, it is the first derivative of the option premium on the price of the underlying). This term is fundamental in theory (it is a hypothesis in the construction of the Black & Scholes model as we saw above) and in practice and we will use it frequently. It is therefore a measure of the correlation between the movement of the option (or other financial assets and derivatives) and the underlying assets.

✍**Example:**

Let us consider for example, that a Call on the ABC share has a delta of 0.25 with a price of the underlying (spot) of 90.- and a premium at 5.-. This mean that when the price of the share ABC changes from 90.- to 91.-, the premium of the option will then increase by 1 delta, and then becomes 5.25.-. When the price of the ABC share goes from 90.- to 88.-, the premium of the option will decrease by 2 times delta, and becomes 4.50.-. This variation in terms of delta (integer) is then denoted δ_t.

Remark

Many practitioners prefer to use the "delta cash" defined by the product of the delta and the spot price. So in our example above the delta cash is worth 90 times 0.25.- which is worth 22.5.-. If the share price increases from 90.- to 91.- i.e. 1.09% increase, the variation of the Call is the product of the delta cash by the variation in $\%$ ie 22.5.- times 1.09% which gives a positive variation of 0.25.- and then we fall back on our $5+0.25=5.25$.-.

The delta is therefore an important parameter for a practitioner who wants to cover himself against the risk. Indeed, in order to obtain the global delta of a position, it is sufficient to multiply the value of the delta of each option by its position. Then we add up all these deltas.

For example, if on the same underlying we are a seller of 5 calls C_1 and a buyer of 7 Call C_2 then our global delta will be equal to:

$$7 \cdot \Delta_{C_2} - 5 \cdot \Delta_{C_1} \tag{15.3.1011}$$

The value of this parameter informs us about the quantity of underlyings to be bought or sold (opposite position on the underlying) in order to immunize the valuation of our portfolio to changes in the price of this underlying. We then say that it is a "delta-neutral strategy" or a "delta-hedging strategy". More precisely, it is a dynamic strategy (dynamic hedging) because it is necessary to maintain a delta-neutral portfolio throughout the life of the option (in theory instantly for recall!). Contrary to statistical strategies (static hedging). For example, a static strategy to hedge the sale of a Call of strike 125.- out of $1,000$ shares (spot price 100.-), may consist of buying immediately $1,000$ shares on the market for $100,000$.-, and wait for the due date. In this situation, if the buyer exercises the Call the seller is able to deliver the $1,000$ shares for $125,000$.-. But if he does not exercise it, the seller stays with $1,000$ shares... Similarly, if the final price is set at eg 80.-, the seller records a loss of $20,000$.-. Delta-hedging eliminates this risk.

However, the strategy of dynamic hedging has a vicious side because if the majority of the market players buy underlying to hedge against an increase in the prices, then this will increase the value of the underlying even more... Supply and Demand rule...) and thus they will buy even more underlyings, which will have the effect of increasing even more its value and so on and then we go in circles until reaching a potential Crash of the markets (the 11987 crash - according to holocene calendar - would be originally due to this type of perverse dynamics, same for some automated trading bots). The effect will be the same (but opposite) to protect against a decrease... It is for this reason that it is strongly recommended to make delta hedging with other diversified financial assets than the underlying itself!!!!!

Thus, the managers, will between the date on which they received the premium (by having sold an option contract) and its maturity T, naturally manage in delta-neutral over time a self-funded portfolio made up of δ_t underlying assets S (or equivalent replicated one) at every instant t, in order to dispose of the stochastic target at certainty (thus without risk) at maturity. We are also talking about "portfolio hedging". However this strategy masks a terrible fault at the global level, indeed if a market player applies this strategy by selling massively (for example to protect itself from a bearish trend), then all the other actors will also perhaps sell then increasing by extension the delta and thus amplifying the volatility and so on until the crash.

D2. The "theta" of an option gives the sensitivity of the option price to its maturity and is given by:

$$\boxed{\theta = \frac{\partial F}{\partial t}} \tag{15.3.1012}$$

Applied to our imaginary portfolio, the theta simply gives us the value lost or gained after one day passed for example.

D3. The "rho" calculates the sensitivity of the option price to the geometric interest market rate without risk and is given by:

$$\boxed{\rho=\frac{\partial F}{\partial r}} \tag{15.3.1013}$$

This indicator seems to be relatively little used by professionals.

D4. The "vega", represented by the lowercase greek letter nu because the name vega is not itself a Greek letter name..., measures the sensitivity of the option to volatility and is given by:

$$\boxed{\nu=\frac{\partial F}{\partial \sigma}} \tag{15.3.1014}$$

D5. The "gamma" corresponds to the derivative of the delta and is therefore given by:

$$\boxed{\Gamma=\frac{\partial^2 F}{\partial S^2}} \tag{15.3.1015}$$

A possible reading of the gamma is the direction of evolution of the delta as a function of the price of the underlying. A positive gamma indicates that price of the underlying and the delta move in the same direction, whereas a negative gamma shows the opposite.

In order to avoid adjusting the Delta in delta-neutral strategy, and thus to pay the transaction costs but also the inherent spreads, a good way is to have the delta as stable as possible. Having the most stable delta means little or no change in its initial value, thus having a "Gamma-Neutral strategy" in addition to having a delta-neutral strategy. However, since the delta-neutral strategy means that we already play with the underlying to make the delta constant, we can not use the same underlying to make the gamma neutral. The gamma hedging principle of a portfolio containing at least one option is then to find another option on the market in proportions that compensate for the gamma of the original position.

Remark

As we will see later during our study of risk analysis in Finance using Taylor series developments, the delta does in fact allow for hedging only in the first order (that is, for small variations of the underlying). By supplementing with gamma-hedging we eliminate the effects of the second order. So a good strategy is to ensure the instantaneous values of delta and gamma to be zero.

✍**Example:**

Let us consider as summary of all these Greeks a Call with an underlying with a spot price of 100.-, a strike of 100.-, a volatility return of 24% and a geometric average market interest rate without risk of 5%. Consider that we have the following values:

$$\delta=0.62 \qquad \Gamma=0.02 \qquad \theta=-0.02.\text{-} \qquad \nu=0.37.\text{-} \qquad \rho=0.5.\text{-} \tag{15.3.1016}$$

The value of the delta thus tells us that if the price of the underlying increase of 1.-, the value of the option will increase by 0.62.-. The gamma tells us that if the underlying price increase of 1.-, the delta of the option will go from 0.62.- to 0.64.-. The value of the theta tells us at the end of the day that the value of the option will have decreased by 0.02.-. The value of the vega tells us that if the volatility of the underlying increases from 24% to 25%, the value of the option will increase by 0.37. Finally, the value of the rho indicates that if the value of the risk-free geometric average market rate increases from 5% to 5.5%, the value of the option will increase by 0.25.-.

D6. The "Black & Scholes linear differential operator" L_{BS} given by:

$$L_{\text{BS}}=\frac{\partial}{\partial t}+\frac{1}{2}\sigma^2S^2\frac{\partial^2}{\partial S^2}+rS\frac{\partial}{\partial S}-r \tag{15.3.1017}$$

seems to have a financial interpretation as a measure of the difference between the return of an option (the first two terms) and a set of a risk-free return portfolio containing that option (the last two terms).

In short, this being said, we can therefore have the following technical writing of the Black & Scholes PDE (with non-constant coefficient S) using the Greeks:

$$\boxed{\theta+\frac{1}{2}\sigma^2S^2\Gamma+rS\Delta-rF=0} \tag{15.3.1018}$$

Here is a quite good visual summary of all Greeks for a special case:

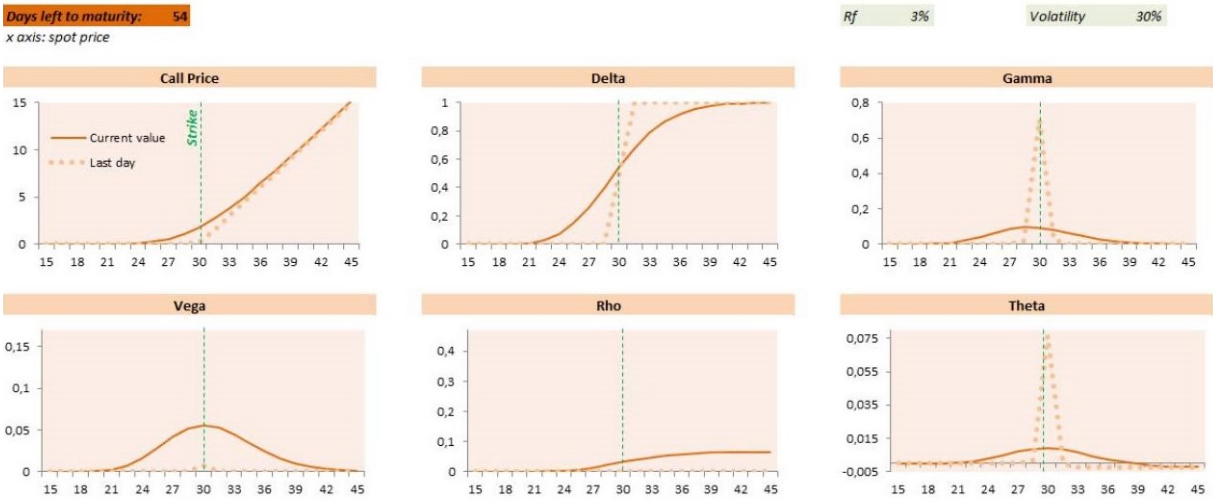

Figure 15.186: **Greeks summary**

15.3.10.3.9.11 Solving the Black & Scholes differential equation

Before solving the Black & Scholes PDE let us first already give the solutions with a reminder of the terms (this will allow to have a preliminary idea of the concepts used during the developments and I do not risk to write these before some years due to lack of time so it's better to have them already while waiting...):

Let $F(S,t)$ denote the value of a Call $C(S,t)$ or Put $P(S,t)$ option, σ the yield volatility of the underlying, E the strike, T the date of expiration and r the interest and S the price of the underlying. We will solve the differential equation of BS (with non-constant coefficient S) written the following form:

$$\frac{\partial C}{\partial t}+\frac{1}{2}\sigma^2 S^2\frac{\partial^2 C}{\partial S^2}+rS\frac{\partial C}{\partial S}-rC=0 \qquad (15.3.1019)$$

The trick (which led to a Nobel Prize in Economics for recall) is to see that it is a differential equation with partial differentials and more particularly with differentials of the first order in t and second order in S. There exists a differential equation of this type which is very well known in physics: the heat equation (see section Thermodynamics page 3684). The idea is then by changes of variables to get back to it. The difficulty was to find the right changes of variables and our predecessors took care of this error and trials... for us (thanks to them!). We then start by writing (this choice also allows to shift to initial conditions similar to those of the equation of heat):

$$C(t,S)=Ku(\tau,S) \qquad \tau=\sigma^2(T-t) \qquad x=\ln\left(\frac{S}{K}\right) \qquad (15.3.1020)$$

and therefore explicitly:

$$C(t,S)=Ku(\tau,S)=Ku\left(\sigma^2(T-t),\ln\left(\frac{S}{K}\right)\right) \qquad (15.3.1021)$$

We will use further below the fact that:

$$\frac{\partial\tau}{\partial t}=-\sigma^2 \qquad \frac{\partial x}{\partial S}=\frac{1}{S} \qquad (15.3.1022)$$

For practical purposes, let us write the inverse transformation (which will be useful to us much later) that follows:

$$u(\tau,x)=\frac{1}{K}C(t,S)=\frac{1}{K}C\left(T-\frac{\tau}{\sigma^2},Ke^x\right) \qquad (15.3.1023)$$

A part of the underlying idea of this choice of change of variables is to transform the fact that in the differential equation of Black & Scholes we know the final conditions (since at maturity the price of the option is perfectly Determined) whereas with the heat equation we need initial and not final conditions! We will see immediately that this choice of change of variables allows this. Indeed, remember that at maturity we know that:

$$C(T,S)=(S_T-K)^+ \qquad (15.3.1024)$$

Therefore:

$$\frac{1}{K}C(T,S)=\left(\frac{S_T}{K}-1\right)^{+} \tag{15.3.1025}$$

As:

$$x=\ln\left(\frac{S_T}{K}\right)\Rightarrow\frac{S_T}{K}=e^x \tag{15.3.1026}$$

We then have:

$$\frac{1}{K}C(T,S)=\left(e^x-1\right)^{+} \tag{15.3.1027}$$

And the fact what allows us to have an initial condition is that:

$$\frac{1}{K}C(T,S)=\left(e^x-1\right)^{+}=u(\tau,x)=u\left(\sigma^2(T-t),x\right)\underset{t=T}{=}u(0,x) \tag{15.3.1028}$$

To transform our differential equation to partial derivatives (with non-constant coefficient S):

$$\frac{\partial C}{\partial t}+\frac{1}{2}\sigma^2S^2\frac{\partial^2C}{\partial S^2}+rS\frac{\partial C}{\partial S}-rC=0 \tag{15.3.1029}$$

With these new variables we have to calculate some partial derivatives of C. We then have:

$$\begin{aligned}\frac{\partial C}{\partial t}&=\frac{\partial}{\partial t}\left[K\cdot u\left(\sigma^2(T-t),\ln\left(\frac{S}{K}\right)\right)\right]=K\frac{\partial}{\partial t}\left[u\left(\sigma^2(T-t),\ln\left(\frac{S}{K}\right)\right)\right]\\&=K\frac{\partial}{-\frac{\partial\tau}{\sigma^2}}\left[u\left(\sigma^2(T-t),\left(\frac{S}{K}\right)\right)\right]=-K\sigma^2\frac{\partial u}{\partial\tau}\end{aligned} \tag{15.3.1030}$$

and:

$$\begin{aligned}\frac{\partial C}{\partial S}&=\frac{\partial}{\partial S}\left[K\cdot u\left(\sigma^2(T-t),\ln\left(\frac{S}{K}\right)\right)\right]=K\frac{\partial}{\partial t}\left[u\left(\sigma^2(T-t),\ln\left(\frac{S}{K}\right)\right)\right]\\&=K\frac{\partial}{S\partial x}\left[u\left(\sigma^2(T-t),\left(\frac{S}{K}\right)\right)\right]=\frac{K}{S}\frac{\partial u}{\partial x}\end{aligned} \tag{15.3.1031}$$

And also that:

$$\begin{aligned}\frac{\partial^2C}{\partial S^2}&=\frac{\partial}{\partial S}\left(\frac{K}{S}\frac{\partial u}{\partial x}\right)=-\frac{K}{S^2}\frac{\partial u}{\partial x}+\frac{K}{S}\left[\frac{\partial}{\partial S}u_x\left(\sigma^2(T-t),\left(\frac{S}{K}\right)\right)\right]\\&=-\frac{K}{S^2}\frac{\partial u}{\partial x}+\frac{K}{S}\frac{\partial}{\partial S}u_x=-\frac{K}{S^2}\frac{\partial u}{\partial x}+\frac{K}{S}\frac{\partial}{S\partial x}u_x=-\frac{K}{S^2}\frac{\partial u}{\partial x}+\frac{K}{S^2}\frac{\partial}{\partial x}u_x=-\frac{K}{S^2}\frac{\partial u}{\partial x}+\frac{K}{S^2}\frac{\partial^2u}{\partial^2x}\\&=\frac{K}{S^2}\left(\frac{\partial^2u}{\partial^2x}-\frac{\partial u}{\partial x}\right)\end{aligned} \tag{15.3.1032}$$

By injecting this into the differential equation, it comes:

$$\left[-K\frac{\partial u}{\partial \tau}\sigma^2\right]+\frac{1}{2}\sigma^2 S^2\left[\frac{K}{S^2}\left(\frac{\partial^2 u}{\partial x^2}-\frac{\partial u}{\partial x}\right)\right]+rS\left[\frac{K}{S}\frac{\partial u}{\partial x}\right]-r\left[Ku\right]=0 \qquad (15.3.1033)$$

We simplify the S:

$$-K\frac{\partial u}{\partial \tau}\sigma^2+\frac{1}{2}K\left(\frac{\partial^2 u}{\partial x^2}-\frac{\partial u}{\partial x}\right)\sigma^2+rK\frac{\partial u}{\partial x}-rKu=0 \qquad (15.3.1034)$$

We multiply on both sides by:

$$-\frac{1}{K\sigma^2} \qquad (15.3.1035)$$

To get:

$$\frac{\partial u}{\partial \tau}-\frac{1}{2}\left(\frac{\partial^2 u}{\partial x^2}-\frac{\partial u}{\partial x}\right)-\frac{r}{\sigma^2}\frac{\partial u}{\partial x}+\frac{r}{\sigma^2}u=0 \qquad (15.3.1036)$$

Therefore:

$$\frac{\partial u}{\partial \tau}=\frac{1}{2}\frac{\partial^2 u}{\partial x^2}+\left(\frac{r}{\sigma^2}-\frac{1}{2}\right)\frac{\partial u}{\partial x}-\frac{r}{\sigma^2}u \qquad (15.3.1037)$$

Let us put as it is usual:

$$\frac{r}{\sigma^2}=\kappa \qquad (15.3.1038)$$

Then there comes the differential equation (with constant coefficient this time!):

$$\frac{\partial u}{\partial \tau}=\frac{1}{2}\frac{\partial^2 u}{\partial x^2}+\left(\kappa-\frac{1}{2}\right)\frac{\partial u}{\partial x}-\kappa u \qquad (15.3.1039)$$

With for recall the initial condition:

$$u(0,x)=\left(e^x-1\right)^+ \qquad (15.3.1040)$$

Remark

In the prior-previous relation, the sum $\dfrac{\partial u}{\partial \tau}+\left(\dfrac{1}{2}-\kappa\right)\dfrac{\partial u}{\partial x}$ is sometimes named the "advection part", κu the "source term" and $\dfrac{1}{2}\dfrac{\partial^2 u}{\partial x^2}$ the "diffusion term", all this in analogy to fluid mechanics and thermodynamics.

What follows also very clever and tricky consists in making another change of variable by putting:

$$\nu(\tau,x)=e^{\alpha\tau+\beta x}\cdot u(\tau,x) \qquad (15.3.1041)$$

We will determine the two parameters α, β which allow to write the partial differential equation with constant coefficients in the form of a heat equation!

We shall proceed first as above by determining the equivalence of the different partial derivatives of u. We have then:

$$\frac{\partial u}{\partial \tau}=\frac{\partial\left(e^{-\alpha\tau-\beta x}\cdot\nu(\tau,x)\right)}{\partial \tau}=\left(-\alpha\nu+\frac{\partial \nu}{\partial \tau}\right)e^{-\alpha\tau-\beta x} \tag{15.3.1042}$$

and:

$$\frac{\partial u}{\partial x}=\frac{\partial\left(e^{-\alpha\tau-\beta x}\cdot\nu(\tau,x)\right)}{\partial x}=\left(-\beta\nu+\frac{\partial \nu}{\partial x}\right)e^{-\alpha\tau-\beta x} \tag{15.3.1043}$$

And also that:

$$\begin{aligned}\frac{\partial^2 u}{\partial x^2}&=\frac{\partial}{\partial x}\left(-\beta\nu e^{-\alpha\tau-\beta x}+\frac{\mathrm{d}\nu}{\mathrm{d}x}e^{-\alpha\tau-\beta x}\right)=\left[-\beta\frac{\partial \nu}{\partial x}+\beta^2\nu+\frac{\partial^2 \nu}{\partial x^2}-\beta\frac{\partial \nu}{\partial x}\right]e^{-\alpha\tau-\beta x}\\&=\left[\frac{\partial^2 \nu}{\partial x^2}-2\beta\frac{\partial \nu}{\partial x}+\beta^2\nu\right]e^{-\alpha\tau-\beta x}\end{aligned} \tag{15.3.1044}$$

Then comes a trick very difficult to guess (at least a priori because I did not personally find something simpler...). Indeed before substituting these last three relations in the P.D.E., Let us recall that:

$$\nu(\tau,x)=e^{\alpha\tau+\beta x}\cdot u(\tau,x) \tag{15.3.1045}$$

So the last three relations can be written (finding a mixture function of u and v is very counter-intuitive):

$$\begin{aligned}\frac{\partial u}{\partial \tau}&=\left(-\alpha\nu+\frac{\partial \nu}{\partial \tau}\right)e^{-\alpha\tau-\beta x}=-\alpha u+\frac{\partial \nu}{\partial \tau}^{-\alpha\tau-\beta x}\\\frac{\partial u}{\partial x}&=\left(-\beta\nu+\frac{\partial \nu}{\partial x}\right)e^{-\alpha\tau-\beta x}=-\beta u+\frac{\partial \nu}{\partial x}e^{-\alpha\tau-\beta x}\\\frac{\partial^2 u}{\partial x^2}&=\left[\frac{\partial^2 \nu}{\partial x^2}-2\beta\frac{\partial \nu}{\partial x}+\beta^2\nu\right]e^{-\alpha\tau-\beta x}=\frac{\partial^2 \nu}{\partial x^2}e^{-\alpha\tau-\beta x}-2\beta\frac{\partial \nu}{\partial x}e^{-\alpha\tau-\beta x}+\beta^2 u\end{aligned} \tag{15.3.1046}$$

and now only let us do the (partial!) substitution in the P.D.E.! We then move from:

$$\frac{\partial u}{\partial \tau}=\frac{1}{2}\frac{\partial^2 u}{\partial x^2}+\left(\kappa-\frac{1}{2}\right)\frac{\partial u}{\partial x}-\kappa u \tag{15.3.1047}$$

to:

$$\begin{aligned}&\left[-\alpha u+e^{-\alpha\tau-\beta x}\frac{\partial \nu}{\partial \tau}\right]\\&=\frac{1}{2}\left[\beta^2 u-2\beta e^{-\alpha\tau-\beta x}\frac{\partial \nu}{\partial x}+e^{-\alpha\tau-\beta x}\frac{\partial^2 \nu}{\partial x^2}\right]+\left(\kappa-\frac{1}{2}\right)\left[-\beta u+e^{-\alpha\tau-\beta x}\frac{\partial \nu}{\partial x}\right]-\kappa u\end{aligned} \tag{15.3.1048}$$

Let us write this last equality a little differently by factoring on the left and right what contains u:

$$\begin{gathered}\left[-\alpha\right]u+e^{-\alpha\tau-\beta x}\frac{\partial\nu}{\partial\tau}=\\ \left[\frac{1}{2}\beta^2-\beta\left(\kappa-\frac{1}{2}\right)-\kappa\right]u-\frac{1}{2}\left[2\beta e^{-\alpha\tau-\beta x}\frac{\partial\nu}{\partial x}-e^{-\alpha\tau-\beta x}\frac{\partial^2\nu}{\partial x^2}\right]+\left(\kappa-\frac{1}{2}\right)e^{-\alpha\tau-\beta x}\frac{\partial\nu}{\partial x}\end{gathered}\tag{15.3.1049}$$

and then let:

$$-\alpha=\left(\frac{1}{2}\beta^2-\beta\left(\kappa-\frac{1}{2}\right)-\kappa\right)\tag{15.3.1050}$$

The differential equation is then simplified as:

$$e^{-\alpha\tau-\beta x}\frac{\partial\nu}{\partial\tau}=-\frac{1}{2}\left[2\beta e^{-\alpha\tau-\beta x}\frac{\partial\nu}{\partial x}-e^{-\alpha\tau-\beta x}\frac{\partial^2\nu}{\partial x^2}\right]+\left(\kappa-\frac{1}{2}\right)e^{-\alpha\tau-\beta x}\frac{\partial\nu}{\partial x}\tag{15.3.1051}$$

The exponential can be simplified and it remains:

$$\frac{\partial\nu}{\partial\tau}=-\frac{1}{2}\left[2\beta\frac{\partial\nu}{\partial x}-\frac{\partial^2\nu}{\partial x^2}\right]+\left(\kappa-\frac{1}{2}\right)\frac{\partial\nu}{\partial x}\tag{15.3.1052}$$

That can be rewritten in the form:

$$\frac{\partial\nu}{\partial\tau}=\left(\left(\kappa-\frac{1}{2}\right)-\beta\right)\frac{\partial\nu}{\partial x}+\frac{1}{2}\frac{\partial^2\nu}{\partial x^2}\tag{15.3.1053}$$

And if we choose:

$$\left(\kappa-\frac{1}{2}\right)=\beta\tag{15.3.1054}$$

We then have:

$$\frac{\partial\nu}{\partial\tau}=\frac{1}{2}\frac{\partial^2\nu}{\partial x^2}\tag{15.3.1055}$$

Or otherwise written (in the physicist way of life...):

$$\nu_t=\frac{1}{2}\nu_{xx}\tag{15.3.1056}$$

We thus recognize the heat equation (or "diffusion equation") proved in the section Thermodynamics but where the coefficient of thermal expansion is equal to $1/2$.

It follows from these developments that:

$$\begin{gathered}-\alpha=\left(\frac{1}{2}\beta^2-\beta\left(\kappa-\frac{1}{2}\right)-\kappa\right)\\ \beta=\left(\kappa-\frac{1}{2}\right)\end{gathered}\tag{15.3.1057}$$

Either by injecting the second equality into the first and after some elementary simplifications:

$$\begin{aligned}\alpha &= -\frac{1}{2}\left[\kappa-\frac{1}{2}\right]^2+\left[\kappa-\frac{1}{2}\right]\left(\kappa-\frac{1}{2}\right)+\kappa=\frac{1}{2}\left(\kappa-\frac{1}{2}\right)^2+\kappa=\frac{1}{2}\left(\kappa^2-\kappa+\frac{1}{4}\right)+\kappa\\ &=\frac{1}{2}\kappa^2-\frac{1}{2}\kappa+\frac{1}{8}+\kappa=\frac{1}{2}\kappa^2+\frac{1}{2}\kappa+\frac{1}{8}=\frac{1}{2}\left(\kappa+\frac{1}{2}\right)^2\end{aligned} \tag{15.3.1058}$$

So we see that finally:

$$e^{-\alpha\tau-\beta x}=e^{-\frac{1}{2}(\kappa+\frac{1}{2})^2\tau-(\kappa-\frac{1}{2})x} \tag{15.3.1059}$$

Now we have to transform the condition into u:

$$u(0,x)=\left(e^x-1\right)^+ \tag{15.3.1060}$$

In an initial condition in v using:

$$\nu(\tau,x)=e^{\frac{1}{2}(\kappa+\frac{1}{2})^2\tau+(\kappa-\frac{1}{2})x}u(\tau,x) \tag{15.3.1061}$$

So it comes immediately:

$$\begin{aligned}\nu(0,x)&=e^{\frac{1}{2}(\kappa+\frac{1}{2})^2\cdot 0+(\kappa-\frac{1}{2})x}u(0,x)=e^{(\kappa-\frac{1}{2})x}\cdot\left(e^x-1\right)^+=\left(e^{(\kappa-\frac{1}{2})x+x}-e^{(\kappa-\frac{1}{2})x}\right)^+\\ &=\left(e^{(\kappa+\frac{1}{2})x}-e^{(\kappa-\frac{1}{2})x}\right)^+\\ &=\left(e^{\left(\kappa-\frac{1}{2}\right)x+x}-e^{\left(\kappa-\frac{1}{2}\right)x}\right)^+\\ &=e^{\left(\kappa-\frac{1}{2}\right)x}\cdot(e^x-1)^+\end{aligned} \tag{15.3.1062}$$

We now have a nice, clear problem that we know how to solve ("Cauchy problem" type):

$$\begin{aligned}\nu_t&=\frac{1}{2}\nu_{xx}\\ \nu(0,x)&=\left(e^{(\kappa+\frac{1}{2})x}-e^{(\kappa-\frac{1}{2})x}\right)^+\end{aligned} \tag{15.3.1063}$$

And as we saw in the discussion about the Heat Equation / Diffusion Equation (see section Thermodynamics page 3684), we solve this problem using Fourier transform that leads using exactly the same development to:

$$\nu(\tau,x)=\int_{-\infty}^{+\infty}\nu(0,x)\frac{1}{\sqrt{2\pi\tau}}e^{-\frac{(y-x)^2}{2\tau}}\mathrm{d}y \tag{15.3.1064}$$

Hence:

$$\nu(\tau,x)=\int_{-\infty}^{+\infty}\left(e^{\left(\kappa+\frac{1}{2}\right)y}-e^{\left(\kappa-\frac{1}{2}\right)y}\right)^+\frac{1}{\sqrt{2\pi\tau}}e^{-\frac{(y-x)^2}{2\tau}}\mathrm{d}y \tag{15.3.1065}$$

Let's examine:

$$\left(e^{\left(\kappa+\frac{1}{2}\right)y}-e^{\left(\kappa-\frac{1}{2}\right)y}\right)^+ \tag{15.3.1066}$$

When:

$$e^{\left(\kappa+\frac{1}{2}\right)y}-e^{\left(\kappa-\frac{1}{2}\right)y}\geq 0 \tag{15.3.1067}$$

then:

$$\left(e^{\left(\kappa+\frac{1}{2}\right)y}-e^{\left(\kappa-\frac{1}{2}\right)y}\right)^{+}=\left(e^{\left(\kappa+\frac{1}{2}\right)y}-e^{\left(\kappa-\frac{1}{2}\right)y}\right) \tag{15.3.1068}$$

But when:

$$e^{\left(\kappa+\frac{1}{2}\right)y}-e^{\left(\kappa-\frac{1}{2}\right)y}\leq 0 \tag{15.3.1069}$$

then:

$$\left(e^{\left(\kappa+\frac{1}{2}\right)y}-e^{\left(\kappa-\frac{1}{2}\right)y}\right)^{+}=0 \tag{15.3.1070}$$

Let's find the values of y such that

$$\begin{aligned}&e^{\left(\kappa+\frac{1}{2}\right)y}-e^{\left(\kappa-\frac{1}{2}\right)y}\geq 0\\&e^{\left(\kappa+\frac{1}{2}\right)y}\geq e^{\left(\kappa-\frac{1}{2}\right)y}\\&\left(\kappa+\frac{1}{2}\right)y\geq\left(\kappa-\frac{1}{2}\right)y\end{aligned} \tag{15.3.1071}$$

Therefore:

$$y\geq 0 \tag{15.3.1072}$$

So if we only integrate over $y>0$ then we can eliminate the function because the integrand is zero when $y<0$.

The old integral:

$$\int\limits_{-\infty}^{+\infty}\left(e^{\left(\kappa+\frac{1}{2}\right)y}-e^{\left(\kappa-\frac{1}{2}\right)y}\right)^{+}\frac{1}{\sqrt{2\pi\tau}}e^{-\frac{(y-x)^2}{2\tau}}\mathrm{d}y \tag{15.3.1073}$$

Then becomes:

$$\int\limits_{0}^{+\infty}\left(e^{\left(\kappa+\frac{1}{2}\right)y}-e^{\left(\kappa-\frac{1}{2}\right)y}\right)^{+}\frac{1}{\sqrt{2\pi\tau}}e^{-\frac{(y-x)^2}{2\tau}}\mathrm{d}y \tag{15.3.1074}$$

Next, we change variables again. Let:

$$z=\frac{y-x}{\sqrt{\tau}} \tag{15.3.1075}$$

so that:

$$z^2=\frac{(y-x)^2}{\tau} \tag{15.3.1076}$$

Now since:

$$z=\frac{y-x}{\sqrt{\tau}} \tag{15.3.1077}$$

Then:

$$y=x+\sqrt{\tau}z \tag{15.3.1078}$$

so that:

$$\mathrm{d}y=\sqrt{\tau}\mathrm{d}z \tag{15.3.1079}$$

Finally, y varies $[0,+\infty]$ and:

$$z=\frac{y-x}{\sqrt{\tau}} \tag{15.3.1080}$$

So when $y=+\infty$ we have $z=+\infty$. And when $y=0$, we have:

$$z=\frac{-x}{\sqrt{\tau}} \tag{15.3.1081}$$

So z varies between

$$z\in\left[-\frac{x}{\sqrt{\tau}},+\infty\right[\tag{15.3.1082}$$

Remember that when we change the variables in an integration we also must change the bounds of integration. So let's put all these changes into our integration!

So from the old integral:

$$\int\limits_0^{+\infty}\left(e^{\left(\kappa+\frac{1}{2}\right)y}-e^{\left(\kappa-\frac{1}{2}\right)y}\right)^+\frac{1}{\sqrt{2\pi\tau}}e^{-\frac{(y-x)^2}{2\tau}}\mathrm{d}y \tag{15.3.1083}$$

We get a new integral:

$$\int\limits_{-x/\sqrt{\tau}}^{+\infty}\left(e^{\left(\kappa+\frac{1}{2}\right)\left(x+\sqrt{\tau}z\right)}-e^{\left(\kappa-\frac{1}{2}\right)\left(x+\sqrt{\tau}z\right)}\right)^+\frac{1}{\sqrt{2\pi\tau}}e^{-\frac{z^2}{2}}\mathrm{d}z\sqrt{\tau} \tag{15.3.1084}$$

Which simplifies to:

$$\frac{1}{\sqrt{2\pi}}\int\limits_{\frac{-x}{\sqrt{\tau}}}^{+\infty}\left(e^{\left(\kappa+\frac{1}{2}\right)\left(x+\sqrt{\tau}z\right)}-e^{\left(\kappa-\frac{1}{2}\right)\left(x+\sqrt{\tau}z\right)}\right)^+e^{-\frac{z^2}{2}}\mathrm{d}z \tag{15.3.1085}$$

This is a real mess, so let's split the problem into two integrals.

We go from the old problem:

$$\nu(\tau,x)=\frac{1}{\sqrt{2\pi}}\int\limits_{\frac{-x}{\sqrt{\tau}}}^{+\infty}\left(e^{\left(\kappa+\frac{1}{2}\right)\left(x+\sqrt{\tau}z\right)}-e^{\left(\kappa-\frac{1}{2}\right)\left(x+\sqrt{\tau}z\right)}\right)^+e^{-\frac{z^2}{2}}\mathrm{d}z \tag{15.3.1086}$$

To a new one by writing:

$$\nu(\tau,x)=I_1-I_2 \tag{15.3.1087}$$

With:

$$I_1=\frac{1}{\sqrt{2\pi}}\int\limits_{\frac{-x}{\sqrt{\tau}}}^{+\infty}e^{\left(\kappa+\frac{1}{2}\right)\left(x+\sqrt{\tau}z\right)}e^{-\frac{z^2}{2}}\mathrm{d}z \tag{15.3.1088}$$

and:

$$I_2=\frac{1}{\sqrt{2\pi}}\int\limits_{\frac{-x}{\sqrt{\tau}}}^{+\infty}e^{\left(\kappa-\frac{1}{2}\right)\left(x+\sqrt{\tau}z\right)}e^{-\frac{z^2}{2}}\mathrm{d}z \tag{15.3.1089}$$

Let us solve first:

$$I_1=\frac{1}{\sqrt{2\pi}}\int\limits_{\frac{-x}{\sqrt{\tau}}}^{+\infty}e^{\left(\kappa+\frac{1}{2}\right)\left(x+\sqrt{\tau}z\right)}e^{-\frac{z^2}{2}}\mathrm{d}z \tag{15.3.1090}$$

Let's work directly on the exponent first:

$$\begin{aligned}
&\left(\kappa+\frac{1}{2}\right)\left(x+\sqrt{\tau}z\right)-\frac{1}{2}z^2\\
&\left(\kappa+\frac{1}{2}\right)x+\left(\kappa+\frac{1}{2}\right)\sqrt{\tau}z-\frac{1}{2}z^2\\
&\left(\kappa+\frac{1}{2}\right)x-\frac{1}{2}\left[z^2-2\left(\kappa+\frac{1}{2}\right)\sqrt{\tau}z\right]\\
&\left(\kappa+\frac{1}{2}\right)x-\frac{1}{2}\left[z^2-2\left(\kappa+\frac{1}{2}\right)\sqrt{\tau}z-\left(\kappa+\frac{1}{2}\right)^2\tau\right]+\frac{1}{2}\left(\kappa+\frac{1}{2}\right)^2\tau\\
&\left(\kappa+\frac{1}{2}\right)x-\frac{1}{2}\left[z-\left(\kappa+\frac{1}{2}\right)\sqrt{\tau}\right]^2+\frac{1}{2}\left(\kappa+\frac{1}{2}\right)^2\tau
\end{aligned} \tag{15.3.1091}$$

This means we can re-write I_1 under the following form:

$$I_1=\frac{1}{\sqrt{2\pi}}\int\limits_{\frac{-x}{\sqrt{\tau}}}^{+\infty}e^{\left(\kappa+\frac{1}{2}\right)\left(x+\sqrt{\tau}z\right)}e^{-\frac{z^2}{2}}\mathrm{d}z \tag{15.3.1092}$$

In an equivalent new integral:

$$\begin{aligned}
I_1&=\frac{1}{\sqrt{2\pi}}\int\limits_{\frac{-x}{\sqrt{\tau}}}^{+\infty}e^{\left(\kappa+\frac{1}{2}\right)x-\frac{1}{2}\left[z-\left(\kappa+\frac{1}{2}\right)\sqrt{\tau}\right]^2+\frac{1}{2}\left(\kappa+\frac{1}{2}\right)^2\tau}\mathrm{d}z\\
&=e^{\left(\kappa+\frac{1}{2}\right)x+\frac{1}{2}\left(\kappa+\frac{1}{2}\right)^2\tau}\cdot\frac{1}{\sqrt{2\pi}}\int\limits_{\frac{-x}{\sqrt{\tau}}}^{+\infty}e^{-\frac{1}{2}\left[z-\left(\kappa+\frac{1}{2}\right)\sqrt{\tau}\right]^2}\mathrm{d}z
\end{aligned} \tag{15.3.1093}$$

Now let us recall that in statistics we often use the following formula for the cumulative density function of the Normal centered reduced random variable:

$$\Phi(Q):=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{Q} e^{-\frac{1}{2}z^2}\mathrm{d}z \tag{15.3.1094}$$

In our case, what we have is more similar to:

$$\frac{1}{\sqrt{2\pi}}\int\limits_{-Q}^{+\infty} e^{-\frac{1}{2}(z-\mu)^2}\mathrm{d}z \tag{15.3.1095}$$

where:

$$Q=\frac{x}{\sqrt{\tau}} \qquad \text{and} \qquad \mu=\left(\kappa+\frac{1}{2}\right)\sqrt{\tau} \tag{15.3.1096}$$

Let us make this change of variables:

$$-w=(z-\mu) \tag{15.3.1097}$$

Therefore:

$$-\mathrm{d}w=\mathrm{d}z \tag{15.3.1098}$$

As $-w=(z-\mu)$, we have then when $z=+\infty$:

$$-w=(+\infty-\mu)\Rightarrow w=-\infty \tag{15.3.1099}$$

And when $z=-Q$, we have then:

$$-w=(-Q-\mu)\Rightarrow \text{so} \qquad w=Q+\mu \tag{15.3.1100}$$

Making this change of variables $-w=(z-\mu)$ gives us:

$$\begin{aligned}\int\limits_{-Q}^{+\infty} e^{-\frac{1}{2}(z-\mu)^2}\mathrm{d}z &\rightarrow \int\limits_{Q+\mu}^{-\infty} e^{-\frac{1}{2}[-w]^2}(-\mathrm{d}w)=-\int\limits_{Q+\mu}^{-\infty} e^{-\frac{1}{2}w^2}\mathrm{d}w\\ &=\int\limits_{-\infty}^{Q+\mu} e^{-\frac{1}{2}w^2}\mathrm{d}w=\Phi(Q+\mu)\end{aligned} \tag{15.3.1101}$$

Therefore:

$$\begin{aligned}I_1&=e^{\left(\kappa+\frac{1}{2}\right)x+\frac{1}{2}\left(\kappa+\frac{1}{2}\right)^2\tau}\cdot\frac{1}{\sqrt{2\pi}}\int\limits_{\frac{-x}{\sqrt{\tau}}}^{+\infty} e^{-\frac{1}{2}\left[z-\left(\kappa+\frac{1}{2}\right)\sqrt{\tau}\right]^2}\mathrm{d}z\\ &=e^{\left(\kappa+\frac{1}{2}\right)x+\frac{1}{2}\left(\kappa+\frac{1}{2}\right)^2\tau}\cdot\Phi\left(\frac{x}{\sqrt{\tau}}+\left(\kappa+\frac{1}{2}\right)\sqrt{\tau}\right)\end{aligned} \tag{15.3.1102}$$

Finally, let us put:

$$\frac{x}{\sqrt{\tau}}+\left(\kappa+\frac{1}{2}\right)\sqrt{\tau}=d_1 \tag{15.3.1103}$$

Then:

$$I_1=e^{\frac{1}{2}\left(\kappa+\frac{1}{2}\right)^2\tau+\left(\kappa+\frac{1}{2}\right)x}\cdot\Phi\left(d_1\right) \tag{15.3.1104}$$

Now we must focus on the second integral, that is (for recall):

$$I_2=\frac{1}{\sqrt{2\pi}}\int\limits_{\frac{-x}{\sqrt{\tau}}}^{+\infty}e^{\left(\kappa-\frac{1}{2}\right)\left(x+\sqrt{\tau}z\right)}e^{-\frac{z^2}{2}}\mathrm{d}z \tag{15.3.1105}$$

We work directly on the exponent first:

$$\begin{gathered}\left(\kappa-\frac{1}{2}\right)\left(x+\sqrt{\tau}z\right)-\frac{1}{2}z^2\\ \left(\kappa-\frac{1}{2}\right)x+\left(\kappa-\frac{1}{2}\right)\sqrt{\tau}z-\frac{1}{2}z^2\\ \left(\kappa-\frac{1}{2}\right)x-\frac{1}{2}\left[z^2-2\left(\kappa-\frac{1}{2}\right)\sqrt{\tau}z\right]\\ \left(\kappa-\frac{1}{2}\right)x-\frac{1}{2}\left[z^2-2\left(\kappa-\frac{1}{2}\right)\sqrt{\tau}z+\left(\kappa-\frac{1}{2}\right)^2\tau\right]+\frac{1}{2}\left(\kappa-\frac{1}{2}\right)^2\tau\\ \left(\kappa-\frac{1}{2}\right)x-\frac{1}{2}\left[z-\left(\kappa-\frac{1}{2}\right)\sqrt{\tau}\right]^2+\frac{1}{2}\left(\kappa-\frac{1}{2}\right)^2\tau\end{gathered} \tag{15.3.1106}$$

So we can re-write I_2:

$$\begin{aligned}I_2&=\frac{1}{\sqrt{2\pi}}\int\limits_{\frac{-x}{\sqrt{\tau}}}^{+\infty}e^{\left(\kappa-\frac{1}{2}\right)\left(x+\sqrt{\tau}z\right)}e^{-\frac{z^2}{2}}\mathrm{d}z\\ &=\frac{1}{\sqrt{2\pi}}\int\limits_{\frac{-x}{\sqrt{\tau}}}^{+\infty}e^{\left(\kappa-\frac{1}{2}\right)x-\frac{1}{2}\left[z-\left(\kappa-\frac{1}{2}\right)\sqrt{\tau}\right]^2+\frac{1}{2}\left(\kappa-\frac{1}{2}\right)^2\tau}\mathrm{d}z\\ &=e^{\frac{1}{2}\left(\kappa-\frac{1}{2}\right)^2\tau+\left(\kappa-\frac{1}{2}\right)x}\cdot\frac{1}{\sqrt{2\pi}}\int\limits_{\frac{-x}{\sqrt{\tau}}}^{+\infty}e^{-\frac{1}{2}\left[z-\left(\kappa-\frac{1}{2}\right)\sqrt{\tau}\right]^2}\mathrm{d}z\\ &=e^{\frac{1}{2}\left(\kappa-\frac{1}{2}\right)^2\tau+\left(\kappa-\frac{1}{2}\right)x}\cdot\Phi\left(\frac{x}{\sqrt{\tau}}+\left(\kappa-\frac{1}{2}\right)\sqrt{\tau}\right)\end{aligned} \tag{15.3.1107}$$

Set:

$$d_2=\frac{x}{\sqrt{\tau}}+\left(\kappa-\frac{1}{2}\right)\sqrt{\tau} \tag{15.3.1108}$$

We therefore have:

$$I_2 = e^{\frac{1}{2}\left(\kappa-\frac{1}{2}\right)^2\tau+\left(\kappa-\frac{1}{2}\right)x} \cdot \Phi\left(d_2\right) \tag{15.3.1109}$$

Now we put together I_1 and I_2:

$$\nu(\tau,x) = I_1 - I_2 \tag{15.3.1110}$$

so we can see our final solution to:

$$\nu(\tau,x) = e^{\frac{1}{2}\left(\kappa+\frac{1}{2}\right)^2\tau+\left(\kappa+\frac{1}{2}\right)x} \cdot \Phi\left(d_1\right) - e^{\frac{1}{2}\left(\kappa-\frac{1}{2}\right)^2\tau+\left(\kappa-\frac{1}{2}\right)x} \cdot \Phi\left(d_2\right) \tag{15.3.1111}$$

This is for recall the solution to:

$$\begin{aligned} \nu_t &= \frac{1}{2}\nu_{xx} \\ \nu(0,x) &= \left(e^{\left(\kappa+\frac{1}{2}\right)x} - e^{\left(\kappa-\frac{1}{2}\right)x}\right)^+ \end{aligned} \tag{15.3.1112}$$

Now that we have a solution for ν we need to reverse all the transforms we did to get back to a solution for $C(t,S)$.

The first transform to reverse is:

$$u(\tau,x) = e^{-\alpha\tau-\beta x} \cdot \nu(\tau,x \tag{15.3.1113}$$

Thus explicitly:

$$\begin{aligned} u(\tau,x) &= e^{-\frac{1}{2}\left(\kappa+\frac{1}{2}\right)^2\tau+\left(\kappa-\frac{1}{2}\right)x}\left(e^{\frac{1}{2}\left(\kappa+\frac{1}{2}\right)^2\tau-\left(\kappa+\frac{1}{2}\right)x} \cdot \Phi\left(d_1\right) - e^{\frac{1}{2}\left(\kappa-\frac{1}{2}\right)^2\tau+\left(\kappa-\frac{1}{2}\right)x} \cdot \Phi\left(d_2\right)\right) \\ &= e^{-\left(\kappa-\frac{1}{2}\right)x+\left(\kappa+\frac{1}{2}\right)x} \cdot \Phi\left(d_1\right) - e^{-\frac{1}{2}\left(\kappa+\frac{1}{2}\right)^2\tau+\frac{1}{2}\left(\kappa-\frac{1}{2}\right)^2\tau} \cdot \Phi\left(d_2\right) \\ &= e^x \cdot \Phi\left(d_1\right) - e^{-\frac{1}{2}\left(\kappa+\frac{1}{2}\right)^2\tau+\frac{1}{2}\left(\kappa-\frac{1}{2}\right)^2\tau} \cdot \Phi\left(d_2\right) \end{aligned} \tag{15.3.1114}$$

The second exponent is a little bit more complicated to simplify:

$$\begin{aligned} &\frac{1}{2}\tau\left[-\left(\kappa+\frac{1}{2}\right)^2\tau+\left(\kappa-\frac{1}{2}\right)^2\right] \\ &\frac{1}{2}\tau\left[-\left(\kappa^2+\kappa+\frac{1}{4}\right)+\left(\kappa^2-\kappa+\frac{1}{4}\right)\right] \\ &\frac{1}{2}\tau\left[-2\kappa\right] = -\tau\kappa \end{aligned} \tag{15.3.1115}$$

After those simplifications we are left with:

$$u(\tau,x) = e^x\Phi(d_1) - e^{-\tau\kappa}\Phi(d_2) \tag{15.3.1116}$$

The first transform and change of variables we did was:

$$C(t,S) = K \cdot u(\tau,x) \tag{15.3.1117}$$

with:

$$\tau=\sigma^2(T-t) \qquad \text{and} \qquad x=\ln\left(\frac{S}{K}\right) \tag{15.3.1118}$$

Also recall that we later set $\kappa=\dfrac{r}{\sigma^2}$ to make our calculations easier!

Now let's reverse all of those starting from:

$$u(\tau,x)=e^x\Phi(d_1)-e^{-\tau\kappa}\Phi(d_2) \tag{15.3.1119}$$

Therefore:

$$C(t,S)=K\cdot e^{\ln\left(\frac{S}{K}\right)}\Phi(d_1)-Ke^{-\sigma^2(T-t)\frac{r}{\sigma^2}}\Phi(d_2)=S\Phi(d_1)-Ke^{-r(T-t)}\Phi(d_2) \tag{15.3.1120}$$

with:

$$d_1=\frac{x}{\sqrt{\tau}}+\left(\kappa+\frac{1}{2}\right)\sqrt{\tau}\rightarrow d_1=\frac{\ln\left(\dfrac{S}{K}\right)}{\sqrt{\sigma^2(T-t)}}+\left(\frac{r}{\sigma^2}+\frac{1}{2}\right)\sqrt{\sigma^2(T-t)} \tag{15.3.1121}$$

and:

$$d_2=\frac{x}{\sqrt{\tau}}+\left(\kappa-\frac{1}{2}\right)\sqrt{\tau}\rightarrow d_2=\frac{\ln\left(\dfrac{S}{K}\right)}{\sqrt{\sigma^2(T-t)}}+\left(\frac{r}{\sigma^2}-\frac{1}{2}\right)\sqrt{\sigma^2(T-t)} \tag{15.3.1122}$$

Let's simplify these:

$$\begin{aligned}d_1&=\frac{\ln\left(\dfrac{S}{K}\right)}{\sqrt{\sigma^2(T-t)}}+\left(\frac{r}{\sigma^2}+\frac{1}{2}\right)\sqrt{\sigma^2(T-t)}\cdot\frac{\sqrt{\sigma^2(T-t)}}{\sqrt{\sigma^2(T-t)}}\\&=\frac{\ln\left(\dfrac{S}{K}\right)+\left(\dfrac{r}{\sigma^2}+\dfrac{1}{2}\right)\sigma^2(T-t)}{\sqrt{\sigma^2(T-t)}}\\&=\frac{\ln\left(\dfrac{S}{K}\right)+\left(r+\dfrac{1}{2}\sigma^2\right)(T-t)}{\sigma\sqrt{(T-t)}}\end{aligned} \tag{15.3.1123}$$

and:

$$\begin{aligned}d_2&=\frac{\ln\left(\dfrac{S}{K}\right)}{\sqrt{\sigma^2(T-t)}}+\left(\frac{r}{\sigma^2}-\frac{1}{2}\right)\sqrt{\sigma^2(T-t)}\cdot\frac{\sqrt{\sigma^2(T-t)}}{\sqrt{\sigma^2(T-t)}}\\&=\frac{\ln\left(\dfrac{S}{K}\right)+\left(r-\dfrac{1}{2}\sigma^2\right)(T-t)}{\sigma\sqrt{(T-t)}}\end{aligned} \tag{15.3.1124}$$

Note that we also have:

$$\begin{aligned}d_1-\sigma\sqrt{(T-t)}&=\frac{\ln\left(\dfrac{S}{K}\right)+\left(r+\dfrac{1}{2}\sigma^2\right)(T-t)}{\sigma\sqrt{(T-t)}}-\sigma\sqrt{(T-t)}\cdot\frac{\sigma\sqrt{(T-t)}}{\sigma\sqrt{(T-t)}}\\&=\frac{\ln\left(\dfrac{S}{K}\right)+\left(r+\dfrac{1}{2}\sigma^2\right)(T-t)-\sigma^2(T-t)}{\sigma\sqrt{(T-t)}}\\&=\frac{\ln\left(\dfrac{S}{K}\right)+\left(r-\dfrac{1}{2}\sigma^2\right)(T-t)}{\sigma\sqrt{(T-t)}}=d_2\end{aligned}\tag{15.3.1125}$$

Hence $d_2=d_1-\sigma\sqrt{(T-t)}$.

So finally to summarize:

- For the European Call (the value of the purchase option with maturity T and strike K), the solution (whose demonstration still needs to be written in this section) is for a non-dividend-paying share-based underlying and for a geometric Brownian motion:

$$\boxed{C^{\text{BS}}(S,t)=S\Phi(d_1)-Ke^{-r(T-t)}\Phi(d_2)}\tag{15.3.1126}$$

where for recall (see section Statistics page 692):

$$\Phi(x)=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{x}e^{-\frac{1}{2}y^2}\mathrm{d}y\tag{15.3.1127}$$

The centered reduced Normal cumulative distribution function with:

$$d_1=\frac{\ln\left(\dfrac{S}{K}\right)+\left(r+\dfrac{1}{2}\sigma^2\right)(T-t)}{\sigma\sqrt{T-t}}\tag{15.3.1128}$$

and:

$$d_2=d_1-\sigma\sqrt{T-t}\tag{15.3.1129}$$

where to reader has to remember that μ,σ are both expressed in percentages!

Some textbooks write the Black-Scholes European Call pricing equation explicitly in the following way (a quite nice and beautiful way to write it!):

$$\begin{aligned}C_0^{\text{BS}} &= \mathrm{E}\left[\left(S_T^{\text{BS}}-K\right)^+\right]\\ &= \int\limits_{-\infty}^{+\infty}\left(S_0\exp\left(\left(r-\frac{\sigma_{\text{BS}}^2}{2}\right)T+\sigma_{\text{BS}}\sqrt{T}x\right)-K\right)^+\frac{1}{\sqrt{2\pi}}\exp\left(-\frac{x^2}{2}\right)\mathrm{d}x\\ &= \int\limits_{\frac{\log\left(\frac{K}{S_0}\right)+\left(r+\frac{\sigma_{\text{BS}}^2}{2}\right)T}{\sigma_{\text{BS}}\sqrt{T}}}^{+\infty}\left(S_0\exp\left(\left(r-\frac{(\sigma_{\text{BS}})^2}{2}\right)T+\sigma_{\text{BS}}\sqrt{T}x\right)-K\right)\frac{1}{\sqrt{2\pi}}\exp\left(-\frac{x^2}{2}\right)\mathrm{d}x\\ &= S_0\Phi\left(\frac{\log\left(\frac{S_0}{K}\right)+\left(r+\frac{1}{2}\sigma_{\text{BS}}^2\right)T}{\sigma_{\text{BS}}\sqrt{T}}\right)-K\Phi\left(\frac{\log\left(\frac{S_0}{K}\right)+\left(r-\frac{1}{2}\sigma_{\text{BS}}^2\right)T}{\sigma_{\text{BS}}\sqrt{T}}\right)\end{aligned} \tag{15.3.1130}$$

Remarks

R1. If we have a Call or Put at the money (for reminder it means that $S=K$) then the two coefficients above simplify since the Napierian logarithm is then null.

R2. Sometimes we write:

$$d_1=\frac{\ln\left(\dfrac{S}{K}\right)+\left(r+\dfrac{1}{2}\sigma^2\right)(T-t)}{\sigma\sqrt{T-t}}=\frac{\ln\left(M(t)\right)+\left(r+\dfrac{1}{2}\sigma^2\right)(T-t)}{\sigma\sqrt{T-t}} \tag{15.3.1131}$$

where $M(t)$ is the moneyness of which we have already spoken several times.

From the relation:

$$C^{\text{BS}}(S,t)=S\Phi(d_1)-Ke^{-r(T-t)}\Phi(d_2) \tag{15.3.1132}$$

We obviously deduce that a Call option can not have a value greater than the underlying (otherwise there would be an arbitrage opportunity to buy the underlying and sell the Call option - at least if we find a rather stupid buyer ... - and in extenso it would make us win every time).

- For the European Put (the value of the sell option of maturity T and strike K) for a non-dividend-paying share-based underlying and for a geometric Brownian motion:

$$P^{\text{BS}}(S,t)=-S\Phi(-d_1)+Ke^{-r(T-t)}\Phi(-d_2)=S(\Phi(d_1)-1)-Ke^{-r(T-t)}(\Phi(d_2)-1) \tag{15.3.1133}$$

From this last relation we conclude that a Put option can never have a value greater than the strike K otherwise there would also be an arbitrage opportunity by selling the Put and buying the underlying.

If necessary for the curious reader here is an example of valuing a vanilla Call option on a Bloomberg terminal:

Figure 15.187: **Valuation of a vanilla Call option on 1 underlying of the S&P 500**

It is relatively easy to verify that the solutions above satisfy the Put-Call parity equation:

$$S+P-C=Ke^{-r(T-t)} \qquad (15.3.1134)$$

where we recall that K is the strike price of the two options P and C.

Now, as promised earlier, we can prove the explicit relations of the Greeks for the closed relations of the Calls (the principle being the same for the Put), besides the relations demonstrated above, notice that:

$$\mathcal{N}(d_2)=\mathcal{N}(d_1)\frac{S}{K}e^{r(T-t)} \qquad (15.3.1135)$$

Indeed:

$$\begin{aligned}\mathcal{N}(d_2)&=\frac{\partial\Phi(d_2)}{\partial d_2}=\frac{1}{\sqrt{2\pi}}e^{-\frac{d_2^2}{2}}=\frac{1}{\sqrt{2\pi}}e^{-\frac{(d_1-\sigma\sqrt{T-t})^2}{2}}=\frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}}e^{d_2\sigma\sqrt{T-t}}e^{-\frac{\sigma^2(T-t)}{2}}\\&=\frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}}e^{\ln\left(\frac{S}{K}\right)+\left(r+\frac{\sigma^2}{2}\right)(T-t)}e^{-\frac{\sigma^2(T-t)}{2}}=\frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}}\frac{S}{K}e^{r(T-t)}\\&=\mathcal{N}(d_1)\frac{S}{K}e^{r(T-t)}\end{aligned} \qquad (15.3.1136)$$

and also that:

$$d_2=d_1-\sigma\sqrt{T-t} \qquad (15.3.1137)$$

We have immediately:

$$\frac{\partial d_1}{\partial S}=\frac{\partial d_2}{\partial S} \qquad (15.3.1138)$$

So now let's go!

- The Delta of the Call:

$$\begin{aligned}\Delta_C &= \frac{\partial C^{\text{BS}}}{\partial S} = \frac{\partial\left(S\Phi(d_1)-Ke^{-r(T-t)}\Phi(d_2)\right)}{\partial S} = \Phi(d_1)+S\frac{\partial\Phi(d_1)}{\partial S}-Ke^{-r(T-t)}\frac{\partial\Phi(d_2)}{\partial S}\\ &= \Phi(d_1)+S\frac{\partial\Phi(d_1)}{\partial d_2}\frac{\partial d_1}{\partial S}-Ke^{-r(T-t)}\frac{\partial\Phi(d_2)}{\partial d_2}\frac{\partial d_2}{\partial S}\\ &= \Phi(d_1)+S\mathcal{N}(d_1)\frac{\partial d_2}{\partial S}-Ke^{-r(T-t)}\mathcal{N}(d_1)\frac{S}{K}e^{r(T-t)}\frac{\partial d_2}{\partial S}\\ &= \Phi(d_1)+S\mathcal{N}(d_1)\frac{\partial d_1}{\partial S}-S\mathcal{N}(d_1)\frac{\partial d_2}{\partial S}=\mathcal{N}(d_1)+S\mathcal{N}(d_1)\frac{\partial d_1}{\partial S}-S\mathcal{N}(d_1)\frac{\partial d_1}{\partial S}\\ &= \Phi(d_1)>0\end{aligned} \tag{15.3.1139}$$

Since the derivative is always positive, we can conclude that the price of Call only increases if the underlying increases in value (this is obviously the reverse for Put).

The "delta of the Put" is given by (it should also be quite immediate):

$$\Delta_P = \frac{\partial C^{\text{BS}}}{\partial S} = \Phi(d_1)-1 \tag{15.3.1140}$$

which is therefore always a negative value.

- The Gamma of the Call:

$$\Gamma_C = \frac{\partial^2 C^{\text{BS}}}{\partial S^2} = \frac{\partial}{\partial S}(\Phi(d_1)) = \frac{\partial\Phi(d_1)}{\partial d_1}\frac{\partial d_1}{\partial S} = \frac{\mathcal{N}(d_1)}{S\sigma\sqrt{T-t}}>0 \tag{15.3.1141}$$

- The Vega of the Call:

$$\begin{aligned}\nu_C &= \frac{\partial C^{\text{BS}}}{\partial \sigma} = \frac{\partial\left(S\Phi(d_1)-Ke^{-r(T-t)}\Phi(d_2)\right)}{\partial\sigma} = S\frac{\partial\Phi(d_1)}{\partial\sigma}-Ke^{-r(T-t)}\frac{\partial\Phi(d_2)}{\partial\sigma}\\ &= S\frac{\partial\Phi(d_1)}{\partial d_1}\frac{\partial d_1}{\partial\sigma}-Ke^{-r(T-t)}\frac{\partial\Phi(d_2)}{\partial d_2}\frac{\partial d_2}{\partial\sigma}\\ &= S\mathcal{N}(d_1)\frac{\partial d_1}{\partial\sigma}-Ke^{-r(T-t)}\mathcal{N}(d_2)\frac{\partial d_2}{\partial\sigma}=S\mathcal{N}(d_1)\frac{\partial d_1}{\partial\sigma}-S\mathcal{N}(d_1)\frac{\partial d_2}{\partial\sigma}\\ &= S\mathcal{N}(d_1)\left(\frac{\partial d_1}{\partial\sigma}-\frac{\partial d_2}{\partial\sigma}\right)=S\mathcal{N}(d_1)\left(\frac{\partial d_1}{\partial\sigma}-\frac{(d_1-\sigma\sqrt{T-t}}{\partial\sigma}\right)\\ &= S\mathcal{N}(d_1)\left(\frac{\partial d_1}{\partial\sigma}-\frac{\partial d_1}{\partial\sigma}-\frac{\partial\sigma\sqrt{T-t}}{\partial\sigma}\right)=S\mathcal{N}(d_1)\sqrt{T-t}>0\end{aligned} \tag{15.3.1142}$$

We thus find here a variation of the price of the option which is proportional to the square root of the elapsed time (the origin of this property being well known to us!).

- The Theta of the Call:

$$\begin{aligned}
\theta_C=\frac{\partial C^{\text{BS}}}{\partial t}&=\frac{\partial\left(S\Phi(d_1)-Ke^{-r(T-t)}\Phi(d_2)\right)}{\partial t}\\
&=S\frac{\partial\Phi(d_1)}{\partial t}+rKe^{-r(T-t)}\Phi(d_2)-Ke^{-r(T-t)}\frac{\partial\Phi(d_2)}{\partial t}\\
&=S\frac{\partial\Phi(d_1)}{\partial d_1}\frac{\partial d_1}{\partial t}+rKe^{-r(T-t)}\Phi(d_2)-Ke^{-r(T-t)}\frac{\partial\Phi(d_2)}{\partial d_2}\frac{\partial d_2}{\partial t}\\
&=S\mathcal{N}(d_1)\frac{\partial d_1}{\partial t}+rKe^{-r(T-t)}\Phi(d_2)-Ke^{-r(T-t)}\mathcal{N}(d_2)\frac{\partial d_2}{\partial t}\\
&=S\mathcal{N}(d_1)\frac{\partial d_1}{\partial t}+rKe^{-r(T-t)}\Phi(d_2)-Ke^{-r(T-t)}\mathcal{N}(d_1)\frac{S}{K}e^{r(T-t)}\frac{\partial d_2}{\partial t}\\
&=S\mathcal{N}(d_1)\frac{\partial d_1}{\partial t}+rKe^{-r(T-t)}\Phi(d_2)-S\mathcal{N}(d_1)\frac{\partial d_2}{\partial t}\\
&=S\mathcal{N}(d_1)\frac{\partial d_1}{\partial t}+rKe^{-r(T-t)}\Phi(d_2)-S\mathcal{N}(d_1)\frac{\partial\left(d_1-\sigma\sqrt{T-t}\right)}{\partial t}\\
&=S\mathcal{N}(d_1)\frac{\partial d_1}{\partial t}+rKe^{-r(T-t)}\Phi(d_2)-S\mathcal{N}(d_1)\frac{\partial d_1}{\partial t}+S\mathcal{N}(d_1)\sigma\frac{\partial(\sqrt{T-t})}{\partial t}\\
&=rKe^{-r(T-t)}\Phi(d_2)-S\mathcal{N}(d_1)\sigma\left(\frac{1}{2}\frac{-1}{\sqrt{T-t}}\right)\\
&=rKe^{-r(T-t)}\Phi(d_2)+\frac{S\mathcal{N}(d_1)\sigma}{2\sqrt{T-t}}
\end{aligned}\tag{15.3.1143}$$

- The rho of the Call:

$$\begin{aligned}
\rho_C=\frac{\partial C^{\text{BS}}}{\partial r}&=\frac{\partial\left(S\Phi(d_1)-Ke^{-r(T-t)}\Phi(d_2)\right)}{\partial r}\\
&=S\frac{\partial\Phi(d_1)}{\partial r}+(T-t)Ke^{-r(T-t)}\Phi(d_2)-Ke^{-r(T-t)}\frac{\partial\Phi(d_2)}{\partial r}\\
&=S\frac{\partial\Phi(d_1)}{\partial d_1}\frac{\partial d_1}{\partial r}+(T-t)Ke^{-r(T-t)}\Phi(d_2)-Ke^{-r(T-t)}\frac{\partial\Phi(d_2)}{\partial d_2}\frac{\partial d_2}{\partial r}\\
&=S\mathcal{N}(d_1)\frac{\partial d_1}{\partial r}\frac{\partial d_1}{\partial r}+(T-t)Ke^{-r(T-t)}\Phi(d_2)-Ke^{-r(T-t)}\mathcal{N}(d_2)\frac{\partial d_2}{\partial r}\\
&=S\mathcal{N}(d_1)\frac{\partial d_1}{\partial r}+(T-t)Ke^{-r(T-t)}\Phi(d_2)-Ke^{-r(T-t)}\mathcal{N}(d_1)e^{r(T-t)}\frac{\partial d_2}{\partial r}\\
&=S\mathcal{N}(d_1)\frac{\partial d_1}{\partial r}+(T-t)Ke^{-r(T-t)}\Phi(d_2)-S\mathcal{N}(d_1)\frac{\partial d_2}{\partial r}\\
&=S\mathcal{N}(d_1)\frac{\partial d_1}{\partial r}+(T-t)Ke^{-r(T-t)}\Phi(d_2)-S\mathcal{N}(d_1)\frac{\partial\left(d_1-\sigma\sqrt{T-t}\right)}{\partial r}\\
&=S\mathcal{N}(d_1)\frac{\partial d_1}{\partial t}+(T-t)Ke^{-r(T-t)}\Phi(d_2)-S\mathcal{N}(d_1)\frac{\partial d_1}{\partial r}\\
&=(T-t)Ke^{-r(T-t)}\Phi(d_2)>0
\end{aligned}\tag{15.3.1144}$$

So we can easily understand why the price of a Call is as high as r is large (at least in the standard values of r such that we can observe them in markets).

A common question from students (and practitioners) is to know whether the price of a Call increases or decreases depending on the distance at maturity. It is difficult to conclude in just a few seconds by deriving relatively to T so it is better to go through computer tools and hence it is quite easy to verify that the intuition that the price of Call increases with time at maturity is correct. Moreover, we can also confirm another intuition that the price of Call tends towards the value of the strike, the more T is distant.

The same goes for the price of a Call depending on the strike. There it is easier to do it by hand:

$$\begin{aligned}\frac{\partial C^{\text{BS}}}{\partial K}&=\frac{\partial\left(S\Phi(d_1)-Ke^{-r(T-t)}\Phi(d_2)\right)}{\partial S}=S\frac{\partial\Phi(d_1)}{\partial K}-e^{-r(T-t)}\Phi(d_2)-e^{-r(T-t)}\frac{\partial\Phi(d_2)}{\partial K}\\&=S\frac{\partial\Phi(d_1)}{\partial d_1}\frac{\partial d_1}{\partial K}-e^{-r(T-t)}\Phi(d_2)-Ke^{-r(T-t)}\frac{\partial\Phi(d_2)}{\partial d_2}\frac{\partial d_2}{\partial K}\\&=S\mathcal{N}(d_1)\frac{\partial d_1}{\partial K}-e^{-r(T-t)}\Phi(d_2)-Ke^{-r(T-t)}\mathcal{N}(d_1)\frac{S}{K}e^{r(T-t)}\frac{\partial d_2}{\partial K}\\&=S\mathcal{N}(d_1)\frac{\partial d_1}{\partial K}-e^{-r(T-t)}\Phi(d_2)-S\mathcal{N}(d_1)\frac{\partial d_2}{\partial K}\\&=S\mathcal{N}(d_1)\frac{\partial d_1}{\partial K}-e^{-r(T-t)}\Phi(d_2)-S\mathcal{N}(d_1)\frac{\partial d_1}{\partial K}\\&=-e^{-r(T-t)}\Phi(d_2)\end{aligned}\tag{15.3.1145}$$

So the higher the price of the strike, the less the price of the Call will be.

Here are the commands built into the Microsoft® Excel® 14.0.6129 to do the calculation with arbitrary input values:

	A	B	C
1	S	292.85	Underlying spot price
2	E	300.00	Strike price
3	T	0.25	Maturity in years
4	r	4.00%	Average geometric rate without risk
5	σ	40.0%	Volatility
6	t	-	Time
7			
8	d_1	=(LN(B1/B2)+(B4+B5^2/2)*(B3-B6))/(B5*SQRT(B3-B6))	
9	d_2	=B8-B5*SQRT(B3-B6)	
10			
11			
12	$C(S,T)$	=B1*NORMSDIST(B8)-B2*EXP(-B4*(B3-B6))*NORMSDIST(B9)	
13	$P(S,T)$	=B2*EXP(-B4*(B3-B6))*NORMSDIST(-B9)-B1*NORMSDIST(-B8)	
14	Delta du call européen	=NORMSDIST(B8)	
15	Delta du put européen	=B14-1	

Figure 15.188: **Application of Black & Scholes pricing version of Microsoft® Excel® 14.0.6129**

Remark

It is clear that the Black & Scholes have allowed the developments of options markets, allowing for more secure speculation. This remains speculation (the players speculate relative to each other on the volatility of equities), but this speculation remains almost secured by the coverage equation, which avoids that the losses are too large. There are nevertheless disadvantages to their use. The most important is surely the effect of runaway that they cause. For example, suppose that you are the seller of an option on the stock of a company A. Imaging that this company announces results slightly lower than expected. Its price falls, and that's normal. The Black & Scholes coverage equation then recommends that you reduce the number of shares of that company in your portfolio, which you do (at least if you did the error of not replicate). But almost all market players will do the same reasoning, causing a further decline in the share price. The coverage equation of Black & Scholes recommends that you sell more shares, etc. This can trigger a real runaway on the market, both downward and upward. This is accentuated by the fact that, often, purchase or sales orders are new automated, implemented directly in softwares, and no longer require human intervention. On the other hand, the coverage equation of Black & Scholes is efficient for small price fluctuations, but not for brutal and important "unscrewing". Thus, just a year after receiving their Nobel Prize in Economics, Robert Merton and Myron Scholes were involved in the collapse of the US investment fund LTCM in autumn 11998 (holocene calendar), following the severe Russian crisis of the 11998 (holocene calendar) summer.

In fact, option prices are not calculated using the Black & Scholes formula (especially since the return is assumed to be constant ... hence the use of Monte Carlo techniques and binomial trees that we will see further below). Most of the time, these prices are simply the result of the law of supply and demand, which prevails in most markets (for which reason, in markets, Calls for an underlying of a given spot and same strike and maturity do not have the same price!). When we then look at the non-reduced expression:

$$\boxed{C^{\text{BS}}(S,t)=S\Phi\left(\dfrac{\ln\left(\frac{S}{K}\right)+\left(r+\frac{\sigma^2}{2}\right)(T-t)}{\sigma\sqrt{T-t}}\right)-Ke^{-r(T-t)}\Phi\left(\dfrac{\ln\left(\frac{S}{K}\right)+\left(r-\frac{\sigma^2}{2}\right)(T-t)}{\sigma\sqrt{T-t}}\right)} \tag{15.3.1146}$$

It is therefore an equation with one unknown, since the only value then lacking in market practice is the yield volatility that we then name "implied volatility" (as opposed to the volatility used when we value options and which we classically named "empirical (observed) volatility") and which should (...) in theory be equal in the markets for a Call and a Put having the same maturity and the same exercise price.

In practice, the calculation of implied volatility is made, for a given underlying, for several K and T values at the spot and yield given by the market at present or in the future. In the end, instead of having only one point, we get a tablecloth like the one below:

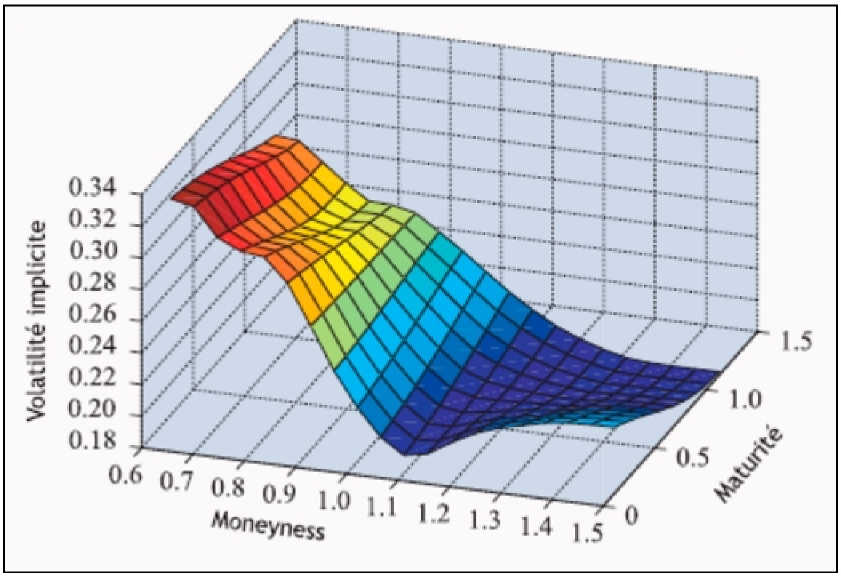

Figure 15.189: Typical profile of an implied volatility surface

where the "moneyness" represents the ratio between S and K. If the Black & Scholes equation was respected, we should have if the above a plane (so something completely flat)...

Figure 15.190: Typical profile of implied volatility in the Bloomberg terminal

On the markets, practitioners (especially traders) constantly look at the surfaces of implied volatilities (of which the interpretations can be multiple!). The concern is that these surfaces are not static: they change every day. The knowledge (in fact rather the approximation...) of the dynamics of the volatility sheets is therefore a crucial and subjectively complex subject (whole textbooks are dedicated only to this subject!)...

A typical approach is to make assumptions about the behaviour of the underlying. Sometimes there are closed formulas (as in the Black & Scholes model), but often it is necessary to use numerical methods to obtain the price of the corresponding option and then to reverse the problem to find the local volatility.

Definitions (#15.3.697):

- D1. We name "historical volatility" or "statistical volatility" or "realized volatility", the past volatility of a financial instrument underlying an option.
- D2. We name "implied volatility" or "forward volatility", the volatility injected into the Black & Scholes model which is an estimate of the average of the future projection of volatility over a given period.
- D3. We name "local volatility" the volatility of an option calculated a posteriori option from the Dupire model (inversion of the Black & Scholes relation) in a way.
- D4. We name "observed volatility" the true volatility of an option as observed in financial markets.

Now let us talk about the case of the underlying that pay dividends! If the underlying whose spot price we inject into the option valuation equation is S it is supposed as we know to be the present value estimated by the economic agents. If the underlying pays dividends then this price is actually not its actual face value since it implicitly contains the present values of the dividends! To obtain its true value, it is then necessary to subtract from S the updated values of the dividends before injecting the value of the evaluation relations.

✍**Example:**

Let us consider a Call on 1 year of a BMW share with a strike price of 40.-. Suppose the current spot price of the BMW share is 35.-, the instantaneous annual risk-free market interest rate is 5%, the volatility is 20% per year, and there are two dividends during the period of one year of respectively 1.- at two months and 0.5.- to eight months.

Therefore, the present value of the dividends is:

$$1\cdot e^{-\frac{2}{12}5\%}+5\cdot e^{-\frac{8}{12}5\%}$$

and not 35.-. And thus this deterministic amount is implicitly included in the current spot price of the market. Therefore, the spot value S that we have to inject into the evaluation of the Call is:

$$35-1.4753=33.5247\text{.-}$$

and not 35.-.

In the case where the underlying pays dividends which in constant continuous rate q then its true face value discounted on the time T will be given using the continuous rate (if necessary review the construction of the concept of continuous rate!):

$$Se^{-qT} \tag{15.3.1147}$$

By injecting this last relation into the evaluation of the options, we have for example for the Call:

$$\begin{aligned}C_d^{\text{BS}} &= Se^{-q(T-t)}\Phi\left(\frac{\ln\left(\frac{Se^{-q(T-t)}}{K}\right)+\left(r+\frac{\sigma^2}{2}\right)(T-t)}{\sigma\sqrt{T-t}}\right)\\ &-Ke^{-r(T-t)}\Phi\left(\frac{\ln\left(\frac{Se^{-q(T-t)}}{K}\right)+\left(r-\frac{\sigma^2}{2}\right)(T-t)}{\sigma\sqrt{T-t}}\right)\\ &= Se^{-q(T-t)}\Phi\left(\frac{\ln\left(\frac{S}{K}\right)-q(T-t)+\left(r+\frac{\sigma^2}{2}\right)(T-t)}{\sigma\sqrt{T-t}}\right)\\ &-Ke^{-r(T-t)}\Phi\left(\frac{\ln\left(\frac{S}{K}\right)-q(T-t)+\left(r-\frac{\sigma^2}{2}\right)(T-t)}{\sigma\sqrt{T-t}}\right)\\ &= Se^{-q(T-t)}\Phi\left(\frac{\ln\left(\frac{S}{K}\right)+\left((r-q)+\frac{\sigma^2}{2}\right)(T-t)}{\sigma\sqrt{T-t}}\right)\\ &-Ke^{-r(T-t)}\Phi\left(\frac{\ln\left(\frac{S}{K}\right)-\left((r-q)-\frac{\sigma^2}{2}\right)(T-t)}{\sigma\sqrt{T-t}}\right)\end{aligned} \tag{15.3.1148}$$

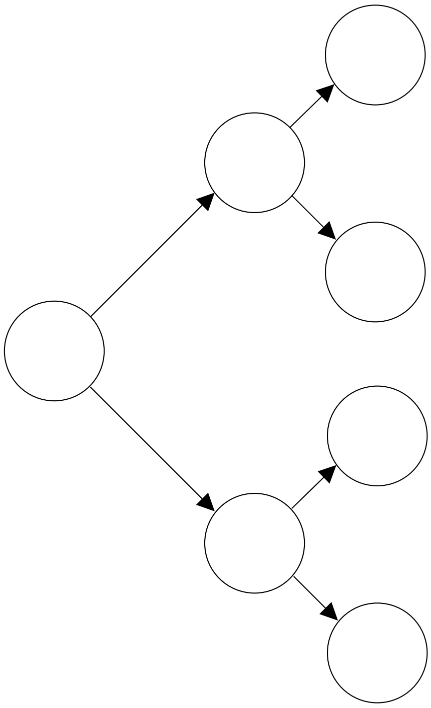
It is quite obvious that this last equality is a generalization of the options on the underlying type of assets paying no dividends. We could, by the way, here again calculate the corresponding Greeks ...

15.3.10.3.10 Binomial option pricing model (CRR model)

There is an older style approach to the previous continuous-time option pricing model that is not used anymore in practice in the simple form we will see here (CRR model) but that has inspired quite a lot of much more modern and complicated models that are still sometimes used today[28].

The binomial pricing model (we should speak in the plural because there are many binomial pricing models!) is a technique which assumes that at each time period, the financial instrument of interest can only have two different values compared to a given initial value: a higher or lower value (in the case of the trinomial model we add the case where the value remains constant).

To represent this, we use what we know as being named a "binomial tree", that is to say a succession of sequences of two branches which represent the possible changes in price at nodes:



We will see that the asymptotic limit of the (discrete time) binomial CRR model will take us back to the Black & Scholes formula. But before doing this let us recall that:

1. A portfolio is a "replicating portfolio" of an option if the portfolio and the option have exactly the same payoff in each state of future.
2. By using "no arbitrage argument", the cost or price of the replication portfolio is the same as the value of the option.

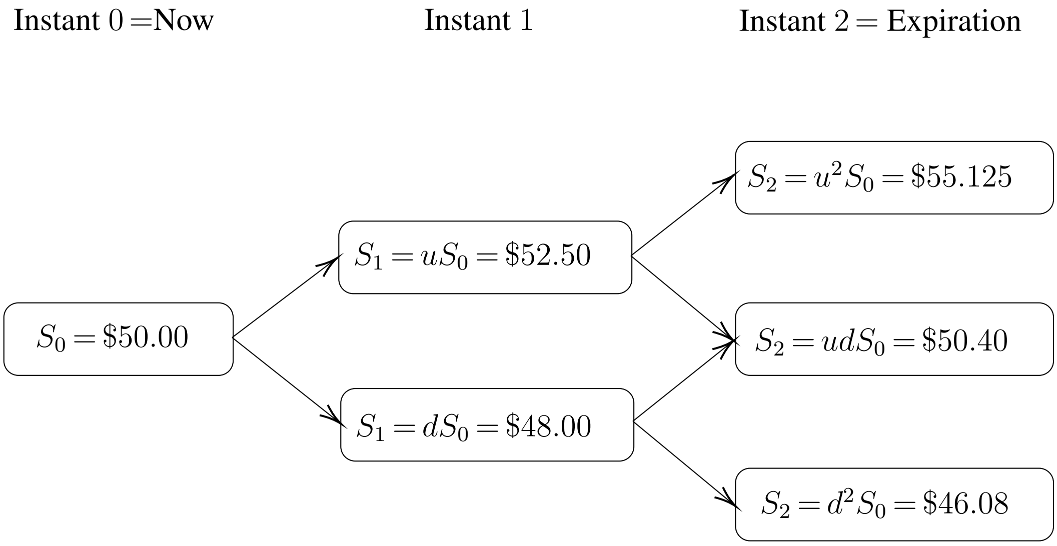
---

[28] Indeed the binomial tree (apart from the special case of CRR!) remains used by practitioners because it can take into account many complications that purely theoretical models cannot in a single block such as, for example, the costs of transactions, dividends, empirical criteria of the portfolio client, etc. What will also make us prefer the binomial tree to the Monte Carlo method or vice versa will be mainly the complexity of the algorithm for the calculations (i.e. calculation time) but not only!

Remark

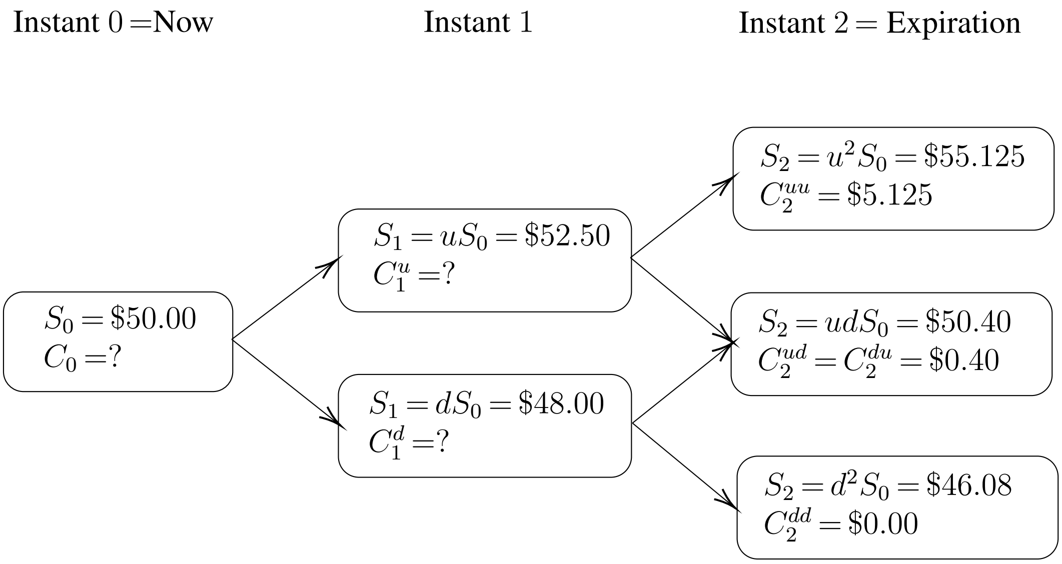
The finance literature has revealed no fewer than 11 alternative version of the binomial option pricing model for options on log-normally assets (CRR with or without drift, Jarrow-Rudd model, Tian model, Leisen-Reimer model, ...). These models are derived under a variety of assumption and in some cases require information that is ordinarily unnecessary to value options [94].

The basic building element for the Black & Scholes formula is the assumption that over one instant, the stock price can only move up or down (this is named a "binomial process"). So you must first understand how to work in such a world. Over two instants, the stock price can move up twice, move up once and move down once, or move down twice. Use the letter u to describe the stock price multiplier when an up move occurs, and d to describe the stock price multiplier when a down move occurs. You can represent the stock price process with a binomial tree - where one branch represents a price-up movement and the other a price-down movement. For example if $d=0.96$ (which means that on a down move, the stock price declines by 4%) and $u=1.05$ (the stock price increases by 5%), the stock price is as follows:



Note that at Instant 2, the middle outcome occurs on two possible paths, while the two extreme outcomes occur only on one path each; $u\cdot d\cdot S_0$ can come about if there is one u followed by one d, or if there is one d followed by one u. This is already a statistical distribution that shares with a bell-shaped (Normal) distribution the feature that middle outcomes are more likely than extreme outcomes (with many bell shaped distributions and binomial trees we indeed end up with a continuous distribution that looks a lot like a bell-shaped curve).

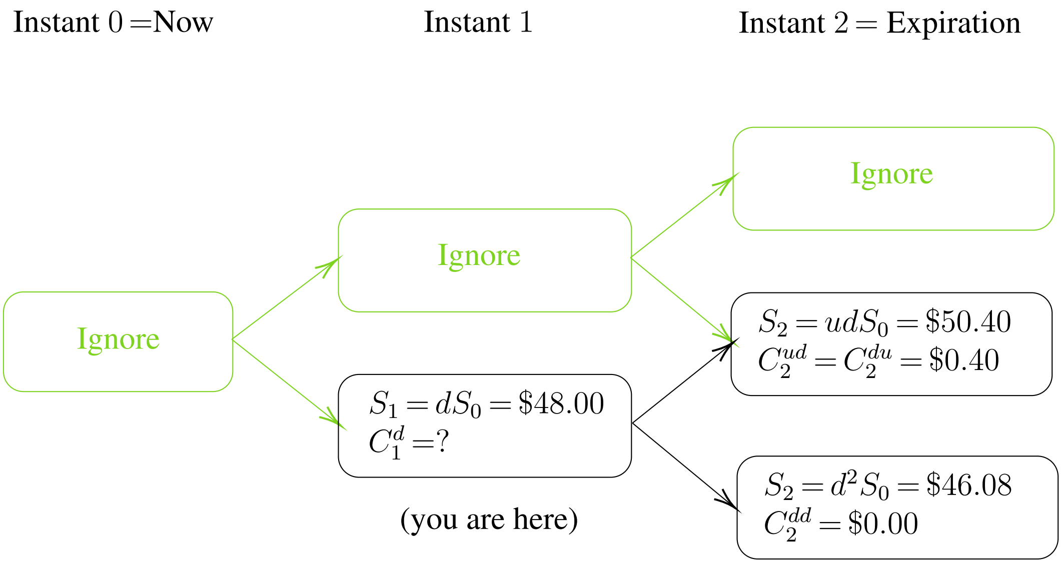
If we know that our underlying stock follows this binomial process, and we know the values of u and d, can we price a Call option with a strike price of $\$50$.-? On inspection of the tree, realize that the Call option pays \$ 0 if the stock moves down twice, $\$0.40$.- if the stock price moves up once and down once (or vice versa), and $\$5.125$.- if the stock price moves up twice:



Instant $0 =$Now
Instant 1
Instant $2 =$ Expiration
$S_0 = \$50.00$
$C_0 = ?$
$S_1 = uS_0 = \$52.50$
$C_1^u = ?$
$S_1 = dS_0 = \$48.00$
$C_1^d = ?$
$S_2 = u^2S_0 = \$55.125$
$C_2^{uu} = \$5.125$
$S_2 = udS_0 = \$50.40$
$C_2^{ud} = C_2^{du} = \$0.40$
$S_2 = d^2S_0 = \$46.08$
$C_2^{dd} = \$0.00$

As we know it, the purpose of the seller of the Call is to calculate the risk premium C_0 of the Call and this should be made such that he can hedge the option risk. This should be made using arbitrage opportunity with an another investment on the market. So the risk premium should be calculated at each instant to what would happen (what will be the cost) if we hedge the Call option by buying buy immediately a portfolio Δ with a quantity δ of the underlying stocks and (assumed) a given quantity b risk-free bonds.

First let us place ourselves into the position where the stock price has moved down once already, that is, where the stock price stands at $\$48.00$.-:



Instant $0 =$Now
Instant 1
Instant $2 =$ Expiration
Ignore
Ignore
Ignore
$S_1 = dS_0 = \$48.00$
$C_1^d = ?$
(you are here)
$S_2 = udS_0 = \$50.40$
$C_2^{ud} = C_2^{du} = \$0.40$
$S_2 = d^2S_0 = \$46.08$
$C_2^{dd} = \$0.00$

So the equation is: what would be the minimum cost (and therefore the composition) of a replication portfolio such that we receive \$ 0 if the underlying stocks of our Call moves down and if we receive $\$0.40$.- if the stocks moves up. That is assuming a risk-free rate of (for example) 0.1% and that we know the underling is traded at $\$48.00$.- the following system of two linear equations with two unknowns:

$$\begin{gathered}\delta\cdot d\cdot S_0+b(1+r)=C_d\\ \delta\cdot u\cdot S_0+b(1+r)=C_u\end{gathered}\tag{15.3.1149}$$

That is with our numerical values:

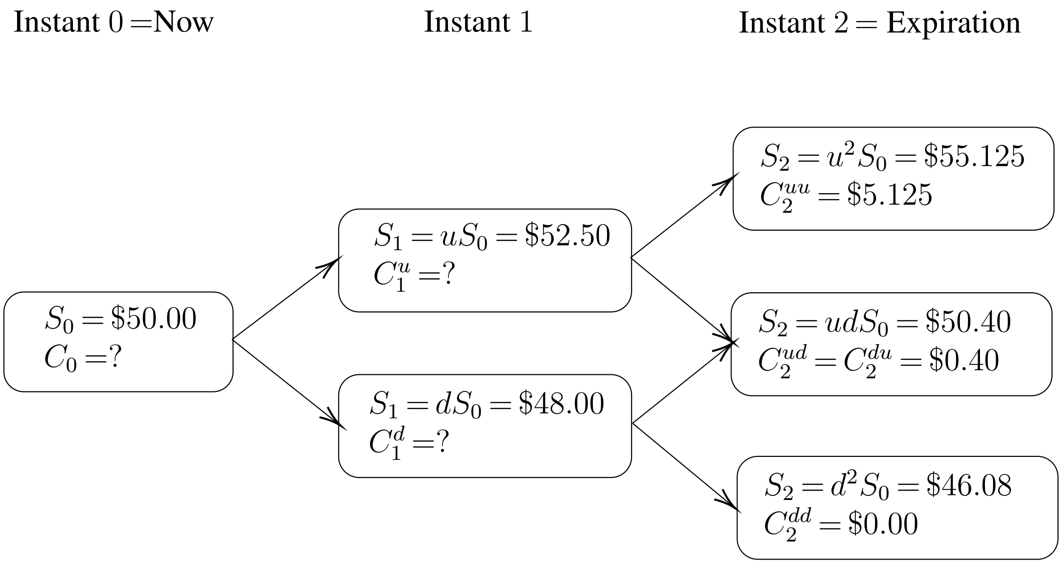
$$\begin{gathered}\delta\cdot 0.96\cdot \$48.00+b(1.001)=\$0.00\\ \delta\cdot 1.05\cdot \$48+b(1.001)=\$0.40\end{gathered}\tag{15.3.1150}$$

The solution is given after elementary simplifications by:

$$\delta=\frac{C_u-C_d}{u\cdot S_0-d\cdot S_0}=\frac{C_u-C_d}{S_0(u-d)}\cong 0.0926\qquad b\cong -\$4.262\tag{15.3.1151}$$

That is if we purchase a replication portfolio of 0.0926 underlying (which costs $0.0926\cdot \$48\cong \$4.444$.-) and borrow $\$4.262$.- for a net outlay of $4.444-4.262=\$0.182$.-, then in the next period, this replication portfolio will pay off $\$0$.- in the downstate and $\$0.40$.- in the upstate. Because this is exactly the same as the payoff on the Call option, the C_1^d Call option should also be worth $\$0.182$.-.

Now to continue we must still consider still at Instant 1:



Instant 0 =Now
Instant 1
Instant 2 = Expiration
$S_2=u^2S_0=\$55.125$
$C_2^{uu}=\$5.125$
$S_1=uS_0=\$52.50$
$C_1^u=?$
$S_0=\$50.00$
$C_0=?$
$S_2=udS_0=\$50.40$
$C_2^{ud}=C_2^{du}=\$0.40$
$S_1=dS_0=\$48.00$
$C_1^d=?$
$S_2=d^2S_0=\$46.08$
$C_2^{dd}=\$0.00$

Now we repeat the same reasoning where the stock price stands at $\$52.50$.- and such that at the next instant we can end up with either $\$0.40$.- in the downstate or $\$5.125$.- in the upstate. In this case, we simply have to solve:

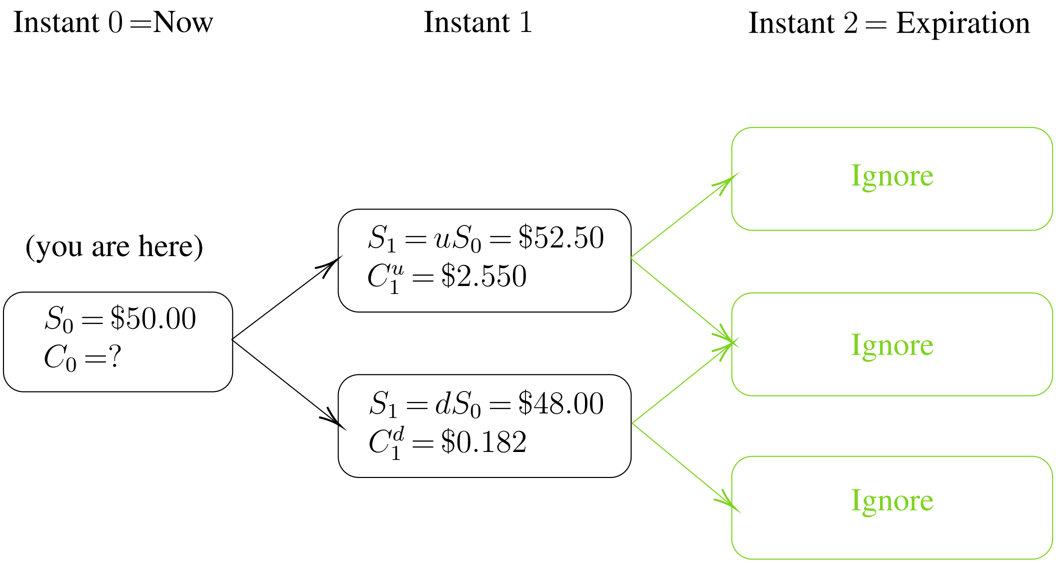
$$\begin{gathered}\delta\cdot 0.96\cdot \$52.50+b(1.001)=\$0.40.\text{-}\\ \delta\cdot 1.05\cdot \$52.50+b(1.001)=\$5.125.\text{-}\end{gathered}\tag{15.3.1152}$$

and the solutions are:

$$\delta=1.00\qquad b\cong -\$49.95.\text{-}\tag{15.3.1153}$$

That is if we purchase a replication portfolio of 1.00 underlying (which costs $1.00\cdot\$52.50=\$52.50$.-) and borrow $\$49.95$.- for a net outlay of $52.50-49.95=\$2.550$.-, then in the next period, this replication portfolio will pay off $\$5.125$ in the upstate and $\$0.40$.- in the downstate. Because this is exactly the same as the payoff on the Call option, the C_1^u Call option should also be worth $\$2.550$.-.

And finally:



To determine the value of the Call C_0 at the outset we have to find the price of the underlying that will be worth $\$0.182$ if the stock moves from $\$50$ to $\$48$, and worth $\$2.55$ if the stock moves from $\$50$ to $\$52.50$:

$$\begin{aligned}\delta\cdot 0.96\cdot\$50.00+b(1.001)&=\$0.182\\ \delta\cdot 1.05\cdot\$50.00+b(1.001)&=\$2.550\end{aligned}\tag{15.3.1154}$$

and the solutions are:

$$\delta\cong 0.5262\qquad b\cong -\$25.05\tag{15.3.1155}$$

So the trader has to purchase 0.5262 shares (cost today: $\$26.31$), and borrow $\$25.05$ dollars. The replication portfolio's total net outlay is then $\$26.31-\$25.05\cong\$1.26$. Therefore, it follows that, by arbitrage, the price of the Call option C_0 must be about $\$1.26$ today.

Remark

American Call options are priced the same way but at the opposite that we can exercise before maturity (early exercise)! In fact we see quickly with the example above that American Call option have then no interest to be exercised before maturity! However for America options, it's not the same! Indeed, American Puts are equals to or more valuable than European Puts if and only if the underlying pays dividends!!! The reason for this is the time value of money. In a Put, we get the option to sell a stock at a given strike price. If we exercise this option at $t=0$, we receive the strike price at $t=0$ and can invest it at the risk-free rate. Lets imagine the r_f rate is 10% and the strike price is $10\$$. this means at $t=1$, we would get $\$11.0517$.-. If, on the other hand, we didn't exercise the option early, at $t=1$ we would simply receive the strike price ($\$10$.-). Basically, the strike price, which is our payoff for a Put option, doesn't earn interest!

In real life, the stock price can move many more times than just twice. You need a tree with many more levels, so you need to generalize this binomial process to more levels. For example, if there are 10 instants, what would be the worst possible outcome? Ten instant down movements mean that the stock price would be:

$$d^{10}S_0=0.96^{10}\cdot\$50\cong\$33.24.\text{-}\qquad(15.3.1156)$$

The second-worst outcome would be one instant of up movement, and nine instants of down movement:

$$d^9u^1S_0=0.96^9\cdot 1.05^1\cdot\$50\cong\$36.36.\text{-}\qquad(15.3.1157)$$

Although the worst scenario can only occur if there are exactly 10 down movements, there are 10 different ways to fall into the second-worst scenario, ranging from $duuuuuuuuu$, $uduuuuuuuu$, ... , to $uuuuuuuuud$. This should bring to the memories of combinatorics (see section Probabilities page 528). These are the 10 possible combinations, better written as:

$$\binom{10}{1}=\frac{10!}{1!9!}=10\qquad(15.3.1158)$$

Thus in general:

$$\binom{N}{i}=\frac{N!}{i!(N-i)!}\qquad(15.3.1159)$$

Therefore, with N levels in the tree, the stock price will be:

$$u^id^{N-i}S_0=u^i(1-u)^{N-i}S_0\qquad(15.3.1160)$$

in $\displaystyle\binom{N}{i}$ paths.

Now let us introduce probabilities! If we have a constant probability p of going up, then we have a probability $(1-p)$ of going down then we can write obviously:

$$(pu)^i((1-p)d)^{N-i}S_0=p^i(1-p)^{N-i}u^i(1-u)^{N-i}S_0\qquad(15.3.1161)$$

that gives the expected value we can get after N paths for i given downside movements (and $N-i$ upside) with a probability p whatever the order of the movements!

We recognize here a well known pattern!!!! Something of the type:

$$p^i(1-p)^{N-i}u^i(1-u)^{N-i}S_0=P_if(x_i)\qquad(15.3.1162)$$

So we could think to a geometric distribution (see section Statistics page 654) but this would be a mistake as all possible identical patterns interest us! So we must multiply that relation by the number of way we can get a same pattern. That is:

$$\binom{N}{i}p^i(1-p)^{N-i}u^i(1-u)^{N-i}S_0\qquad(15.3.1163)$$

that gives the expected total we can get after N paths for i given downside movements (and $N-i$ upside) with a probability p whatever the order of the movements!

And if we want to take into account ALL possible movements, then we are just writing the expected mean and it comes:

$$\text{E}(S_N)=\sum_{i=0}^{N}\binom{N}{i}p^i(1-p)^{N-i}u^i(1-u)^{N-i}S_0 \tag{15.3.1164}$$

But... but... If we consider that we are considering that we are pricing a Call option, we are not interested to all path where $S_0<K$ (since the Call we not be used!). Then for this case we should write:

$$\text{E}(S_N)=\sum_{i=0}^{N}\binom{N}{i}p^i(1-p)^{N-i}\max(S_0u^i(1-u)^{N-i}-K,0) \tag{15.3.1165}$$

But we must not forget that we are looking also to the price compared to a risk-free return investment. So we should write:

$$\boxed{C^{\text{CRR}}=e^{-r_fN}\sum_{i=0}^{N}\binom{N}{i}p^i(1-p)^{N-i}\max(S_0u^i(1-u)^{N-i}-K,0)} \tag{15.3.1166}$$

This relation is known under the name "Cox-Ross-Rubinstein model" (or simply "CRR model") of option pricing as first proposed in 11979 according to holocene calendar (almost 6 years after the publication of Black & Scholes model).

Now to continue we will see why some companies prefer to use binomial pricing rather than Black & Scholes model (as that latter overestimate prices). To fall back on the Black & Scholes equations starting from CCR model we must first impose that:

$$u=\frac{1}{d} \tag{15.3.1167}$$

that is to say that the original stock price will be retained after an equal number of upward and downward price movements in any up-down sequences (quite strong assumption!).

Now let S^* be the random price of the underlying at the end of the N periods. For n upward price movements over the N periods since:

$$S^*=u^nd^{N-n}S_0 \tag{15.3.1168}$$

we get:

$$\ln\left(\frac{S^*}{S_0}\right)=n\ln(u)+(N-n)\ln(d)=n\ln\left(\frac{u}{d}\right)+N\ln(d) \tag{15.3.1169}$$

Here, $\ln(S^*/S)$, is the natural logarithm of one-plus-return for holding the stock over the N periods; it is equivalent to a continuously compounded return over the N periods.

For a binomial distribution with the probability of each upward movement being p, the expected value and the variance of n are (see section Statistics page 658):

$$\text{E}(n)=Np \qquad \text{and} \qquad \text{V}(n)=Np(1-p) \tag{15.3.1170}$$

Then we have immediately involving:

$$\mathrm{E}\left[\ln\left(\frac{S^*}{S_0}\right)\right]=Np\ln\left(\frac{u}{d}\right)+N\ln(d) \tag{15.3.1171}$$

and:

$$\mathrm{V}\left[\ln\left(\frac{S^*}{S_0}\right)\right]=Np(1-p)\left[\ln\left(\frac{u}{d}\right)\right] \tag{15.3.1172}$$

We can capture the above expressions more succinctly by defining (they are both the factors of the N):

$$\hat{\mu}=p\ln(u)+(1-p)\ln(d)=\hat{\sigma}^2=p(1-p)\left[\ln\left(\frac{u}{d}\right)\right]^2 \tag{15.3.1173}$$

as being the fraction time expected and volatility instantaneous return.

And using our previous assumption ($u=1/d$):

$$\begin{aligned}\hat{\mu}&=p\ln(u)+(1-p)\ln\left(\frac{1}{u}\right)=(2p-1)\ln(u)\\ \hat{\sigma}^2&=p(1-p)\left[\ln\left(\frac{u}{1/u}\right)\right]^2=4p(1-p)(\ln(u))^2\end{aligned} \tag{15.3.1174}$$

For algebraic convenience that will soon be clear, let us put:

$$p=\frac{1}{2}+b \tag{15.3.1175}$$

where the parameter b has yet to be determined. Accordingly, we can write:

$$\hat{\mu}=(2p-1)\ln(u)=2b\ln(u) \tag{15.3.1176}$$

and:

$$\hat{\sigma}^2=4p(1-p)(\ln(u))^2=(1-4b^2)(\ln(u))^2=(\ln(u))^2-\hat{\mu}^2 \tag{15.3.1177}$$

If we express u as an exponential function of the form $u=e^h$ the both relations above reduce to:

$$\hat{\mu}=2bh \qquad \text{and} \qquad \hat{\sigma}^2=h^2-\hat{\mu}^2=h^2(1-4b^2) \tag{15.3.1178}$$

Now we suppose also that the convergence of the Black & Scholes and Cox-Ross-Rubinstein models requires that $\hat{\mu}N/T$ and $\hat{\sigma}N/T$ converge to the parameters μ and σ^2, respectively as N approaches infinity!

Now we must found a value for b and h such that when $N\rightarrow+\infty$ we get $\hat{\mu}=\mu$ and $\hat{\sigma}=\sigma$. There are various combinations for this but we must found one where none of the values diverge! One such proposition is after trial and errors:

$$h=\sigma\sqrt{\frac{T}{N}} \qquad \text{and} \qquad b=\frac{\mu\sqrt{T}}{2\sigma\sqrt{N}} \tag{15.3.1179}$$

It follows that:

$$\hat{\mu}=2bh=2\frac{\mu\sqrt{T}}{2\sigma\sqrt{N}}\sigma\sqrt{\frac{T}{N}}=\mu\frac{T}{N} \tag{15.3.1180}$$

Therefore we have indeed:

$$\mu=\hat{\mu}\frac{N}{T} \tag{15.3.1181}$$

It also follows that:

$$\hat{\sigma}^2=h^2(1-4b^2)=\sigma^2\frac{T}{N}\left(1-4\frac{\mu^2T}{4\sigma^2N}\right)=\sigma^2\frac{T}{N}\left(1-\frac{\mu^2T}{\sigma^2N}\right) \tag{15.3.1182}$$

and here we see that if $N\rightarrow+\infty$ we get:

$$\hat{\sigma}^2=\sigma^2\frac{T}{N}\left(1-\underbrace{\frac{\mu^2T}{\sigma^2N}}_{\rightarrow 0}\right)=\sigma^2\frac{T}{N} \tag{15.3.1183}$$

Therefore:

$$\sigma=\hat{\sigma}^2\frac{N}{T} \tag{15.3.1184}$$

Finally we have (what some authors put as a definition):

$$u=\frac{1}{d}=e^{\sigma\sqrt{T/N}} \tag{15.3.1185}$$

and:

$$p=\frac{1}{2}+\frac{\mu}{2\sigma}\sqrt{\frac{T}{N}} \tag{15.3.1186}$$

that we name the "physical probability" for obvious reasons we will see further below.

Oufff!!!! This is done! Now let us come back to the CRR model:

$$C^{\text{CRR}}=e^{-r_fN}\sum_{i=0}^{N}\binom{N}{i}p^i(1-p)^{N-i}\max(S_0u^i(1-u)^{N-i}-K,0) \tag{15.3.1187}$$

When the final stock price is greater than the strike price, that is, when:

$$S_0u^id^{N-i}>K \tag{15.3.1188}$$

Or:

$$\ln\left(\frac{S_0}{K}\right)>-i\ln(u)-(N-i)\ln(d) \tag{15.3.1189}$$

Since:

$$u=e^{\sigma\sqrt{T/N}}\qquad\text{and}\qquad d=e^{-\sigma\sqrt{T/N}} \tag{15.3.1190}$$

The conditions become:

$$\ln\left(\frac{S_0}{K}\right)=N\sigma\sqrt{\frac{T}{N}}-2i\sigma\sqrt{\frac{T}{N}} \tag{15.3.1191}$$

or:

$$j>\frac{N}{2}-\frac{\ln(S_0/K)}{2\sigma\sqrt{T/N}} \tag{15.3.1192}$$

The CRR model can therefore we written:

$$C^{\text{CRR}}=e^{-r_f N}\sum_{i>\alpha}\binom{N}{i}p^i(1-p)^{N-i}(S_0u^i(1-u)^{N-i}-K) \tag{15.3.1193}$$

where:

$$\alpha=\frac{N}{2}-\frac{\ln(S_0/K)}{2\sigma\sqrt{T/N}} \tag{15.3.1194}$$

For convenience, we put:

$$\begin{aligned}U_1&=\sum_{i>\alpha}\binom{N}{i}p^i(1-p)^{N-i}u^i(1-u)^{N-i}\\U_2&=\sum_{i>\alpha}\binom{N}{i}p^i(1-p)^{N-i}\end{aligned} \tag{15.3.1195}$$

So that:

$$C^{\text{CRR}}=e^{-r_f N}(S_0U_1-KU_2) \tag{15.3.1196}$$

Let us consider first U_2 as it is well known (see section Statistics page 658); a binomial distribution approaches a Normal distribution as the number of trials approaches infinity according to the central limit theorem (see section Statistics page 938). Specifically, when there are N trials and p is the probability of success, the probability distribution of the number of successes is approximately Normal with mean Np and standard deviation $\sqrt{Np(1-p)}$ (see section Statistics page 692). The variable U_2 above is the probability of the number of successes being more than α. From the properties of the Normal distribution, it follows that, for large N:

$$U_2=\Phi\left(\frac{Np}{\sqrt{Np(1-p)}}\right) \tag{15.3.1197}$$

Substituting for α, we get:

$$U_2=\Phi\left(\frac{\ln(S_0/K)}{2\sigma\sqrt{T}\sqrt{p(1-p)}}+\frac{\sqrt{N}\left(p-\dfrac{1}{2}\right)}{\sqrt{p(1-p)}}\right) \tag{15.3.1198}$$

From the result we get previously:

$$p=\frac{1}{2}+\frac{\mu}{2\sigma}\sqrt{\frac{T}{N}} \tag{15.3.1199}$$

we see that as N tends to infinity:

$$p=\frac{1}{2} \tag{15.3.1200}$$

and therefore:

$$\begin{gathered}p(1-p)=p-p^2=\frac{1}{2}-\frac{1}{4}=\frac{1}{4}\\ \sqrt{N}\left(p-\frac{1}{2}\right)=\sqrt{N}\left(\left(\frac{1}{2}+\frac{\mu}{2\sigma}\sqrt{\frac{T}{N}}\right)-\frac{1}{2}\right)=\frac{\mu}{2\sigma}\sqrt{T}=0\end{gathered} \tag{15.3.1201}$$

and here we see a big problem! The use of physical probability bring us to nothing we expected. We should be able to have an expression with μ, r_f and σ as we know it with the Black & Scholes model since these three parameters appear in the Φ of that latter.

So the idea now is the following: The risk free return r in a non-arbitrage assumption should be equivalent to the expected mean return of the asset. That means under this assumption we can write:

$$\boxed{r=\frac{puS_0+(1-p)dS_0}{S_0}=pu+(1-p)d} \tag{15.3.1202}$$

which implies after rearrangement:

$$p=\frac{r-d}{u-d} \tag{15.3.1203}$$

denoted p_r to make the difference with the "physical probability" introduced earlier before and named the "risk-neutral probability"!

With a continuous rate this is immediately written:

$$p=\frac{e^{r_f t}-d}{u-d} \tag{15.3.1204}$$

The reader may have notice that p is not necessary in $[0,1]$ unless t (i.e. Δt further below) is small enough!

Remark

Unlike investing in stocks, investors do not have to make an upfront payment to take a position in a Futures contract. In a risk-neutral sense, the expected growth rate from holding a Futures contract is zero. That is in the above relation you just have to put $r_f=0$.

An equivalent way to introduce this probability is just to write that in a non-arbitrage universe, the risk neutral expected value of S equals to the binomial expected value of S:

$$S_0e^{r_f\Delta t}=pS_u+(1-p)S_d \tag{15.3.1205}$$

Written in the way of a conditional expectation, we have[29]:

$$\text{E}(S_{t+\Delta t}|S_t)=S_t(pu+(1-p)d)=S_te^{r_f\Delta t} \tag{15.3.1206}$$

---

[29] From which we deduce on the way the conditional variance: $\text{V}\left(S_{t+\Delta t}|S_t\right)=\text{E}\left(S^2_{t+\Delta t}|S_t\right)-\left(\text{E}\left(S_{t+\Delta t}|S_t\right)\right)=p\left(S_tu\right)^2+(1-p)\left(S_td\right)^2-S_t^2\left(pu+(1-p)\,d\right)^2$

Solving for p yields immediately:

$$p=p_r=\frac{e^{r_f\Delta t}-d}{u-d} \tag{15.3.1207}$$

So finally in the CRR universe:

$$\boxed{u=\frac{1}{d}=e^{\sigma\sqrt{T/N}} \qquad p_r=\frac{e^{r_fT/N}-d}{u-d}} \tag{15.3.1208}$$

CRR recognize that the only condition required to prevent arbitrage is the equivalent of this set of relations!

So this done let us come back to:

$$U_2=\Phi\left(\frac{\ln(S_0/K)}{2\sigma\sqrt{T}\sqrt{p(1-p)}}+\frac{\sqrt{N}\left(p-\dfrac{1}{2}\right)}{\sqrt{p(1-p)}}\right) \tag{15.3.1209}$$

As:

$$p=p_r=\frac{e^{r_fT/N}-d}{u-d}=\frac{e^{r_fT/N}-e^{-\sigma\sqrt{T/N}}}{e^{\sigma\sqrt{TN/}}-e^{-\sigma\sqrt{T/N}}} \tag{15.3.1210}$$

By expanding the exponential functions in a Maclaurin series (see section Sequences and Series page 1703) to the first order:

$$e^x\cong 1+x \tag{15.3.1211}$$

we therefore have:

$$p\cong\frac{\left(1+r_f\dfrac{T}{N}\right)-\left(1-\sigma\sqrt{\dfrac{T}{N}}\right)}{\left(1+\sigma\sqrt{\dfrac{T}{N}}\right)-\left(1-\sigma\sqrt{\dfrac{T}{N}}\right)}=\frac{r_f\dfrac{T}{N}+\sigma\sqrt{\dfrac{T}{N}}}{2\sigma\sqrt{\dfrac{T}{N}}}=\frac{\sigma+r_f\sqrt{\dfrac{T}{N}}}{2\sigma} \tag{15.3.1212}$$

Therefore:

$$\begin{aligned}p(1-p)&\cong\left(\frac{\sigma+r_f\sqrt{\dfrac{T}{N}}}{2\sigma}\right)\left(1-\left(\frac{\sigma+r_f\sqrt{\dfrac{T}{N}}}{2\sigma}\right)\right)=\left(\frac{\sigma+r_f\sqrt{\dfrac{T}{N}}}{2\sigma}\right)\left(\frac{\sigma-r_f\sqrt{\dfrac{T}{N}}}{2\sigma}\right)\\&=\frac{\sigma^2-r_f^2\dfrac{T}{N}}{4\sigma^2}\end{aligned} \tag{15.3.1213}$$

As N tends to infinity:

$$p(1-p)\cong\frac{1}{4}\Rightarrow\sqrt{p(1-p)}=\frac{1}{2} \tag{15.3.1214}$$

And second order Taylor development would lead exactly to the same asymptotic value!

For the remaining part to fall back on the Black & Scholes model we need second order Maclaurin development. This is quite boring algebra so let us do it with Maple™ 4.00b:

```
 >p:=(taylor(exp(x),x=0,3)-taylor(exp(-y),y=0,3))/(taylor(exp(y),y=0,3)
-taylor(exp(-y),y=0,3));
>x:=r*T/N;y:=-sigma*sqrt(T/N);
>limit(sqrt(N)*(p-1/2),N=infinity);
```

and this gives:

$$\sqrt{N}\left(p-\frac{1}{2}\right)\cong\frac{(r_f-\sigma^2/2)\sqrt{T}}{2\sigma} \qquad (15.3.1215)$$

Therefore:

$$\begin{aligned}U_2&\cong\Phi\left(\frac{\ln(S_0/K)}{2\sigma\sqrt{T}\sqrt{p(1-p)}}+\frac{\sqrt{N}\left(p-\frac{1}{2}\right)}{\sqrt{p(1-p)}}\right)=\Phi\left(\frac{\ln(S_0/K)}{2\sigma\sqrt{T}\frac{1}{2}}+\frac{\frac{(r_f-\sigma^2/2)\sqrt{T}}{2\sigma}}{\frac{1}{2}}\right)\\&=\Phi\left(\frac{\ln(S_0/K)}{\sigma\sqrt{T}}+\frac{(r_f-\sigma^2/2)\sqrt{T}}{\sigma}\right)=\Phi\left(\frac{\ln(S_0/K)+(r_f-\sigma^2/2)T}{\sigma\sqrt{T}}\right)\end{aligned} \qquad (15.3.1216)$$

Ok this is finish about U_2. We now move on to evaluate U_1 given for recall by:

$$U_1=\sum_{i>\alpha}\binom{N}{i}p^i(1-p)^{N-i}u^i(1-u)^{N-i}=\sum_{i>\alpha}\binom{N}{i}(pu)^i((1-p)d)^{N-i} \qquad (15.3.1217)$$

We put:

$$p^*=\frac{pu}{pu+(1-p)d} \qquad (15.3.1218)$$

It then follows that:

$$1-p^*=\frac{(1-p)pd}{pu+(1-p)d} \qquad (15.3.1219)$$

and we can then write U_1 as following:

$$U_1=[pu+(1-p)d]^N\sum_{i>\alpha}\binom{N}{i}(p^*)^i(1-p^*)^{N-i} \qquad (15.3.1220)$$

Since:

$$pu+(1-p)d=e^{rT/N}=e^{r\Delta t} \qquad (15.3.1221)$$

we have:

$$U_1=e^{r_fT}\sum_{i>\alpha}\binom{N}{i}(p^*)^i(1-p^*)^{N-i} \qquad (15.3.1222)$$

This shows that U_1 also involves a binomial distribution where the probability on an up movement is p^* rather than p. Approximating the binomial distribution with a Normal distribution, we get, similarly to U_2:

$$U_1 = e^{r_f T}\mathcal{N}\left(\frac{Np^* - \alpha}{\sqrt{Np^*(1-p^*)}}\right) \tag{15.3.1223}$$

and substituting for α, gives as with U_2:

$$U_1 = e^{r_f T}\Phi\left(\frac{\ln(S_0/K)}{2\sigma\sqrt{T}\sqrt{p^*(1-p^*)}} + \frac{\sqrt{N}\left(p^* - \dfrac{1}{2}\right)}{\sqrt{p^*(1-p^*)}}\right) \tag{15.3.1224}$$

Substituting for u and d, and the risk-neutral probability in p^* we get:

$$\begin{aligned}
p^* &= \frac{pu}{pu+(1-p)d} = \frac{\left(\dfrac{e^{r_f T/N}-d}{u-d}\right)u}{\left(\dfrac{e^{r_f T/N}-d}{u-d}\right)u + \left(1-\left(\dfrac{e^{r_f T/N}-d}{u-d}\right)\right)d}\\
&= \frac{\left(\dfrac{e^{r_f T/N}-d}{u-d}\right)u}{\left(\dfrac{e^{r_f T/N}-d}{u-d}\right)u + \left(\dfrac{u-e^{r_f T/N}}{u-d}\right)d} = \frac{(e^{r_f T/Nt}-d)u}{(e^{r_f T/N}-d)u+(u-e^{r_f T/N})d}\\
&= \frac{(e^{r_f T/N}-e^{-\sigma\sqrt{T/N}})e^{\sigma\sqrt{T/N}}}{(e^{r_f T/N}-e^{-\sigma\sqrt{T/N}})e^{\sigma\sqrt{T/N}}+(e^{\sigma\sqrt{T/N}}-e^{r_f T/N})e^{-\sigma\sqrt{T/N}}}\\
&= \frac{e^{r_f T/N}-e^{-\sigma\sqrt{T/N}}}{e^{r_f T/N}e^{\sigma\sqrt{T/N}}-1+1-e^{r_f T/N}e^{-\sigma\sqrt{T/N}}}e^{\sigma\sqrt{T/N}}\\
&= \frac{e^{r_f T/N}-e^{-\sigma\sqrt{T/N}}}{e^{\sigma\sqrt{T/N}}-e^{-\sigma\sqrt{T/N}}}\frac{e^{\sigma\sqrt{T/N}}}{e^{r_f T/N}}
\end{aligned} \tag{15.3.1225}$$

By expanding the exponential functions in a Maclaurin series of order 2 we see that, as N tend to infinity that (we can detail the developments on readers requests):

$$p^*(1-p^*) \cong \frac{1}{4} \tag{15.3.1226}$$

and:

$$\sqrt{N}\left(p^* - \frac{1}{2}\right) \cong \frac{(r_f+\sigma^2/2)\sqrt{T}}{2\sigma} \tag{15.3.1227}$$

with the result that:

$$U_1 = e^{r_f T}\mathcal{N}\left(\frac{\ln(S_0/K)+(r_f+\sigma^2/2)T}{\sigma\sqrt{T}}\right) \tag{15.3.1228}$$

So finally:

$$C^{\text{CRR}} = e^{-r_f T}(S_0U_1 - KU_2) = S_0\mathcal{N}(d_1) - Ke^{r_f T}\mathcal{N}(d_2) \tag{15.3.1229}$$

where:

$$d_1 = \frac{\ln(S_0/K) + (r_f + \sigma^2/2)T}{\sigma\sqrt{T}} \tag{15.3.1230}$$

and:

$$d_2 = \frac{\ln(S_0/K) + (r_f - \sigma^2/2)T}{\sigma\sqrt{T}} = d_1 - \sigma\sqrt{T} \tag{15.3.1231}$$

So we see again now that for a risk-neutral option valuation, p and μ are unnecessary, exactly as provided by the Black & Scholes pricing model. The fact that the probability p doesn't appear in this formula means that even if investors have different subjective probabilities for the up and down movements, they do agree on the relation between Call, S and r. So the option's value doesn't depend on the investor's attitude toward risk.

Continuous-time models are admittedly more complicated that their discrete-time counterparts. Nonetheless there are a number of good reasons to deal with them. To begin with, on many markets with very frequent trading the assumption of continuous security tradings is closer to reality than assuming that markets are open only at fixed time points such as once a day. Moreover, in continuous-time models we can often get closed form solutions for derivatives prices which are not available in discrete models. Finally continuous-time modelling is the state-of-the art in the 120th and 121st century (holocene calendar) literature.

So for recall the assumptions (hypothesis) of that model are:

H1. We are in a non-arbitrage context with fixed probability p_r

H2. The price of the asset today is S_0 and known

H3. The assets do not pay dividends

H4. The risk-free rate r is positive and $d < r < u$

However Binomial options pricing model approach is widely used since it is able to handle a variety of conditions for which other models cannot easily be applied. This is largely because the binomial option pricing model is based on the description of an underlying instrument over a period of time rather than a single point. As a consequence, it is used to value American options that are exercisable at any time in a given interval as well as Bermudan options that are exercisable at specific instances of time. Being relatively simple, the model is readily implementable in computer software (including a spreadsheet).

Although computationally slower than the Black & Scholes formula, it is more accurate, particularly for longer-dated options on securities with dividend payments. For these reasons, various versions of the binomial model are widely used by practitioners in the options markets.

15.3.10.3.11 Bachelier option pricing model

We want to illustrate now Louis Bachelier's efforts to obtain applicable formulas for option pricing in pre-computer time. Bachelier's model yields good short-time approximations of prices and volatilities and some banks still use that model in the beginning of the 121st century (holocene calendar) especially in areas where negative interest rates applies...

Remark

On April 8 12020 (holocene calendar), the CME Group posted the note *CME Clearing Plan to Address the Potential of a Negative Underlying in Certain Energy Options Contracts*, saying that after a threshold on price, it would change its standard energy options model from one based on Geometric Brownian Motion and the Black–Scholes model to the Bachelier model! On April 20 2020, oil futures reached negative values for the first time in history, where Bachelier model took an important role in option pricing and risk management.

So let us first recall that we get during our study of Bachelier's speculation theory (see page 7689) that:

$$p=\mathcal{N}\left(0,\sigma\sqrt{t}\right)=\frac{1}{\sigma\sqrt{2\pi t}}e^{-\frac{x^2}{2\sigma^2 t}} \tag{15.3.1232}$$

Let us fix a strike price K, a horizon T and consider the European Call C, whose payoff at time T is modelled by the random variable:

$$C_T^{\text{B}}=(S_T-K)^+=\max(S_T-K,0) \tag{15.3.1233}$$

Applying Bachelier's fundamental principle (zero mean and standard deviation proportional to the square root of time) we get for the price of the option at time $t=0$ considering the point of view of Bachelier that if we write the price of underlying as $S_T=S_0+x$ then the Call price is therefore given by:

$$C_T^{\text{B}}=(S_T-K)^+=\max((S_0+x)-K,0) \tag{15.3.1234}$$

and as according to Bachelier assumptions we have the amount of profit that follow:

$$p=(S_0+x)-K=\mathcal{N}\left(0,\sigma\sqrt{t}\right)=\frac{1}{\sigma\sqrt{2\pi t}}e^{-\frac{x^2}{2\sigma^2 t}} \tag{15.3.1235}$$

and that therefore the integration bounds are $K-S_0$ (indeed, this is the limit above which

$S_0+x-K\geq 0$) to $+\infty$:

$$\begin{aligned}C^{\mathrm{B}}(t=0)=\mathrm{E}\left(\max(S_T-K,0)\right)&=\int\limits_{K-S_0}^{+\infty}(S_0+x-K)\frac{1}{\sigma\sqrt{2\pi T}}e^{-\frac{x^2}{2\sigma^2T}}\mathrm{d}x\\&=(S_0-K)\int\limits_{K-S_0}^{+\infty}\frac{1}{\sigma\sqrt{T}\sqrt{2\pi}}e^{-\frac{x^2}{2(\sigma\sqrt{T})^2}}\mathrm{d}x+\int\limits_{K-S_0}^{+\infty}\frac{x}{\sigma\sqrt{T}\sqrt{2\pi}}e^{-\frac{x^2}{2(\sigma\sqrt{T})^2}}\mathrm{d}x\\&=(S_0-K)\int\limits_{-\infty}^{S_0-K}\frac{1}{\sigma\sqrt{T}\sqrt{2\pi}}e^{-\frac{x^2}{2(\sigma\sqrt{T})^2}}\mathrm{d}x+\int\limits_{K-S_0}^{+\infty}\frac{x}{\sigma\sqrt{T}\sqrt{2\pi}}e^{-\frac{x^2}{2(\sigma\sqrt{T})^2}}\mathrm{d}x\\&=(S_0-K)\Phi\left(\frac{S_0-K}{\sigma\sqrt{T}}\right)+\int\limits_{K-S_0}^{+\infty}\frac{x}{\sigma\sqrt{T}\sqrt{2\pi}}e^{-\frac{x^2}{2(\sigma\sqrt{T})^2}}\mathrm{d}x\end{aligned}\tag{15.3.1236}$$

as for recall (see section Statistics page 692):

$$P(x\leq X)=F(x)=\Phi\left(\frac{x-\mu}{\sigma}\right)\tag{15.3.1237}$$

Let us do now the change of variable:

$$y=\frac{x}{\sqrt{2}\sigma\sqrt{T}}\tag{15.3.1238}$$

Therefore:

$$\int\limits_{K-S_0}^{+\infty}\frac{x}{\sigma\sqrt{T}\sqrt{2\pi}}e^{-\frac{x^2}{2(\sigma\sqrt{T})^2}}\mathrm{d}x=\int\limits_{\frac{K-S_0}{\sqrt{2}\sigma\sqrt{T}}}^{+\infty}\frac{y}{\sqrt{\pi}}e^{-y^2}\sqrt{2}\sigma\sqrt{T}\mathrm{d}y=\frac{\sqrt{2}\sigma\sqrt{T}}{\sqrt{\pi}}\int\limits_{\frac{K-S_0}{\sqrt{2}\sigma\sqrt{T}}}^{+\infty}ye^{-y^2}\mathrm{d}y\tag{15.3.1239}$$

Let us now put $u=-y^2$. It follows that $\mathrm{d}u=-2y\mathrm{d}y$. Therefore:

$$\begin{aligned}\frac{\sqrt{2}\sigma\sqrt{T}}{\sqrt{\pi}}\int\limits_{\frac{K-S_0}{\sqrt{2}\sigma\sqrt{T}}}^{+\infty}ye^{-y^2}\mathrm{d}y=\frac{\sqrt{2}\sigma\sqrt{T}}{\sqrt{\pi}}\int\limits_{\frac{K-S_0}{\sqrt{2}\sigma\sqrt{T}}}^{+\infty}-\frac{1}{2}\left(-2ye^{-y^2}\right)\mathrm{d}y&=\frac{\sqrt{2}\sigma\sqrt{T}}{\sqrt{\pi}}\int\limits_{-\frac{(K-S_0)^2}{2\sigma^2T}}^{-\infty}-\frac{1}{2}e^u\mathrm{d}u\\&=-\frac{\sqrt{2}\sigma\sqrt{T}}{2\sqrt{\pi}}e^u\Bigg|_{-\frac{(K-S_0)^2}{2\sigma^2T}}^{-\infty}=-\frac{\sqrt{2}\sigma\sqrt{T}}{2\sqrt{\pi}}\left(-e^{-\frac{(K-S_0)^2}{2\sigma^2T}}\right)\\&=\sigma\sqrt{T}\frac{1}{\sqrt{2\pi}}e^{-\frac{1}{2}\left(\frac{S_0-K}{\sigma\sqrt{T}}\right)^2}\end{aligned}\tag{15.3.1240}$$

Hence:

$$\begin{aligned}C^{\mathrm{B}}(t=0)&=(S_0-K)\Phi\left(\frac{S_0-K}{\sigma\sqrt{T}}\right)+\int\limits_{K-S_0}^{+\infty}\frac{x}{\sigma\sqrt{T}\sqrt{2\pi}}e^{-\frac{x^2}{2(\sigma\sqrt{T})^2}}\mathrm{d}x\\&=(S_0-K)\Phi\left(\frac{S_0-K}{\sigma\sqrt{T}}\right)+\sigma\sqrt{T}\frac{1}{\sqrt{2\pi}}e^{-\frac{1}{2}\left(\frac{S_0-K}{\sigma\sqrt{T}}\right)^2}\\&=(S_0-K)\Phi\left(\frac{S_0-K}{\sigma\sqrt{T}}\right)+\sigma\sqrt{T}\phi\left(\frac{S_0-K}{\sigma\sqrt{T}}\right)\end{aligned}\tag{15.3.1241}$$

where $\phi(x)$ denotes for recall the density of the standard normal distribution.

Finally:

$$\boxed{C^{\text{B}}(t=0)=(S_0-K)\Phi\left(\frac{S_0-K}{\sigma\sqrt{T}}\right)+\sigma\sqrt{T}\phi\left(\frac{S_0-K}{\sigma\sqrt{T}}\right)} \tag{15.3.1242}$$

Interestingly, Bachelier explicitly wrote down the formula:

$$C^{\text{B}}(t=0)=\int\limits_{K-S_0}^{+\infty}(S_0+x-K)\frac{1}{\sigma\sqrt{2\pi T}}e^{-\frac{x^2}{2\sigma^2 T}}\mathrm{d}x \tag{15.3.1243}$$

but did not bother to spell out formula:

$$C^{\text{B}}(t=0)=(S_0-K)\Phi\left(\frac{S_0-K}{\sigma\sqrt{T}}\right)+\sigma\sqrt{T}\phi\left(\frac{S_0-K}{\sigma\sqrt{T}}\right) \tag{15.3.1244}$$

The main reason seems to be that at his time option prices – at least in Paris – were quoted the other way around: while today the strike prices K is fixed and the option price fluctuates according to supply and demand, at Bachelier's times the option prices were fixed (at 10, 20 and 50 cents for a "rent", i.e., a perpetual bond with par value of 100.-) and therefore the strike prices K fluctuated. What Bachelier really needed was the inverse version of the above relation between the option price C_B^0 and the strike price K.

Caution! Remember for later that the σ of Bachelier is not the same as the σ_{BS} of Black & Scholes! σ for Black & Scholes is in percentage terms, when σ for Bachelier is in numeraire (currency) terms!!

15.3.10.3.12 Black Model (Future options pricing model)

The "Black model" (sometimes known as the Black-76 model) is a variant of the Black–Scholes option pricing model. Its primary applications are for pricing options on Future contracts, bond options, Interest rate cap and floors, and swaptions. It was first presented in a paper written by Fischer Black in 11976 (holocene calendar).

Black's model can be generalized into a class of models known as log-normal Forward models, also referred to as LIBOR market model.

The Black formula is therefore similar to the Black-Scholes formula for valuing stock options except that the spot price of the underlying is replaced by a discounted Futures price F.

Let us recall that in the case of a Call on an underlying type of share we have its price at any time that is given by:

$$C=\max(S_t-K,0) \tag{15.3.1245}$$

While for a Future (corresponding to a Forward for the conditions we had demonstrated earlier above) we have:

$$C_F=\max(F_t-K,0) \tag{15.3.1246}$$

But we have proved in our very brief introduction on Forwards and Futures that:

$$F_t=S_te^{(r-y)\tau}=S_te^{(r-y)(T-t)} \tag{15.3.1247}$$

So since we solved the Black & Scholes equation just before for S_t it is enough to use the previous relation which gives us:

$$S_t=F_te^{(r-y)(T-t)} \tag{15.3.1248}$$

Therefore, we have:

$$C_F^{\text{Bk}}=\max\left(F_te^{-(r-y)(T-t)}-K,0\right)=e^{-(r-y)(T-t)}\max\left(F_t-K^{(r-y)(T-t)},0\right) \tag{15.3.1249}$$

So a Call option on a future can be seen as a Call on a share underlying type that does not pay dividends but in quantity $e^{(r-y)(T-t)}$ and with strike instead $K^{-(r-y)(T-t)}$ instead of K.

If we write the Call function of an underlying that does not pay dividends in the following way (the order of the arguments is chosen to be the same as in MATLAB® and as most software do not manage other calculations than those based explicitly on $t=0$ and $y=0$):

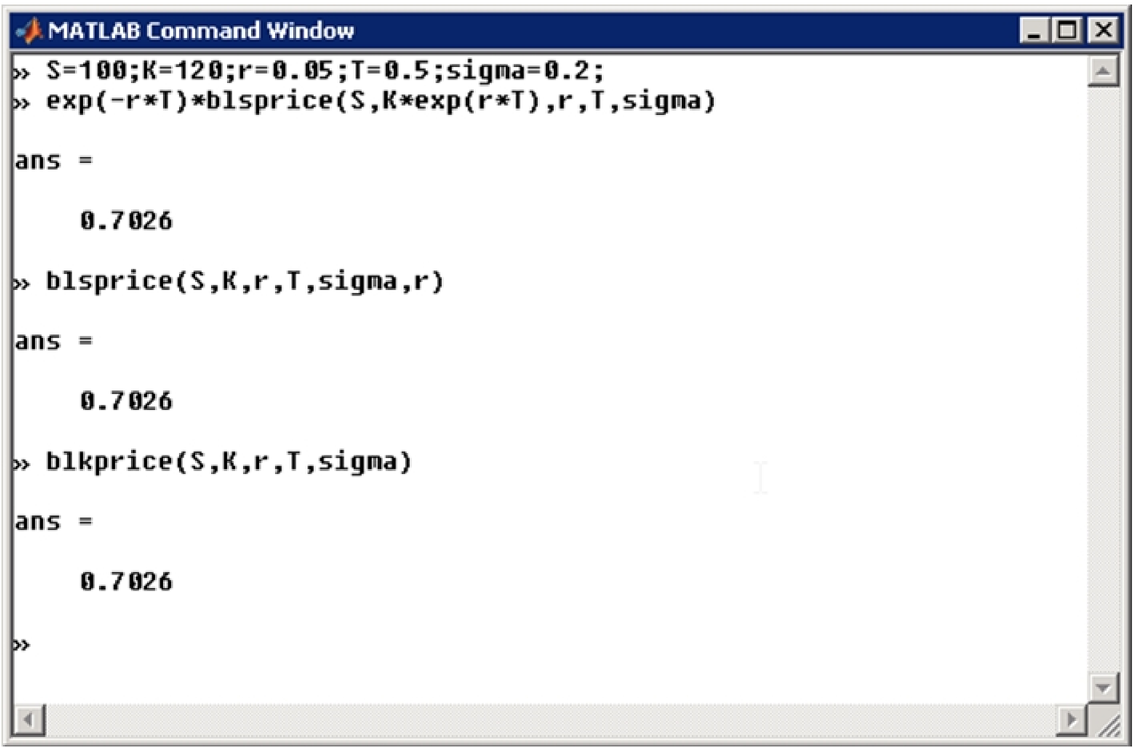
$$C(S_0,K,r,T,\sigma) \tag{15.3.1250}$$

So in view of the above we see immediately that a Call on an underlying of type Future type can be obtained from a Call on an underlying of Share type by writing:

$$C_F=e^{-rT}C(F_0,Ke^{rT},r,T,\sigma) \tag{15.3.1251}$$

This last implicit expression (and also the explicit version) constitutes what we name the "Black model" or also says "Black-76 model" for a Call (the idea for a Put is the same!).

This equivalence can easily be checked for example with MATLAB® (so you do not have to waste time with Microsoft® Excel®):



```
>> S=100;K=120;r=0.05;T=0.5;sigma=0.2;
>> exp(-r*T)*blsprice(S,K*exp(r*T),r,T,sigma)

ans =

    0.7026

>> blsprice(S,K,r,T,sigma,r)

ans =

    0.7026

>> blkprice(S,K,r,T,sigma)

ans =

    0.7026

>>
```

Figure 15.191: **Black model with MATLAB® 2016a**

Now let us recall the explicit Black & Scholes relation for a Call paying no dividends:

$$C^{\text{BS}}(S,t)=S\Phi\left(\frac{\ln\left(\frac{S}{K}\right)+\left(r+\frac{\sigma^2}{2}\right)(T-t)}{\sigma\sqrt{T-t}}\right)-Ke^{-r(T-t)}\Phi\left(\frac{\ln\left(\frac{S}{K}\right)+\left(r-\frac{\sigma^2}{2}\right)(T-t)}{\sigma\sqrt{T-t}}\right)$$

(15.3.1252)

Therefore the Black model is explicitly:

$$\boxed{C_F^{\text{Bk}}(S,t)=e^{-rT}\left[S\Phi\left(\frac{\ln\left(\frac{F}{Ke^{rT}}\right)+\left(r+\frac{\sigma^2}{2}\right)(T-t)}{\sigma\sqrt{T-t}}\right)-Ke^{rT}e^{-r(T-t)}\Phi\left(\frac{\ln\left(\frac{S}{Ke^{rT}}\right)+\left(r-\frac{\sigma^2}{2}\right)(T-t)}{\sigma\sqrt{T-t}}\right)\right]}$$

(15.3.1253)

15.3.10.3.13 VIX volatility index

The "Volatility IndeX" (VIX), also sometimes named "fear index" (....), plays a very important role in the financial derivatives pricing, trading, risk control strategy. The volatility index is a weighted average of implied volatilities for volatilities for several series of Puts and Calls options on a particular index (i.e. expected volatility). Obviously there wouldn't be a financial market without the financial market volatility. If there is a lack of risk management tools and the market volatility is too large, the investors may be worried about the risk and give up trading, then the market is less attractive.

VIX plays a more and more important role in the financial derivatives pricing, trading, risk control strategy. After the global stock market crash in 11987 (holocene calendar), it is to stabilize the stock market and protect the investors, that the New York Stock Exchange (NYSE) in 11990 (holocene calendar) introduced a circuit breaker mechanism (Circuit-breakers). When the stock price changes unusually, it occurs a temporary suspension of trading, and it is helpful to try to reduce the market volatility in order to restore the investor confidence on the stock market. However, due to the introduction of circuit breaker mechanism, there is many new insights for how to measure market volatility, and it is gradually producing a dynamic display of market volatility requirements. Therefore, not long after the New York Stock Exchange (NYSE) used Circuit-Breakers to solve the problem of excessive volatility in the market, the Chicago Board Options Exchange began to introduce the CBOE market volatility index[30] (VIX) in 11993 (holocene calendar), which is used to measure market volatility implied by at the money S&P 100 Index (OEX) option prices.

When the stock option transactions began in April 11973 (holocene calendar), Chicago Board Options Exchange (CBOE) has envisaged that the market volatility index can be constructed by the option price, which could be shown that the expectation of the future volatility in the option market. Since then there were gradually many various calculation methods proposed by some scholars, Whaley (11993 according to holocene calendar) proposed a calculation approach which is the preparation of market volatility index as a measure of future stock market price volatility. In the same year, Chicago Board Options Exchange (CBOE) started to research the compilation of the CBOE Volatility Index (VIX), which is based on the implied volatility of the S&P 100 Index options, and at the same time also calculate implied volatility of Call option and Put option in order to take into account the right of traders to buy or sell option under the preferences.

After ten years of development and improvement, the VIX index gradually was agreed by the stock market, CBOE calculated several other volatility indexes including, in 12001 (holocene calendar) NASDAQ 100 index as the underlying volatility index (NASDAQ Volatility Index, VXN), in 12003 (holocene calendar) the VIX index based on the S&P 500 Index, which is much closer to the actual stock market than the S&P 100 Index, CBOE DJIA volatility Index (VXD), CBOE Russell 2000 Volatility Index (RVX), in 12004 (holocene calendar) the first volatility futures (Volatility Index Futures) VIX Futures, and at the same year a second volatility commercialization futures, that is the variance futures (Variance Futures), subject to three month. the S&P 500 Index of realized Variance (Realized Variance). In 12006 (holocene calendar), the VIX Index options began to trade in the Chicago Board Options Exchange. In 12008 (holocene calendar), CBOE pioneered the used of the VIX methodology to estimate the expected volatility of some commodities and foreign currencies. There are many developments. For example, in India, VIX was launched in April, 12008 (holocene calendar) by National stock exchange (NSE). The VIX index of India is based on the Nifty 50 Index Option prices. The methodology of calculating the VIX index is same as that for CBOE VIX index. The current focus on the VIX is due to its inherent property of negative correlation with the underlying price index, and its usefulness for predicting the direction of the price index. Hong Kong got its own volatility index for financial products that allow investors to hedge against excessive market movements. Hang Seng Indexes Company, the company which owns and manages the benchmark indexes in Hong Kong including the Hang Seng index (HSI), launched the HSI Volatility index or "VHSI" on February 21. The index is modelled on the lines of the Chicago Board of Exchanges VIX index. VIX in that it measures the 30-calendar-day expected volatility of the Hang Seng index using prices of options traded on the index.

---

[30] The official white-paper can be found here `https://cdn.cboe.com/resources/vix/vixwhite.pdf`

In order to apply most financial models in practice, it is necessary to be able to use empirical data to measure the degree of variability of asset prices or market indexes. Suppose that S_t is the price of an asset or a market index at time t. The annualized realized annual volatility (see above page 7741) of this asset in a period $[t_1, t_2]$ based on $n+1$ daily observations $S_0, S_1, \ldots, S_{n-1}, S_n$ will be chosen according to the Bachelier temporal evolution of volatility model (page 7689):

$$\bar{\sigma} = \sqrt{\frac{252}{n-1}\sum_{i=1}^{n} r_i^2} \tag{15.3.1254}$$

where:

$$r_i = \ln\left(\frac{S_i}{S_{i-1}}\right), \qquad i = 1, 2, 3, \ldots, n-1, n. \tag{15.3.1255}$$

And 252 if for recall an annualization factor corresponding to the typical number of trading days in a year.

Similarly the historical volatility (see above page 7740)) is defined by a similar relation:

$$\tilde{\sigma} = \sqrt{\frac{252}{n-1}\sum_{i=1}^{n} (r_i - \bar{r})^2} \tag{15.3.1256}$$

where:

$$\bar{r} = \frac{1}{n}\sum_{i=1}^{n} r_i \tag{15.3.1257}$$

is the mean return.

If the returns are supposed to be drawn independently from the same probability distribution, then $\bar{r}$ is the sample mean and the historical volatility is simply the annualized sample standard deviation. The realized volatility is then the annualized sample second moment.

Note that:

$$\sum_{i=1}^{n} (r_i - \bar{r})^2 = \sum_{i=1}^{n} r_i^2 - n\bar{r}^2 \tag{15.3.1258}$$

and hence:

$$\tilde{\sigma}^2 = \bar{\sigma}^2 - \frac{252n\bar{r}}{n-1} \tag{15.3.1259}$$

As we already know, this simply means that the realized volatility is approximately equal to the historical volatility if the sample mean is very close to zero.

CBOE launched the first VIX index (VXO) in 11993 (holocene calendar), which is based on the option model which is proposed by Black, Scholes and Merton (see above page 7804). In this model, except the volatility, we also require other many parameters such as the current stock price, the option price, the strike price, duration, risk-free interest rate, time to expected payment of cash dividends and amount of expected payment of cash dividends. However, the S&P 100 options of CBOE are American options and are related to the cash dividends of the underlying stocks, so when CBOE calculated the VIX index, they used the implied option volatility of the binomial model proposed by Cox, Ross and Rubinstein (see above page 7833).

To estimate the volatility from option data (all the text that follows is completely inspired from [582]) we assume first that the stock price satisfies the following stochastic differential equation:

$$\frac{\mathrm{d}S}{S} = (r-q)\mathrm{d}t + \sigma \mathrm{d}z \tag{15.3.1260}$$

Where r, q, σ are constant denoting the risk free rate, the continuous divided yield and yield volatility respectively, and z is a Wiener process with respect to a risk-neutral probability measure.

At the same time, from the Ito's lemma (see above page 7779):

$$\mathrm{d}\ln(S) = \left(r - q - \frac{\sigma^2}{2}\right)\mathrm{d}t + \sigma \mathrm{d}z \tag{15.3.1261}$$

Then from the both relations above we can obtain:

$$\frac{\mathrm{d}S}{S} - \mathrm{d}\ln(S) = (r-q)\mathrm{d}t + \sigma \cdot \mathrm{d}z - \left(r - q - \frac{\sigma^2}{2}\right)\mathrm{d}t - \sigma \mathrm{d}z = \frac{\sigma^2}{2}\mathrm{d}t \tag{15.3.1262}$$

Therefore:

$$\frac{\sigma^2}{2}\mathrm{d}t = \frac{\mathrm{d}S}{S} - \mathrm{d}\ln(S) \tag{15.3.1263}$$

By integrating from time 0 to time T, we get:

$$\int_0^T \frac{\sigma^2}{2}\mathrm{d}t = \int_0^T \frac{\mathrm{d}S}{S} - \int_0^T \mathrm{d}\ln(S) \tag{15.3.1264}$$

This gives:

$$\frac{1}{2}\sigma^2 T = \int_0^T \frac{\mathrm{d}S}{S} - (\ln(S_T) - \ln(S_0)) = \int_0^T \frac{\mathrm{d}S}{S} - \ln\left(\frac{S_T}{S_0}\right) \tag{15.3.1265}$$

Because the variance is the square of the volatility:

$$\bar{\mathrm{V}}=\sigma^2 \tag{15.3.1266}$$

Then we write obviously:

$$\frac{1}{2}\bar{\mathrm{V}}T=\int\limits_0^T\frac{\mathrm{d}S}{S}-\ln\left(\frac{S_T}{S_0}\right) \tag{15.3.1267}$$

Therefore:

$$\bar{\mathrm{V}}=\frac{2}{T}\int\limits_0^T\frac{\mathrm{d}S}{S}-\frac{2}{T}\ln\left(\frac{S_T}{S_0}\right) \tag{15.3.1268}$$

Because we can take the expectation of:

$$\frac{\mathrm{d}S}{S}=(r-q)\mathrm{d}t+\sigma\mathrm{d}z \tag{15.3.1269}$$

We get that:

$$\mathrm{E}(\bar{\mathrm{V}})=\frac{2}{T}\mathrm{E}\left(\int\limits_0^T\frac{\mathrm{d}S}{S}\right)-\frac{2}{T}\mathrm{E}\left(\ln\left(\frac{S_T}{S_0}\right)\right) \tag{15.3.1270}$$

Has the first term that can therefore be rewritten as:

$$\mathrm{E}\left(\int\limits_0^T\frac{\mathrm{d}S}{S}\right)=\mathrm{E}\left(\int\limits_0^T(r-q)\mathrm{d}t\right)+\mathrm{E}\left(\int\limits_0^T\sigma\mathrm{d}z\right)=(r-q)T \tag{15.3.1271}$$

Hence:

$$\mathrm{E}(\bar{\mathrm{V}})=\frac{2}{T}(r-q)T-\frac{2}{T}\mathrm{E}\left(\ln\left(\frac{S_T}{S_0}\right)\right) \tag{15.3.1272}$$

We know that under Black-Scholes assumptions that:

$$S_T=S_0\exp(X) \tag{15.3.1273}$$

where the random variables:

$$X=\left(r-q-\frac{\sigma^2}{2}\right)T+\sigma z(T) \tag{15.3.1274}$$

is Normally distributed with:

$$\mathrm{E}(X)=\left(r-q-\frac{\sigma^2}{2}\right)T\qquad\text{and}\qquad\hat{\mathrm{V}}(X)=\sigma^2T \tag{15.3.1275}$$

Then as we already know:

$$\mathrm{E}(S_T)=S_0\exp\left[\mathrm{E}(X)+\frac{\hat{\mathrm{V}}(X)}{2}\right]=S_0e^{(r-q)T} \tag{15.3.1276}$$

And if we define the notation (forward price of the asset for a contract maturing at time T):

$$F_0 = \mathrm{E}(S_T) \tag{15.3.1277}$$

We get therefore:

$$\mathrm{E}(\bar{\mathrm{V}}) = \frac{2}{T}(r-q)T - \frac{2}{T}\mathrm{E}\left(\ln\left(\frac{S_T}{S_0}\right)\right) = \frac{2}{T}\ln\left(\frac{F_0}{S_0}\right) - \frac{2}{T}\mathrm{E}\left(\ln\left(\frac{S_T}{S_0}\right)\right) \tag{15.3.1278}$$

Now before continuing. To express the second term above, we will use a clever trick (i.e. result) that will need a few pages. After we will come back to the above relation.

Let us consider:

$$\int\limits_0^{S^*} \frac{1}{K^2}\max(K-S_T,0)\mathrm{d}K \tag{15.3.1279}$$

where S^* is some value of S.

We consider obviously two cases:

- If $S^* < S_T$ then:

$$\int\limits_0^{S^*} \frac{1}{K^2}\max(K-S_T,0)\mathrm{d}K = 0 \tag{15.3.1280}$$

- If $S^* > S_T$ then:

$$\begin{aligned}\int\limits_0^{S^*} \frac{1}{K^2}\max(K-S_T,0)\mathrm{d}K &= \int\limits_{S_T}^{S^*} \frac{1}{K^2}(K-S_T)\mathrm{d}K \\ &= \left(\ln(K) + \frac{S_T}{K}\right)\Bigg|_{S_T}^{S^*} \\ &= \ln\left(\frac{S^*}{S_T}\right) + \frac{S_T}{S^*} - 1\end{aligned} \tag{15.3.1281}$$

Secondly, we consider next (still to prepare the future trick!):

$$\int\limits_{S^*}^{+\infty} \frac{1}{K^2}\max(S_T-K,0)\mathrm{d}K \tag{15.3.1282}$$

Always considering the same two cases:

- If $S^* > S_T$ then:

$$\int\limits_{S^*}^{+\infty} \frac{1}{K^2}\max(S_T-K,0)\mathrm{d}K = 0 \tag{15.3.1283}$$

- If $S^* < S_T$ then:

$$\begin{aligned}\int\limits_{S^*}^{+\infty}\frac{1}{K^2}\max(S_T-K,0)\mathrm{d}K&=\int\limits_{S^*}^{S_T}\frac{1}{K^2}(S_T-K)\mathrm{d}K\\&=\left(-\frac{S_T}{K}-\ln(K)\right)\Bigg|_{S^*}^{S_T}\\&=-1-\ln(S_T)+\frac{S_T}{S^*}+\ln(S^*)\\&=\ln\left(\frac{S^*}{S_T}\right)+\frac{S_T}{S^*}-1\end{aligned}\tag{15.3.1284}$$

Then we can get that:

$$\int\limits_{0}^{S^*}\frac{1}{K^2}\max(K-S_T,0)\mathrm{d}K+\int\limits_{S^*}^{+\infty}\frac{1}{K^2}\max(S_T-K,0)\mathrm{d}K=\ln\left(\frac{S^*}{S_T}\right)+\frac{S_T}{S^*}-1\tag{15.3.1285}$$

For all value of S^*, so that after rearranging:

$$\ln\left(\frac{S^*}{S_T}\right)=\frac{S_T}{S^*}-1-\int\limits_{0}^{S^*}\frac{1}{K^2}\max(K-S_T,0)\mathrm{d}K-\int\limits_{S^*}^{+\infty}\frac{1}{K^2}\max(S_T-K,0)\mathrm{d}K\tag{15.3.1286}$$

We can take the expectations with respect to the risk-neutral probability measure of the above relation:

$$\mathrm{E}\left(\ln\left(\frac{S^*}{S_T}\right)\right)=\mathrm{E}\left(\frac{S_T}{S^*}-1\right)-\mathrm{E}\left(\int\limits_{0}^{S^*}\frac{1}{K^2}\max(K-S_T,0)\mathrm{d}K\right)-\mathrm{E}\left(\int\limits_{S^*}^{+\infty}\frac{1}{K^2}\max(S_T-K,0)\mathrm{d}K\right)\tag{15.3.1287}$$

We know that under Black-Scholes framework that:

$$\begin{aligned}\mathrm{E}[\max(K-S_T,0)]&=e^{r_fT}P(K)\\\mathrm{E}[\max(S_T-K,0)]&=e^{r_fT}C(K)\end{aligned}\tag{15.3.1288}$$

Where $C(K)$ and $P(K)$ are the prices of the Call and Put option with the strike price K, T is the maturity time and r_f is the risk-free interest rate for a maturity of T.

And remember that we have put previously:

$$F_0=\mathrm{E}(S_T)\tag{15.3.1289}$$

Then we get:

$$\mathrm{E}\left(\ln\left(\frac{S^*}{S_T}\right)\right)=\frac{F_0}{S^*}-1-\int\limits_{0}^{S^*}\frac{1}{K^2}e^{r_fT}P(K)\mathrm{d}K-\int\limits_{S^*}^{+\infty}\frac{1}{K^2}e^{r_fT}C(K)\mathrm{d}K\tag{15.3.1290}$$

According to:

$$\begin{aligned}\ln\left(\frac{S_T}{S_0}\right)&=\ln(S_T)-\ln(S_0)\\&=\ln(S_T)-\ln(S^*)+\ln(S^*)-\ln(S_0)\\&=\ln\left(\frac{S_T}{S^*}\right)+\ln\left(\frac{S^*}{S_0}\right)\end{aligned}\tag{15.3.1291}$$

Taking the expectation of the above relation we get:

$$\begin{aligned}\mathrm{E}\left(\ln\left(\frac{S_T}{S_0}\right)\right)&=\mathrm{E}\left(\ln\left(\frac{S_T}{S^*}\right)\right)+\mathrm{E}\left(\ln\left(\frac{S^*}{S_0}\right)\right)\\&=\ln\left(\frac{S^*}{S_0}\right)+\mathrm{E}\left(\ln\left(\frac{S_T}{S^*}\right)\right)\end{aligned}\tag{15.3.1292}$$

Now we combine the following three relations that we have established earlier above (in order of appearance):

$$\begin{gathered}\mathrm{E}(\bar{\mathrm{V}})=\frac{2}{T}\ln\left(\frac{F_0}{S_0}\right)-\frac{2}{T}\mathrm{E}\left(\ln\left(\frac{S_T}{S_0}\right)\right)\\ \mathrm{E}\left(\ln\left(\frac{S^*}{S_T}\right)\right)=\frac{F_0}{S^*}-1-\int\limits_0^{S^*}\frac{1}{K^2}e^{r_fT}P(K)\mathrm{d}K-\int\limits_{S^*}^{+\infty}\frac{1}{K^2}e^{r_fT}C(K)\mathrm{d}K\\ \mathrm{E}\left(\ln\left(\frac{S_T}{S_0}\right)\right)=\ln\left(\frac{S^*}{S_0}\right)+\mathrm{E}\left(\ln\left(\frac{S_T}{S^*}\right)\right)\end{gathered}\tag{15.3.1293}$$

To get:

$$\begin{aligned}\mathrm{E}(\bar{\mathrm{V}})&=\frac{2}{T}\ln\left(\frac{F_0}{S_0}\right)-\frac{2}{T}\mathrm{E}\left(\ln\left(\frac{S_T}{S_0}\right)\right)\\&=\frac{2}{T}\ln\left(\frac{F_0}{S_0}\right)-\frac{2}{T}\left[\ln\left(\frac{S^*}{S_0}\right)+\mathrm{E}\left(\ln\left(\frac{S_T}{S^*}\right)\right)\right]\\&=\frac{2}{T}\ln\left(\frac{F_0}{S_0}\right)-\frac{2}{T}\ln\left(\frac{S^*}{S_0}\right)-\frac{2}{T}\mathrm{E}\left(\ln\left(\frac{S_T}{S^*}\right)\right)\\&=\frac{2}{T}\ln\left(\frac{F_0}{S_0}\right)-\frac{2}{T}\ln\left(\frac{S^*}{S_0}\right)-\frac{2}{T}\left[\frac{F_0}{S^*}-1-\int\limits_0^{S^*}\frac{1}{K^2}e^{r_fT}P(K)\mathrm{d}K-\int\limits_{S^*}^{+\infty}\frac{1}{K^2}e^{r_fT}C(K)\mathrm{d}K\right]\\&=\frac{2}{T}(\ln(F_0)-\ln(S_0)-\ln(S^*)+\ln(S_0))-\frac{2}{T}\left[\frac{F_0}{S^*}-1-\int\limits_0^{S^*}\frac{1}{K^2}e^{r_fT}P(K)\mathrm{d}K-\int\limits_{S^*}^{+\infty}\frac{1}{K^2}e^{r_fT}C(K)\mathrm{d}K\right]\\&=\frac{2}{T}(\ln(F_0)-\ln(S^*))-\frac{2}{T}\left[\frac{F_0}{S^*}-1-\int\limits_0^{S^*}\frac{1}{K^2}e^{r_fT}P(K)\mathrm{d}K-\int\limits_{S^*}^{+\infty}\frac{1}{K^2}e^{r_fT}C(K)\mathrm{d}K\right]\\&=\frac{2}{T}\ln\left(\frac{F_0}{S^*}\right)-\frac{2}{T}\left[\frac{F_0}{S^*}-1\right]+\frac{2}{T}\left[\int\limits_0^{S^*}\frac{1}{K^2}e^{r_fT}P(K)\mathrm{d}K+\int\limits_{S^*}^{+\infty}\frac{1}{K^2}e^{r_fT}C(K)\mathrm{d}K\right]\end{aligned}\tag{15.3.1294}$$

In conclusion this gives us the expected value of the average variance from time 0 to time T

(under Black-Scholes framework!):

$$\mathrm{E}(\bar{\mathrm{V}})=\frac{2}{T}\ln\left(\frac{F_0}{S^*}\right)-\frac{2}{T}\left[\frac{F_0}{S^*}-1\right]+\frac{2}{T}\left[\int\limits_0^{S^*}\frac{1}{K^2}e^{r_fT}P(K)\mathrm{d}K+\int\limits_{S^*}^{+\infty}\frac{1}{K^2}e^{r_fT}C(K)\mathrm{d}K\right] \tag{15.3.1295}$$

where for recall F_0 is the forward price of the options for a contract maturing time T, $C(K)$ is the prices of the Call option with the strike price K and time to maturity T, $P(K)$ is the prices of the put option with the strike price K and time to maturity T, r_f is the risk-free interest rate for a maturity of T, and S^* is some value of S.

We can assume that the price of the options with strike prices $K_i\,(1\leq i\leq n)$ are known, and $K_1<K_2<K_3<\ldots<K_{n-1}<K_n$, and we set S^* equal to the first strike price below F_0, then we approximate the integrals as:

$$\int\limits_0^{S^*}\frac{1}{K^2}e^{r_fT}P(K)\mathrm{d}K+\int\limits_{S^*}^{+\infty}\frac{1}{K^2}e^{r_fT}C(K)\mathrm{d}K\cong\sum_{i=1}^{n}\frac{\Delta K_i}{K_i^2}e^{r_fT}Q(K_i) \tag{15.3.1296}$$

where:

$$\Delta K_i=\frac{K_{i+1}-K_{i-1}}{2}\qquad\text{with}\qquad 2\leq i\leq n-1 \tag{15.3.1297}$$

But in particular for the lowest strike price (of the Put options) K_1 we take:

$$\Delta K_1=K_2-K_1 \tag{15.3.1298}$$

and for the highest strike price (of the Call options) K_n we take:

$$\Delta K_n=K_n-K_{n-1} \tag{15.3.1299}$$

We also consider in this discretization that:

- If $K_i<S^*$, the function $Q(K_i)$ is the price of a Put option with strike price K_i.
- If $K_i>S^*$, the function $Q(K_i)$ is the price of a Put option with strike price K_i.
- If $K_i=S^*$, the function $Q(K_i)$ is the average of the price of a Call and a Put option with strike price K_i.

If we put:

$$\int\limits_0^{S^*}\frac{1}{K^2}e^{r_fT}P(K)\mathrm{d}K+\int\limits_{S^*}^{+\infty}\frac{1}{K^2}e^{r_fT}C(K)\mathrm{d}K\cong\sum_{i=1}^{n}\frac{\Delta K_i}{K_i^2}e^{r_fT}Q(K_i) \tag{15.3.1300}$$

into:

$$\mathrm{E}(\bar{\mathrm{V}})=\frac{2}{T}\ln\left(\frac{F_0}{S^*}\right)-\frac{2}{T}\left[\frac{F_0}{S^*}-1\right]+\frac{2}{T}\left[\int\limits_0^{S^*}\frac{1}{K^2}e^{r_fT}P(K)\mathrm{d}K+\int\limits_{S^*}^{+\infty}\frac{1}{K^2}e^{r_fT}C(K)\mathrm{d}K\right] \tag{15.3.1301}$$

we get:

$$\mathrm{E}(\bar{\mathrm{V}}) \cong \frac{2}{T}\ln\left(\frac{F_0}{S^*}\right) - \frac{2}{T}\left[\frac{F_0}{S^*}-1\right] + \frac{2}{T}\left[\sum_{i=1}^{n}\frac{\Delta K_i}{K_i^2}e^{r_f T}Q(K_i)\right] \tag{15.3.1302}$$

or:

$$\mathrm{E}(\bar{\mathrm{V}})T \cong 2\ln\left(\frac{F_0}{S^*}\right) - 2\left[\frac{F_0}{S^*}-1\right] + 2\left[\sum_{i=1}^{n}\frac{\Delta K_i}{K_i^2}e^{r_f T}Q(K_i)\right] \tag{15.3.1303}$$

According to $\ln(N)$ and its following Maclaurin polynomial:

$$\ln(N) = (N-1) - \frac{1}{2}(N-1)^2 + \mathcal{O}\left(\left(\frac{F_0}{S^*}-1\right)^2\right) \tag{15.3.1304}$$

We can get:

$$\ln\left(\frac{F_0}{S^*}\right) = \left(\frac{F_0}{S^*}-1\right) - \frac{1}{2}\left(\frac{F_0}{S^*}-1\right)^2 + \mathcal{O}\left(\left(\frac{F_0}{S^*}-1\right)^2\right) \tag{15.3.1305}$$

So if we choose to approximated the function as follow:

$$\ln\left(\frac{F_0}{S^*}\right) \cong \left(\frac{F_0}{S^*}-1\right) - \frac{1}{2}\left(\frac{F_0}{S^*}-1\right)^2 \tag{15.3.1306}$$

after rearranging we get:

$$\ln\left(\frac{F_0}{S^*}\right) - \left(\frac{F_0}{S^*}-1\right) \cong -\frac{1}{2}\left(\frac{F_0}{S^*}-1\right)^2 \tag{15.3.1307}$$

We can use that later relation and put it in:

$$\mathrm{E}(\bar{\mathrm{V}})T \cong 2\ln\left(\frac{F_0}{S^*}\right) - 2\left[\frac{F_0}{S^*}-1\right] + 2\left[\sum_{i=1}^{n}\frac{\Delta K_i}{K_i^2}e^{r_f T}Q(K_i)\right] \tag{15.3.1308}$$

to get:

$$\mathrm{E}(\bar{\mathrm{V}})T \cong -\left(\frac{F_0}{S^*}-1\right)^2 + 2\left[\sum_{i=1}^{n}\frac{\Delta K_i}{K_i^2}e^{rT}Q(K_i)\right] \tag{15.3.1309}$$

That can be written obviously as:

$$\sigma^2 T = -\left[\frac{F}{K}-1\right]^2 + 2\sum_i \frac{\Delta K_i}{K_i^2}e^{rT}Q(K_i) \tag{15.3.1310}$$

So finally:

$$\sigma_{\text{VIX}}^2 = -\frac{1}{T}\left[\frac{F}{K}-1\right]^2 + \frac{2}{T}\sum_i \frac{\Delta K_i}{K_i^2}e^{rT}Q(K_i) \tag{15.3.1311}$$

That lead us to the definition of the VIX for one option:

$$\boxed{\text{VIX}=100\sigma_{\text{VIX}}=100\sqrt{-\frac{1}{T}\left[\frac{F}{K}-1\right]^2+\frac{2}{T}\sum_i\frac{\Delta K_i}{K_i^2}e^{rT}Q(K_i)}} \tag{15.3.1312}$$

For a number j of options have same lifetime T, we have:

$$\text{VIX}=100\sigma_{\text{VIX}}=100\sqrt{\sum_j\sigma_{\text{VIX},j}^2}=100\sqrt{\sum_j\left(-\frac{1}{T}\left[\frac{F_j}{K_j}-1\right]^2+\frac{2}{T}\sum_i\frac{\Delta K_{i,j}}{K_{i,j}^2}e^{r_jT}Q(K_{i,j})\right)^2} \tag{15.3.1313}$$

And in the case the j options to have the same lifetime T, we have to weight them:

$$\text{VIX}=100\sigma_{\text{VIX}}=100\sqrt{\sum_j\omega_j\sigma_{\text{VIX},j}^2}=100\sqrt{\sum_j\omega_j\left(-\frac{1}{T_j}\left[\frac{F_j}{K_j}-1\right]^2+\frac{2}{T_j}\sum_i\frac{\Delta K_{i,j}}{K_{i,j}^2}e^{r_jT_j}Q(K_{i,j})\right)^2} \tag{15.3.1314}$$

The calculation are heavy and boring to do at hand. Hopefully, some softwares like `R` (see our companion book on the software) or the Bloomberg Terminal, automatically implement such calculations:

Otherwise for a detailed calculation by hand, including the subtleties of the official VIX documentation with multiple volatilities and hence a weight, the reader can refer again to the source of the above text (see [582]).

Investors use volatility derivatives to diversify and hedge their risk in equity and credit portfolios. Since long-term investors in equity funds are exposed to downside risk, volatility can be used as a hedge for the tail risk and replacement for the Put options. In the United States, as we have just seen it, the Chicago Board Options Exchange (CBOE) Volatility Index (VIX) measures the short-term volatility implied by S&P 500 stock index option prices. Many people around the world use the VIX to measure the stock market volatility over the next 30-day period. In Europe, the "EURO STOXX 50 Volatility[31]" (VSTOXX) market index is based on the market prices of a basket of Euro STOXX 50 Index Options (OESX) and measures the implied market volatility over the next 30 days on the EURO STOXX 50 Index. For benchmark strategies utilizing the EURO STOXX 50 Index, the nature of its negative correlation with the VSTOXX presents a viable way of avoiding benchmark-rebalancing costs. The statistical nature of volatility allows traders to perform mean-reverting strategies, dispersion trading, and volatility spread trading, among others.

15.3.10.3.14 Value at Risk

The risk measurements have evolved since Markowitz advanced his famous theory of portfolio diversification in the late 11950s (holocene calendar), a theory that had to revolutionize modern portfolio management. The risk of a portfolio was then related to the matrix of covariances-variances, as we have demonstrated theoretically and by the examples above.

In the 11960s (holocene calendar), Sharpe proposed the unifactory model of valuation of financial assets where the beta is the primary explanatory factor of a portfolio's risk via the beta matrix.

In the early 11990s (holocene calendar), a new measure of risk was introduced (it seems that JP Morgan is at the origin of that one). Indeed, the limits of traditional risk measures were increasingly recognized. Quantitative indicators of the risk of value loss of assets had then to be found. To do this, indicator had to be found that were more closely related to the overall cash flow distribution of a portfolio. It is in this context that a nominal risk measure has been proposed: the "Value at Risk (VaR)" (denoted sometimes "V@R" in project management). The idea is basically to say that we have $x\%$ cumulative probability of not losing more than a given amount y in cash in the next N periods of time (the period can be: days, months, etc.).

This new measure was first used to quantify the market risk to which portfolios are subject. Indeed, the Basel Accords recommended banks since 11997 (holocene calendar) to hold a regulatory capital amount to preserve their stability against standard market risks. However, this capital has since been calculated from the VaR and has become increasingly popular for assessing the risk of institutional or individual portfolios (and not only for this!). However, there is no single measure of VaR. Indeed, it is based on the concept of volatility, which is essentially latent. This is why banks need to use several VaR models in order to define the range of their possible losses. These calculations are all the more complex since the distribution of the yields of the securities measured at high frequency is significantly different from the Normal distribution (therefore for long intervals of time we approach rather often a Normal distribution).

Definition (#15.3.698): The "Value at Risk" (VaR) is the theoretical maximum loss that a portfolio manager (whose value is necessarily implicitly variable) can experience and for a certain period of time with a given cumulative probability (the use of VaR is not limited to financial instruments, it is used in many other areas of risk management in general).

Remark

The VaR is not really relevant if it is not presented with other risk indicators such as the Sharpe ratio, the Treynor ratio or the Greek coefficients (such as the beta). Finally, let us say that in practice the VaR is sometimes indicated in $\%$ of the total value of a portfolio.

15.3.10.3.14.1 Relative Value at Risk

In the classical model of the "relative VaR" (also sometimes named "parametric VaR"), we will assume that the statistical distribution of the results of a portfolio obeys at every moment a Normal distribution... that we will write for what will follow:

$$X = \mathcal{N}(\mu, \sigma^2) \tag{15.3.1315}$$

The next idea is that the random variable X can therefore be rewritten with a random centered reduced variable Normal (see section Statistics page 725) by putting:

$$\varepsilon = \mathcal{N}(0, 1) \tag{15.3.1316}$$

such that (use of the basic properties of the Normal distribution):

$$\boxed{X = \mu + \varepsilon\sigma} \tag{15.3.1317}$$

and this notation is therefore used in many other fields besides finance (project management, quality assurance, supply chain, etc.).

Let α be the critical threshold (in quantiles) associated with the cumulative probability targeted. We can then write:

$$X = \mu + \alpha\sigma \tag{15.3.1318}$$

which is an interesting notation because it deferred the analysis of risk and variability to the estimate of the standard deviation only (what the finance practitioners appreciate ...)! This notation is however a very common abuse of the following rigorous writing (which indicates more clearly that we use the quantile of α):

$$X = \mu + \alpha_q\sigma \tag{15.3.1319}$$

What would be written using the same notation as in the Statistics section when the distribution is Normal:

$$X = \mu + Z_\alpha\sigma \tag{15.3.1320}$$

This type of notation can easily be verified with the spreadsheet software Microsoft® Excel® 11.8346 for the sceptics ... Consider a portfolio P with an annual standard deviation of 10% (that will have to be expressed in cash) and assume that we have $1,000$.- in assets of this portfolio (on average). We then have the first year:

```
=NORMINV(99%;1000;10%*1000)=1000+NORMSINV(99%)*10%*1000
            =1000+2.326*10%*1000 =1,232.6
```

That is to say 99% of cumulative probability of having a portfolio that has a value between 0 and $1,232.6$.- at any time (we consider as negligible the cumulative probability that the portfolio has a negative value with this notation).

But what interests the manager is not to hedge the risk of the mean (because it is zero by construction here!) but of the volatility! In the previous case its value is 100.- (10% of $1,000$.-) and follows a reduced center Normal distribution. Hence the reason for defining the VaR formally as the mathematical relation which gives a confidence interval (or a quantile according to the point of view) of the standard deviation:

$$\boxed{\text{VaR} = \alpha\sigma} \tag{15.3.1321}$$

Thus, for a cumulative probability of 99% softwares gives us in absolute value (see the treatment of the confidence intervals in the section of Statistics page 848):

$$\alpha\texttt{=NORMSINV(99\%)=ABS(NORMSINV(1\%))=2.326}$$

where by tradition the finance practitioner take the α (and thus the VaR) as being positive. Hence the fact that they speak of risk hedged to 99% (implicitly for a given period!) whereas in reality it is to cover again risk that has 1% cumulative probability of taking place (but strictly speaking it is the same thing at the difference that the first one is easier to make understand to a customer... !!!). This is why we sometimes find the VaR in the following form:

$$\text{VaR} = -\alpha\sigma \tag{15.3.1322}$$

It should be noticed that the result of the calculation may also be referred to as a "fractional reserve" (although this has nothing to do with the way in which States impose a fractional reserve to banks) or "mathematical reserve" (although hist has nothing to do with the way in which insurance calculates the mathematical reserve).

If this is not very clear, let us recall the following diagram seen in the section of Statistics:

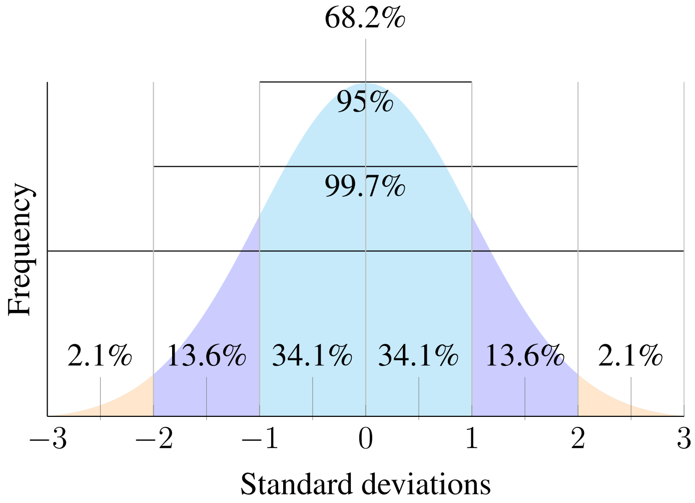

Figure 15.193: **Sigma intervals for the Normal distribution**

which was presented into the following table for some selected values commonly used in the section of Engineering (we will see some of these typical values in finance further below):

Sigma Quality Level	**Left/Right Cumulated %**	**One Sided Cumulative %**
1σ	68.26894	$68.26894/2=34.13447$
2σ	95.4499	$95.4499/2=47.72495$
3σ	99.73002	$99.73002/2=49.86501$
4σ	99.99366	$99.99366/2=49.99683$
5σ	99.999943	$99.999943/2=49.9999715$
6σ	99.9999998	$99.9999998/2=49.9999999$

An interesting information: If we cover the risk at 2σ for example on a daily basis (which is a very poor coverage...) this means that in the one-sided case, we therefore assume about 5% cumulative probability per day, that the adverse event occurs. In extenso if the undesirable events are independent then we can use the geometric law which we proved in the Statistics section - see page 654 - that the expected mean of the first occurrence of the event (undesirable in the present case...) was equal to the inverse of the probability. So with the chosen range, we have the event in question that will appear on average about once every 20 days ($1/5\%$).

Remark

The RiskMetrics model of J.P. Morgan/Reuters proposed in 11996 (holocene calendar) to take an α quantile of 1.65 corresponding to a cumulative probability of 95%. Some practitioners strongly recommend, in view of the strong and simplifying hypothesis of Normality ..., to multiply the VaR by a factor 2 or 3 (we will prove why).

✍**Example:**

A portfolio P of value $1,000$.- has an annual volatility σ_A of 10%. The daily (instantaneous) volatility of the yield is then (we use here the property of the standard Brownian motion where, for recall, the returns are assumed to be independent from one day to another ...):

$$\sigma_{R,d}=\frac{10\%}{\sqrt{252}}\cong 0.63\% \tag{15.3.1323}$$

where 252 is the number of trading days in a given year for a given country. Either in cash:

$$\sigma_d\cong 0.63\%\cdot 1,000\cong 6.29.\text{-} \tag{15.3.1324}$$

The VaR relative to the 99% threshold at one day is then:

$$\text{VaR}_d=\alpha\sigma=2.326\cdot 6.29\cong 14.65.\text{-} \tag{15.3.1325}$$

Also over one year we would have the following relative annual VaR at the following 99% threshold:

$$\text{VaR}_A=2.326\cdot 1,000\cdot 10\%=232.6.\text{-} \tag{15.3.1326}$$

Or a relative VaR of $10\%\cdot 2.326=23.26\%$ (just to give it in percentages as it is customary in the financial field).

Thus, with respect to the relative annual VaR, we then have 99% cumulative probability of winning 232.60.- but also to lose them! Indeed we have 1% cumulative probability of having an annual loss of:

```
=NORMSINV(1%*10%*1000)=-232.6
```

So it would require at least a risk capital (equity) of 232.6.- to cover 99% of the risks (cover this cumulative probability of 1% of being in a bad year respectively). We can also say that we have 99% cumulative probability of not losing more that 232.6.-. We thus find the same numerical result as with the previous example.

The reader will notice that we thus have in the field of the Stock Exchange (this follows from the standard Brownian motion) to change from a daily time horizon to an annual one:

$$\text{VaR}_A=\text{VaR}_d\sqrt{t}=2.326\cdot\sigma_j\sqrt{252} \tag{15.3.1327}$$

Finance practitioners name this property of Brownian motion in the context of the use of VaR:

$$\text{VaR}_T=\text{VaR}_t\sqrt{n\cdot t}=\alpha\sigma_t\sqrt{n\cdot t} \tag{15.3.1328}$$

the "scaling law". It is authorized by the Basel Accords in 11996 (holocene calendar) which presuppose a Normal distribution and advise a time horizon of 10 to 30 days. We have seen, however, in our proof of the standard Brownian motion model, that we underestimate the real risk under this hypothesis and that this reflex of change of scale via the square root is highly criticized by some specialists.

Therefore the VaR, while being an amount putted in provisions for liabilities and charges in order to face a violent but temporary breakdown of the market, is not sufficient to protect an institution from a strong and sustainable return of the market. Reason why banks often provision the minimum minimorum...

In the case where the returns are not independent but are described by an autoregressive process of order 1 (see the Time Series study later in this section at page 7989) such that:

$$R_t=\rho R_{t-1}+\varepsilon_t \tag{15.3.1329}$$

We then have considering the residual variance as negligible and that the yields have an equal variability from one day to the next (that is to say $\text{V}(R_t)=\text{V}(R_{t-1})$):

$$\text{V}(R_t+R_{t+1})=\text{V}(R_t)+\text{V}(R_t)+2\text{cov}(R_t,R_{t-1})=\sigma_d^2+\sigma_d^2+2\rho\sigma_d^2 \tag{15.3.1330}$$

We therefore have:

$$\text{V}(R_t+R_{t+1})=\sigma_j^2 2(1+\rho)\Leftrightarrow\sigma_{2j}=\sigma_j\sqrt{2(1+\rho)} \tag{15.3.1331}$$

If the correlation ρ is zero we fall back on the square root time scale factor. It is interesting to notice also that in the general case (see the study of AR(1) further below at page 7989) where the return has a tendency to increase, the AR(1)-VaR is always higher than the classic VaR.

Remarks

R1. Personally I will advocate covering up by the Six Sigma method at 99.9996% over a time horizon corresponding to the at least to the median position time. But it's personal and very simplistic ...

R2. There is a simplistic and traditional version of the VaR, named "nonparametric VaR", which consists in taking a given percentile of the distribution of historical or simulated losses. Thus, if we have at our disposal N data of loss, the VaR parameter at the threshold of 99% then consists in taking the 99th percentile of the series of values. So nothing special to report at this level ...

The goal now is to prove why the Basel Accords recommends to multiply the VaR by a factor of 3.03.

Remember first that in the section of Statistics (see page 920) a variant of notation of the inequality of Bienaymé-Chebyshev is:

$$P\left(|X-\mathrm{E}(x)|\geq t\sigma\right)\leq\frac{1}{t^2} \tag{15.3.1332}$$

Let us now make the strong hypothesis that the underlying distribution is symmetrical. Hence, it is almost immediate that we are led to write:

$$P\left(X-\mathrm{E}(x)\leq -t\sigma\right)\leq\frac{1}{2}\frac{1}{t^2} \tag{15.3.1333}$$

Suppose we impose to this deviation to the mean to have a cumulative probability of 1%. This is therefore equivalent to write:

$$P\left(X-\mathrm{E}(x)\leq -t\sigma\right)=1\%\Rightarrow 1\%=\frac{1}{2}\frac{1}{t^2}\Leftrightarrow t=7.07 \tag{15.3.1334}$$

Therefore the deviation from the mean at the cumulative probability threshold of 1% can then be written:

$$P\left(X-\mathrm{E}\leq -7.07\sigma\right)=1\% \tag{15.3.1335}$$

Now, let us recall that in the case of a Normal distribution, we have just seen above that:

$$\text{VaR}=\alpha\sigma=2.326\sigma \tag{15.3.1336}$$

There is therefore a ratio of:

$$\frac{7.071\sigma}{2.326\sigma}\cong 3.03 \tag{15.3.1337}$$

We thus fall back on the multiplier proposed in the first Basel Accords concerning the best practices about the VaR. Obviously, it is quite justified that the reader wonders about big difference between the two approaches (almost 300% !!!). It is simple to remember that the inequality of BT is an inequality valid for any symmetric distribution function and the value of 7.071 is therefore the upper limit of the worst (max) for the general case whereas the value of 2.326 is only for the Normal distribution which is a nice distribution (with for recall the probability which decreases exponentially whereas for some symmetric laws the decay is just of power type as it is the case for the Pareto distribution function).

15.3.10.3.14.2 Absolute Value at Risk

The VaR measure we have just given is a relative measure because it does not take into account the average of future losses and gains.

If the volatility is 100.- in the example just given, the relative VaR is therefore 232.6.- But since the average profit is generally non-zero over a long period of time, we must use most of the time the "absolute measure of VaR" (over a very short period, profit being considered sometimes as zero, the calculation of the relative VaR is used).

Let us first recall that following our study of the Bachelier model we have proved that the positive expected mean of the value (or yield) as well as the positive standard deviation of a portfolio are proportional to the square root of time.

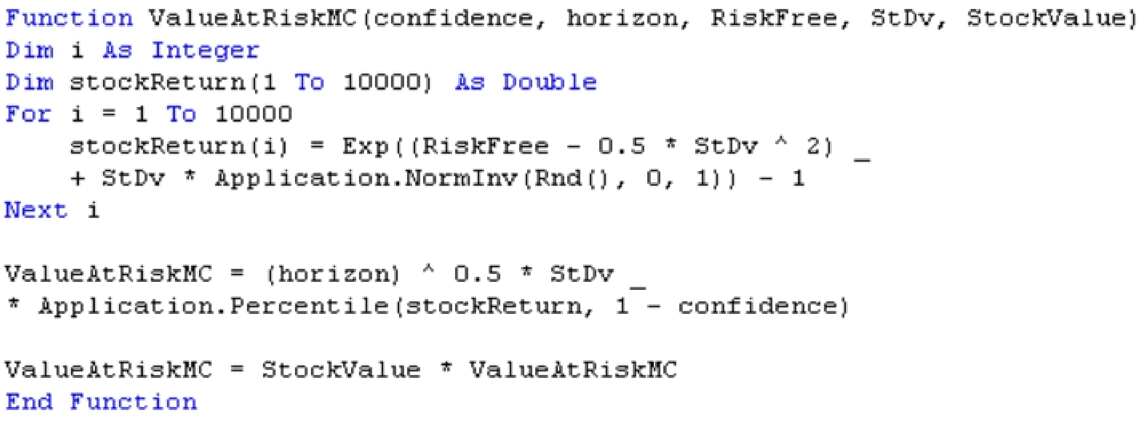
Suppose that the observation period t is in months. The expected monthly return for the portfolio of initial value S is then of μ (its expected mean therefore!!) and the monthly variance of its return is σ^2.

Its relative VaR to the confidence threshold α is therefore after t months given by (you can verify that the relation is indeed homogeneous!):

$$\text{VaR}_r = S \cdot \left(\alpha\sigma\sqrt{t}\right) \tag{15.3.1338}$$

as we were able to verify in the previous example (so far nothing new ...). The square root of time comes, as a reminder, from the Bachelier model (standard Brownian motion).

In Monte Carlo version with VBA (because the version above is named "punctual") this gives:



```
Function ValueAtRiskMC(confidence, horizon, RiskFree, StDv, StockValue)
Dim i As Integer
Dim stockReturn(1 To 10000) As Double
For i = 1 To 10000
    stockReturn(i) = Exp((RiskFree - 0.5 * StDv ^ 2) _
    + StDv * Application.NormInv(Rnd(), 0, 1)) - 1
Next i

ValueAtRiskMC = (horizon) ^ 0.5 * StDv _
* Application.Percentile(stockReturn, 1 - confidence)

ValueAtRiskMC = StockValue * ValueAtRiskMC
End Function
```

Remark

Contrary to what we saw in our study of thresholds/confidence intervals in the section Statistics (see page 848), we do not divide by 2 the `NORMALSINV()` function argument of Microsoft® Excel® 11.8346 to get the α in the above situation because what interests us is only one side of the Normal reduced centered distribution (the "pessimistic" side) and not both.

If we take the same example as before (portfolio of $1,000$.- with 10% annual volatility). The relative VaR is therefore on a 30-day projection of:

$$\text{VaR}_r = S\alpha\sigma\sqrt{t} = 1000 \cdot 2.326 \frac{10\%}{\sqrt{252}} \tag{15.3.1339}$$

But this last relation does not take into account the expected average return portfolio equation over time. The "absolute VaR" is thus obtained by subtracting this yield from the relative VaR over the same time period, that is to say:

$$\boxed{\text{VaR}_a = \text{VaR}_r - S\mu t = -S(\mu \cdot t - \alpha\sigma\sqrt{t})} \tag{15.3.1340}$$

where we make the particular assumption that the return is thus linearly time-dependent... (in accordance with the semi-empirical construction of standard Brownian motion). The absolute VaR is therefore obviously less than the relative VaR of this amount.

It should be noted that the calculation of the absolute VaR may be considered vicious or of little interest because it assumes that the gain obtained from the return will be placed in the fractional reserve to finance the relative VaR. In most cases, however, the earnings will be re-affected in the Market.

Let us come back to our usual example under this assumption (portfolio of $1,000$.- with 10% annual volatility) with an annual return rate of 15%. We have then:

$$\text{VaR}_a = S\alpha\sigma\sqrt{t} - S\mu t = 1000 \cdot 2.326 \cdot 10\% - 1000 \cdot 15\% \cong 232.6 - 150 = 82.6.\text{-} \tag{15.3.1341}$$

Concretely, if we finance the VaR with the gains, then on one year it is enough to have 82.6.- of fractional reserve. In practice it may be interesting to after how much time the earnings cover the entire VaR. In this case it is a simple equation of the second degree such that:

$$S\alpha\sigma\sqrt{t} - S\mu t = 0 \tag{15.3.1342}$$

and we would find in our example 2.4 years. Concretely after 2.4 years the gains will have covered all the risks according to the assumptions of the construction of the VaR...

15.3.10.3.14.3 Delta-Normal Value at Risk

We have just seen that when we work with an asset and the standard deviation is expressed in cash (or in $\%$ then converted into cash), the cash value of the relative VaR is therefore given under the assumption of Normality by:

$$\text{VaR} = \alpha\sigma \tag{15.3.1343}$$

But what about the VaR of a derivative (option typically!) knowing that it depends indirectly on the value of the underlying and that only the latter is measurable on the market as a whole (in order to get a statistical distribution)? Well for this we will re-use the Taylor development used earlier in our study of Itō processes:

$$\Delta F = \frac{1}{1!}\frac{\partial F}{\partial t}\Delta t + \frac{1}{1!}\frac{\partial F}{\partial x}\Delta x + \frac{1}{2!}\frac{\partial^2 F}{\partial t^2}\Delta t^2 + \frac{1}{2!}\frac{\partial^2 F}{\partial x^2}\Delta x^2 + \ldots \tag{15.3.1344}$$

Therefore, by taking only the first order, we have the following affine approximation (thus a coarse approximation valid only in the linear domain):

$$\Delta F = \frac{\partial F}{\partial t}\Delta t + \frac{\partial F}{\partial x}\Delta x \tag{15.3.1345}$$

and leaving aside the temporal variation (...) and taking an infinitely small variation (which, however, makes it possible to make the approximation a little more realistic):

$$\mathrm{d}F = \frac{\partial F}{\partial x}\mathrm{d}x \tag{15.3.1346}$$

And by writing with the traditional notation of the underlying as used during our pricing studies of options and using the notation of the Greeks as defined earlier:

$$\mathrm{d}F = \frac{\partial F}{\partial S}\mathrm{d}S = \Delta \mathrm{d}S \tag{15.3.1347}$$

Thus, the variation of a derivative assumed to depend only on the changes in the first-order of the underlying value is directly proportional to the marginal variation in the price of the option multiplied by the change in the underlying. Thus, if we assume the underlying price distribution of the underlying as Normal - reason for which we speak of "delta-Normal VaR", then a coarse approach naturally consists in writing whether the volatility of the underlying is given in $\%$:

$$\boxed{\text{VaR}_{\Delta\mathcal{N}} \cong \frac{\partial F}{\partial S}\alpha\sigma_S S_0 = \Delta\alpha\sigma_S S_0} \tag{15.3.1348}$$

and if the volatility of the underlying is given directly in cash:

$$\text{VaR}_{\Delta\mathcal{N}} \cong \Delta\alpha\sigma_S \tag{15.3.1349}$$

15.3.10.3.14.4 (Sorted) Historical Value at Risk

A third pragmatic nonparametric way of calculating the relative VaR is based on historical data! This is the easiest way to do the calculation with the ease of use of existing spreadsheet softwares.

Let us assume for the example that we have the last 100 daily performances of a portfolio (including negative and positive returns!). The 10 worst daily performances are given in ascending order:

Historical Data
$-19,000$.-
$-16,450$.-
$-15,000$.-
$-12,500$.-
$-11,950$.-
-11.250.-
$-11,050$.-
$-10,600$.-
$-10,500$.-
$-10,250$.-
...

The 95% historical VaR for 1 day then consist to determine the 5th percentile of these ascending sorted values. Since we have 100 samples, it is easy to determine that this is the 5th value in ascending order of values. Therefore in our example above:

$$\text{VaR}_{H,5\%} = 11,950.\text{-} \tag{15.3.1350}$$

As already mentioned in the section Statistics, spreadsheet software use the `PERCENTILE( )` function which is not necessarily calculated in the same way from one software to another...

Formally, if we denote by X the distribution of returns, the (sorted) historical VaR is defined in the general case by:

$$\boxed{\text{VaR}_{H,\alpha}(X) = F_X^{-1}(1-\alpha)} \tag{15.3.1351}$$

However this definition cannot be used directly for calculations unless we assume that X has some parametric distribution!

Remark

It may be however more secure in practice to take into account only negative returns in the above procedure!

15.3.10.3.14.5 Credit Value at Risk (CVaR)

The "Credit Value at Risk" (CVaR) of a portfolio is the worst loss expected to be suffered due to counterparty default over a given period of time with a given probability. The abbreviation CVaR should not be confused with the Conditional Value at Risk we will see further below!

To introduce the credit VaR ludicrously let us consider a companion example of three portfolios A, B and C, whose credit default probabilities follow a Bernoulli distribution (i.e., a binary event) of respective values of 5%, 10% and 20% and the monetary values are in millions of dollars of 25.-, 30.- and 45.-.

For the following example, we will make the assumptions (which are often implicit even in all we have seen so far) that the risk exposure is constant, that the portfolios are independent and that in case of credit default we lose everything!!!

As the three portfolios are therefore independent, the expected mean of loss (denoted "L" for Loss) is easily computable using the linearity property of the mean:

$$\text{E}(L) = 5\% \cdot 25 + 10\% \cdot 30 + 20\% \cdot 45 = 13.25.\text{-} \tag{15.3.1352}$$

Since the loss of credit is considered a Bernoulli random variable (and the portfolios are always independent), we always have in millions of dollars (the reader can refer to the calculation of the variance of a Bernoulli random variable in the section Statistics):

$$\begin{aligned}\text{V}(L) &= \text{V}(L_A + L_B + L_C) = \text{V}(L_A) + \text{V}(L_B) + \text{V}(L_C)\\ &= 25 \cdot 5\% \cdot (1-5\%) + 30 \cdot 10\% \cdot (1-10\%) + 45 \cdot 20\% \cdot (1-20\%) = 434.688.\text{-}\end{aligned} \tag{15.3.1353}$$

Well this being done for pleasure ... How can we determine as finely as possible the distribution of losses to have the credit VaR at a given threshold? Well, for that we will have to construct the table of all possible outcomes (or build in the state of the art a Kernel Smoothing distribution function but manually this is quite boring to do).

If there are N credits, we have 2^N possible scenarios therefore:

Loss Scenario	**Associated Loss**	**Probability**	**Cumulated Probability**
None	0.-	$(1-0.05)\cdot(1-0.1)\cdot(1-0.2)=68.40\%$	68.40%
A	25.-	$0.05\cdot(1-0.1)\cdot(1-0.2)=3.60\%$	72.00%
B	30.-	$(1-0.05)\cdot 0.1\cdot(1-0.2)=7.60\%$	79.60%
C	45.-	$(1-0.05)\cdot(1-0.1)\cdot 0.2=17.10\%$	96.70%
A,B	55.-	$0.05\cdot 0.1\cdot(1-0.2)=0.40\%$	97.10%
A,C	70.-	$0.05\cdot(1-0.1)\cdot 0.2=0.90\%$	98.00%
B,C	75.-	$(1-0.05)\cdot 0.1\cdot 0.2=1.90\%$	99.00%
A,B,C	100.-	$0.05\cdot 0.1\cdot 0.2=0.1\%$	100%

Thus, the credit VaR closest to 95% is 45 million USD. Since we can expect a loss of 13.25 million USD, the unexpected portion will be considered as 31.75 million USD (that is to say the difference).

15.3.10.3.14.6 Operational Value at Risk

We have already encountered the concept of convolution several times in the section Statistics but for continuous laws explicitly known in their algebraic form .... In practice it is quite different! Thus, actuaries have often at their disposition for a given period (often over a year), an experimental distribution of the frequency of events of interest (accidents, deaths or other) and an experimental distribution of the costs of events of interest. For example, consider the very simplified (in size!) following case:

Frequency Distribution (losses)	
Probability	**Frequency**
0.6	0
0.3	1
0.1	2
Expected mean:	0.5

Distribution of Loss Costs	
Probability	**Frequency**
0.5	$1,000.$-
0.3	$10,000.$-
0.2	$100,000.$-
Expected mean:	$23,500.$-

If we want from these experimental and discrete values to determine the empirical distribution of costs, we will have to make a discrete convolution whose principle is the following:

Number of losses	First loss	Second loss	Total Loss	Probability
0	0	0	0	$=0$
1	$1,000.$-	0	$1,000.$-	$=0.3\cdot 0.6=0.150$
1	$10,000.$-	0	$10,000.$-	$=0.3\cdot 0.3=0.090$
2	$100,000.$-	0	$100,000.$-	$=0.3\cdot 0.2=0.060$
2	$1,000.$-	$1,000.$-	$2,000.$-	$=0.1\cdot 0.5\cdot 0.5=0.025$
2	$1,000.$-	$10,000.$-	$11,000.$-	$=0.1\cdot 0.5\cdot 0.3=0.015$
2	$1,000.$-	$100,000.$-	$101,000.$-	$=0.1\cdot 0.5\cdot 0.2=0.010$
2	$10,000.$-	$1,000.$-	$11,000.$-	$=0.1\cdot 0.3\cdot 0.5=0.015$
2	$10,000.$-	$10,000.$-	$20,000.$-	$=0.1\cdot 0.3\cdot 0.3=0.009$
2	$10,000.$-	$100,000.$-	$110,000.$-	$=0.1\cdot 0.3\cdot 0.2=0.006$
2	$100,000.$-	$1,000.$-	$101,000.$-	$=0.1\cdot 0.2\cdot 0.5=0.010$
2	$100,000.$-	$10,000.$-	$110,000.$-	$=0.1\cdot 0.2\cdot 0.3=0.006$
2	$100,000.$-	$100,000.$-	$200,000.$-	$=0.1\cdot 0.2\cdot 0.2=0.004$

The loss expected mean is then equal to $11,750.$-, which is also equivalent to simply calculate (the expected mean of the product of two independent random variables being equal to the product of the expected man as we have proved it in the section Statistics):

$$0.5\cdot 23,500=11,750.\text{-} \tag{15.3.1354}$$

Then we combine and sort the losses and probabilities:

Loss	**Probability**
$0.$-	60%
$1,000.$-	75%
$2,000.$-	77.5%
$10,000.$-	86.5%
$11,000.$-	89.5%
$20,000.$-	90.4%
$100,000.$-	96.4%
$101,000.$-	98.4%
$110,000.$-	99.6%
$110,000.$-	100%

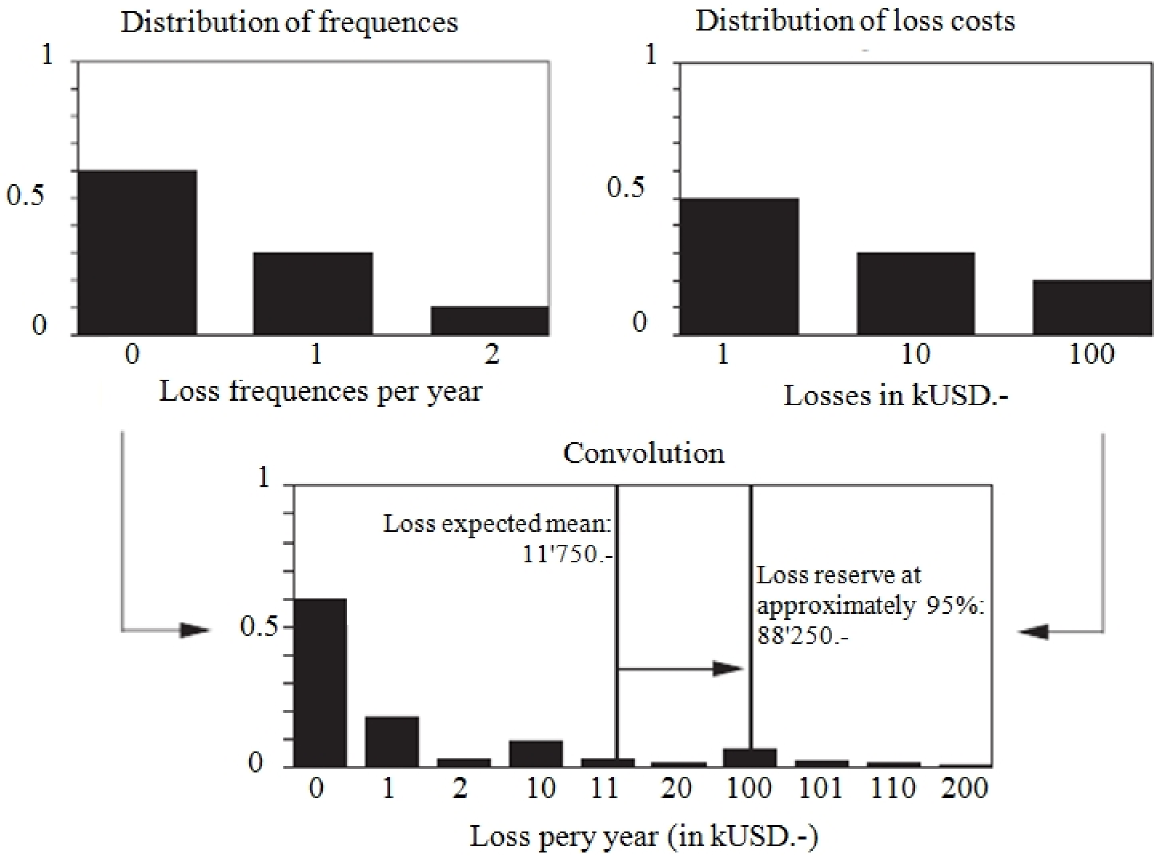
On the side of the operational VaR, if we set it at 95% (the Basel II agreements propose instead to take 99.9%), the nearest value is then:

$$\text{VaR}_{\text{op.}}=100,000.\text{-} \tag{15.3.1355}$$

Therefore, the reserve of unexpected loss is:

$$100,000-11,750=88,250.\text{-} \tag{15.3.1356}$$

Graphically our tables, manipulations and calculations can be summarized as follows:



It is interesting to notice how two simple tables produce a quantity of computations in convolution relatively huge. This is why, in real practical cases, the use of computers is necessary.

15.3.10.3.14.7 Surplus Value at Risk (Pension VaR)

Risks should be seen in a more general context in the case of a portfolio or an accounting system including asset management and liabilities.

Thus, in the case of a portfolio or an accounting, the risk is that the asset values no longer cover the liabilities of the portfolio.

Definition (#15.3.699): We name "surplus", and denote it by S, the difference between the amount of assets $\mathcal{A}$ and liabilities $\mathcal{L}$. But in a totally financial context aspect we will focus mainly on the difference of the mean of the returns between the two such as:

$$\mu_S = \mu_{R,\mathcal{A}} - \mu_{R,\mathcal{L}} \tag{15.3.1357}$$

✍**Example:**

Consider a cash portfolio with $\mathcal{A}_t = 120$ and $\mathcal{L}_t = 100$. Therefore:

$$S_t = \mathcal{A}_t - \mathcal{L}_t = 120 - 100 = 20 \tag{15.3.1358}$$

Suppose we have:

$$\begin{matrix} \mu_{R,\mathcal{A}} = 8\% & \mu_{R,\mathcal{L}} = 5\% \\ \sigma_{R,\mathcal{A}} = 12\% & \sigma_{R,\mathcal{L}} = 3\% \end{matrix} \tag{15.3.1359}$$

With the correlation:

$$\rho_{\mathcal{A},\mathcal{L}} = 0.3 \tag{15.3.1360}$$

Then in this case over the next period it is very likely to have in cash:

$$\begin{aligned} \Delta\mathcal{A} &= \mathcal{A}\mu_{R,\mathcal{A}} = 128 \cdot 8\% = 9.6 \\ \Delta\mathcal{L} &= \mathcal{L}\mu_{R,\mathcal{L}} = 100 \cdot 3\% = 5 \end{aligned} \tag{15.3.1361}$$

So in extenso, we have:

$$\Delta S = \Delta\mathcal{A} - \Delta\mathcal{L} = 4.6 \tag{15.3.1362}$$

So the expected surplus for the next time period will be:

$$S_{t+1} = S_t + \Delta S = 24.6 \tag{15.3.1363}$$

And for the variance of the surplus, we need it to calculate the SVaR, that is the "Surplus Value at Risk", then it comes:

$$\begin{aligned} \mathrm{V}(S) &= \mathrm{V}(\mathcal{A} - \mathcal{L}) = \mathrm{V}(\mathcal{A}) + \mathrm{V}(\mathcal{L}) - 2\mathrm{cov}(\mathcal{A},\mathcal{L}) = \mathrm{V}(\mathcal{A}) + \mathrm{V}(\mathcal{L}) - 2\rho_{\mathcal{A},\mathcal{L}}\sigma_{\mathcal{A}}\sigma_{\mathcal{L}} \\ &= (120 \cdot 12\%)^2 + (100 \cdot 3\%)^2 - 2 \cdot 0.3 \cdot (120 \cdot 12\%)(100 \cdot 3\%) = 190.44 \end{aligned} \tag{15.3.1364}$$

Therefore:

$$\sigma_S = \sqrt{190.44} = 13.80 \tag{15.3.1365}$$

Now, let us recall that under certain hypotheses necessarily realized, we have demonstrated that the absolute VaR was given in the case of a Normal underlying distribution by:

$$\text{VaR}_a = \mu t + Z_\alpha \sigma \sqrt{t} \qquad (15.3.1366)$$

We have then in our example the surplus VaR at one unit time horizon unit and at the 95% threshold:

$$\text{SVaR}_a = -24.6 \cdot 1 + 1.64 \cdot 13.8 + \sqrt{1} = 18.1 \qquad (15.3.1367)$$

So generally the example above gives us explicitly:

$$\boxed{\text{SVaR}_a = [S_t + (\mathcal{A}\mu_{R,\mathcal{A}} - \mathcal{L}\mu_{R,\mathcal{L}})]\, t + Z_\alpha \sqrt{\text{V}(\mathcal{A}) + \text{V}(\mathcal{L}) - 2\text{cov}(\mathcal{A},\mathcal{L})}\sqrt{t}} \qquad (15.3.1368)$$

15.3.10.3.14.8 Variance-Covariance Value at Risk

The variance-covariance VaR is based on a more realistic case of calculating the VaR for a portfolio composed of several financial assets correlated or not (unlike the previous cases where we had only one asset).

In order to introduce this concept, let us consider a companion example of a portfolio P_1 of $5,000,000$.- and daily volatility of 2% (i.e. $100,000$.-/day) and a second portfolio P_2 of $7,000,000$.- and daily volatility of 1% (i.e. $70,000$.-/day).

Our measurements show that their Pearson correlation coefficient ρ is 0.6. The daily global standard deviation is then (see section Statistics page 597):

$$\begin{aligned}\sigma_{1+2} &= \sqrt{\sigma_1^2 + \sigma_2^2 + 2R_{1,2}\sigma_1\sigma_2} = \sqrt{100,000^2 + 70,000^2 + 2 \cdot 0.6 \cdot 100,000 \cdot 70,000} \\ &\cong 152,643.-\end{aligned} \qquad (15.3.1369)$$

where as usual we see that if the correlation is negative this decreases the overall volatility.

Thus, the relative variance-covariance daily VaR at 99% for the global portfolio is (no scaling law to apply here since the standard deviation is daily and we want the daily relative VaR):

$$\text{VaR}_{r,1+2} = \alpha\sigma_{1+2} = 2.326 \cdot 152,634 \cong 355,000.- \qquad (15.3.1370)$$

It is interesting to compare the daily relative VaR with the sum of the relative VaRs of the two portfolios:

$$\text{VaR}_{r,1} + \text{VaR}_{r,2} = \alpha\sigma_1 + \alpha\sigma_2 = 2.326 \cdot 100,000 + 2.326 \cdot 70,000 \cong 395,420.- \qquad (15.3.1371)$$

We then have:

$$\text{VaR}_{r,1+2} \leq \text{VaR}_{r,1} + \text{VaR}_{r,2} \qquad (15.3.1372)$$

This is due to the diversification gain!

Remark

In finance when the merging of risks is less than the sum of the risks, we then technically say that the risk measure is "subadditive".

Many practitioners do the same calculation with yield rather than with cash values. Thus we get the VaR expressed in terms of yield.

Remark

A first trap in calculating the relative variance-covariance VaR would have been to calculate the global standard deviation in $\%$ and then apply to it the relation of the calculation of the global VaR. The result would have been wrong! A second trap is to use the same percentile of the VaR for merging risks as for individual risks because if we can accept individual ruins in a highly competitive market we can not accept it with the same level of risk For the same large structures (we should apply Bonferroni correction or Fisher p-value calculation as seen in the section Statistics).

If we had a single portfolio consisting of several financial instruments such that the total proportion is equal to unity then we should, in accordance with what we saw during our study of the Markowitz model, work with the following relation if we use returns:

$$\sigma_{1+2}=\sqrt{X_1^2\sigma_1^2+X_2^2\sigma_2^2+2R_{1,2}X_1X_2\sigma_1\sigma_2} \qquad (15.3.1373)$$

Thus, if we consider the first portfolio in our companion example above in a proportion of 75% (and therefore in extenso the second in a proportion of 25%). We then have:

$$\sigma_{1+2}=\sqrt{X_1^2\sigma_1^2+X_2^2\sigma_2^2+2R_{1,2}X_1X_2\sigma_1\sigma_2}\cong 1.66\% \qquad (15.3.1374)$$

Thus a corresponding VaR return of (always under the assumption of Normality):

$$\text{VaR}_{r,1+2}=2.326\cdot 1.66\%\cong 3.87\% \qquad (15.3.1375)$$

that therefore represents in $\%$, the amount we could lose on our portfolio.

Therefore the general "variance-covariance (relative) Value at Risk", also named "Portfolio Value at Risk", relation is given by:

$$\boxed{\text{VaR}_{r,\sum_i^n}=\text{VaR}_P=\alpha\sqrt{\sum_{i=1}^{n}\sigma_{P_i}^2+2\sum_{i<j}^{n}\text{cov}(P_i,P_j)}} \qquad (15.3.1376)$$

Obviously (see section Statistics page 597) we could write it in matrix form if we want...

15.3.10.3.14.9 Marginal and Component Value at Risk

In our study of Markowitz's efficient diversification model, we showed that the variance of a portfolio composed of several investments in given proportions X_i was:

$$\mathrm{V}\left(R_p\right)=\sigma^2(R_p)=\sum_{i=1}^{n}X_i^2\sigma_i^2+2\sum_{i<j}\sum X_iX_j\text{cov}(R_j,R_i)=\sum_{i=1}^{n}X_i^2\sigma_i^2+2\sum_{i<j}\sum X_iX_j\sigma_{ij} \tag{15.3.1377}$$

The variation of this variance with respect to a variation of one of the proportions X_i alone gives:

$$\frac{\partial\sigma^2(R_p)}{\partial X_i}=2X_i\sigma_i^2+2\sum_{j\neq i}X_j\text{cov}(R_j,R_i)=2\left(X_i\sigma_i^2+\sum_{j\neq i}X_j\text{cov}(R_j,R_i)\right) \tag{15.3.1378}$$

Let us recall the property of bilinearity of the covariance proved in the section of Statistics (see page 602):

$$\text{cov}(Y,aX+bZ)=a\text{cov}(X,Y)+b\text{cov}\left(Y,Z\right) \tag{15.3.1379}$$

By putting $Y=X=R_i$, $a=X_i$, we have:

$$\text{cov}(R_i,X_iR_i+bZ)=X_i\text{cov}(R_i,R_i)+b\text{cov}(R_i,Z)=X_i\sigma_i^2+b\text{cov}(R_i,Z) \tag{15.3.1380}$$

Let us put $b=1$, $Z=\sum_{j\neq i}X_jR_j$, we have:

$$\text{cov}\left(R_i,X_iR_i+\sum_{j\neq i}X_jR_j\right)=X_i\sigma_i^2+\text{cov}\left(R_i,\sum_{j\neq i}X_jR_j\right)=X_i\sigma_i^2+\sum_{j\neq i}X_j\text{cov}(R_i,R_j) \tag{15.3.1381}$$

Therefore we get:

$$2\left(X_i\sigma_i^2+\sum_{j\neq i}X_j\text{cov}(R_i,R_j)\right)=2\text{cov}\left(R_i,X_iR_i+\sum_{j\neq i}X_jR_j\right)=2\text{cov}(R_i,R_p) \tag{15.3.1382}$$

So finally:

$$\frac{\partial\sigma^2(R_p)}{\partial X_i}=\frac{\partial\sigma_p^2}{\partial X_i}=2\text{cov}(R_i,R_p) \tag{15.3.1383}$$

But we also have:

$$\frac{\partial\sigma_p^2}{\partial X_i}=2\sigma_p\frac{\partial\sigma_p}{\partial X_i}=2\text{cov}(R_i,R_p) \tag{15.3.1384}$$

So we deduce:

$$\frac{\partial\sigma_p}{\partial X_i}=\frac{\text{cov}(R_i,R_p)}{\sigma_p} \tag{15.3.1385}$$

The reader will notice that we fall back on the beta coefficient. Therefore, we can write (by the way we prefer to write the weights according to the most usual notation w_i instead of X_i):

$$\frac{\partial \sigma_p}{\partial w_i}=\frac{\text{cov}\left(R_i,R_p\right)}{\sigma_p}=\beta_i\sigma_p \tag{15.3.1386}$$

Thus, remembering that the relative VaR is given by:

$$\text{VaR}_r=\alpha\sigma \tag{15.3.1387}$$

The "marginal Value at Risk" is then logically given by:

$$\boxed{\Delta\text{VaR}_i=\frac{\partial \text{VaR}}{\partial w_i}=\frac{\partial \alpha\sigma_p}{\partial w_i}=\alpha\frac{\partial \sigma_p}{\partial w_i}=\alpha\frac{\text{cov}\left(R_i,R_p\right)}{\sigma_p}=\alpha\beta_i\sigma_p} \tag{15.3.1388}$$

This gives for a given asset having a given weight w_i in a given portfolio the percentage increase in its contribution to the portfolio's risk when increases its weight by 1%.

We define the "component Value at Risk" as:

$$\boxed{\text{CVaR}_i=w_i\beta_i\alpha\sigma_p} \tag{15.3.1389}$$

Let us recall for close this subject what is the purpose of the VaR? First of all, it is of great utility since it is measured in nominal terms. Once a financial institution has calculated its aggregate VaR, that is, the maximum loss that it can incur over the entire balance sheet for a predetermined probability, it is entitled to use that amount to determine the minimum capital (equity) it must hold in order not to become bankrupt. If it holds less capital and the maximum probability loss occurs, its equity will be negative and it may have to file for bankruptcy. Many studies have proven that this tool is statistically much better that any known qualitative approach encompassing all well known human cognitive bias!

The VaR is therefore very useful for a financial institution because it enables it to determine the level of capital it must maintain in order to survive with a given probability. When VaR is used for this purpose, we refer to it more commonly as "Capital at Risk", which means that the capital that a financial institution must hold is calculated or assessed according to the risks to which it is exposed. The greater the risk, the greater the need to maintain capital. This seems reasonable, because the capital held by a financial institution is first and foremost a safety net. For a bank, it aims to protect deposits in its liabilities. VaR is therefore an appropriate measure to define the regulatory capital that a financial institution must hold. For this reason, the Basel Committee, under the umbrella of the Bank for International Settlements, used this measure to calculate the regulatory capital of a depository institution in 11995 (holocene calendar) and became effective in January 11998 (holocene calendar). They now have to calculate their exposure Risk by using VaR and testing its accuracy by performing stress tests (as opposed to calculations to extreme variations) as well as to back testing by verifying that large deviations (outside the range of confidence) do not occur more than 5 times per stock market year (thus compared to historical data).

15.3.10.3.14.10 Conditional Value at Risk (CVaR)

A forecast of financial losses often used in the academic world of finance is the "conditional loss", often referred to "expected shortfall" or "expected loss" or "expected tail loss" (ETL).

For the sake of simplification, we often limit ourselves to the calculation of the conditional loss of the VaR in the case that it follows a Normal law (we speak then in the field of finance of an "expected shortfall for Gaussian loss distribution") and this is what we are going to do here. The reader will find, however, a more realistic case based on a Pareto type I law in the Probability section when we introduced the concept of conditional expectation.

Let us consider therefore the expected shortfall at a threshold α corresponding to the percentile such as we have seen earlier above. Consistent with what we have seen in the Probability section (see page 499), the conditional expectation of such a threshold will therefore be given by:

$$\text{ES}_\alpha=\frac{\displaystyle\int\limits_{\text{VaR}_\alpha}^{+\infty} yf(y)\mathrm{d}y}{\displaystyle\int\limits_{\text{VaR}_\alpha}^{+\infty} f(y)\mathrm{d}y} \tag{15.3.1390}$$

For the denominator, it is immediate (it is simply the cumulative probability at the level of the quantile threshold of the selected VaR):

$$\boxed{\text{ES}_\alpha=\frac{\displaystyle\int\limits_{\text{VaR}_\alpha}^{+\infty} yf(y)\mathrm{d}y}{1-\alpha}} \tag{15.3.1391}$$

As in finance we can always center and reduce a random variable, let us focus on the case of a centered reduced Normal law to treat the numerator (hence VaR_α the quantile of the centered reduced VaR to the threshold α). We then have:

$$\begin{aligned}\text{ES}_\alpha&=\frac{\displaystyle\int\limits_{\text{VaR}_\alpha}^{+\infty} y\frac{1}{\sigma\sqrt{2\pi}}e^{\left(-\frac{1}{2}\frac{(y-\mu)^2}{\sigma^2}\right)}\mathrm{d}y}{1-\alpha}=\frac{\displaystyle\int\limits_{\text{VaR}_\alpha}^{+\infty} y\frac{1}{\sigma\sqrt{2\pi}}e^{\left(-\frac{1}{2}y^2\right)}\mathrm{d}y}{1-\alpha}\\&=\frac{1}{(1-\alpha)\sqrt{2\pi}}\int\limits_{\text{VaR}_\alpha}^{+\infty} ye^{\left(-\frac{1}{2}y^2\right)}\mathrm{d}y=\frac{1}{(1-\alpha)\sqrt{2\pi}}e^{\left(-\frac{1}{2}y^2\right)}\Bigg|_{\text{VaR}_\alpha}^{+\infty}=-\frac{e^{\left(-\frac{1}{2}\text{VaR}_\alpha^2\right)}}{(1-\alpha)\sqrt{2\pi}}\\&=-\frac{\frac{1}{\sqrt{2\pi}}e^{\left(-\frac{1}{2}\text{VaR}_\alpha^2\right)}}{1-\alpha}=(1-\alpha)^{-1}\Phi\left(\text{VaR}_\alpha^2\right)\end{aligned} \tag{15.3.1392}$$

What is computed with a spreadsheet like Microsoft® Excel® 14.0.7184:

```
=-NORMDIST(NORMINV(alpha),FALSE)/(1-alpha)
```

Or in an equivalent manner:

```
=NORMDIST(NORMINV(1-alpha),FALSE)/(1-alpha)
```

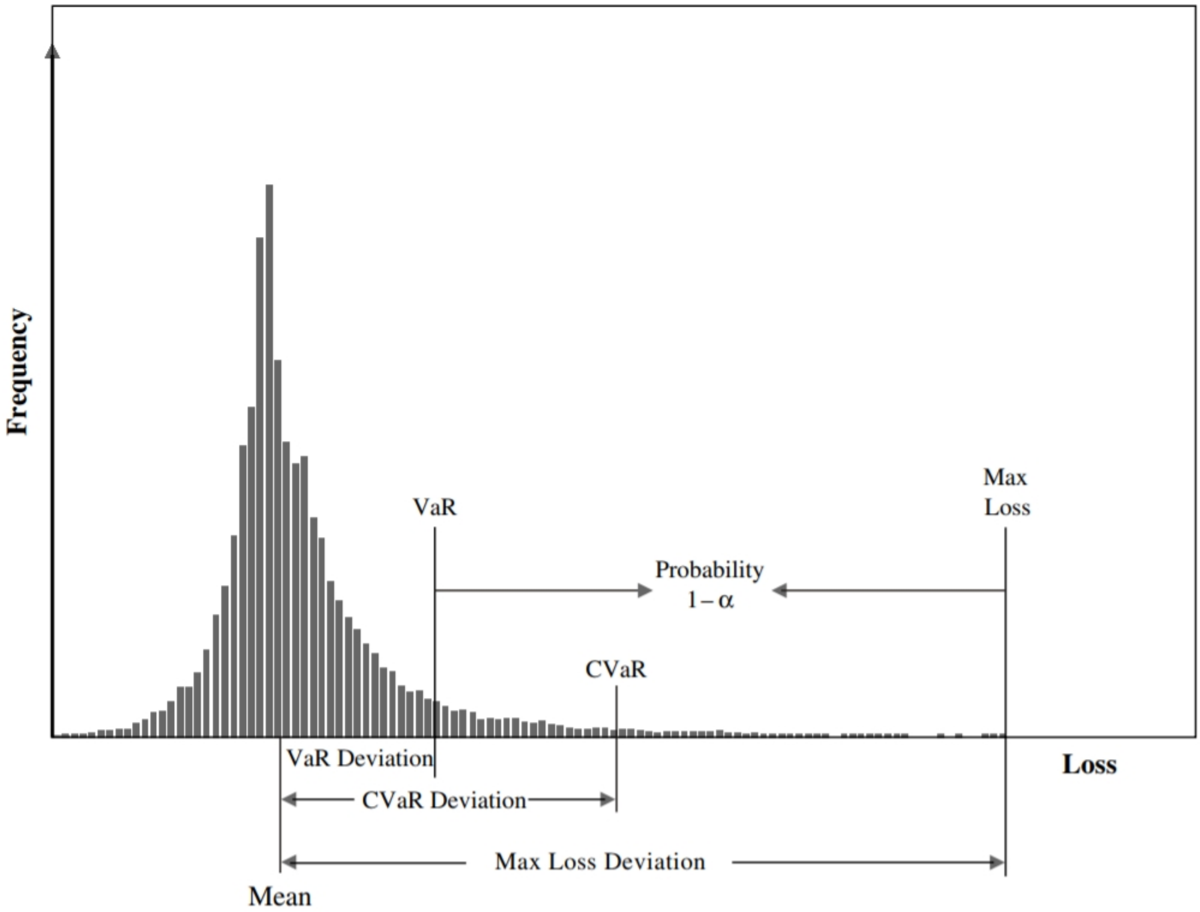


Figure 15.194: Graphical representation of VaR, VaR Deviation, CVaR, CVaR Deviation, Max Loss, and Max Loss Deviation (source: Value-at-Risk vs. Conditional Value-at-Risk in Risk Management and Optimization)

There is a close correspondence between CVaR and VaR: with the same confidence level, VaR is a lower bound for CVaR. The problem of the choice between VaR and CVaR, especially in financial risk management, has been quite popular in academic literature. Reasons affecting the choice between VaR and CVaR are based on the differences in mathematical properties, stability of statistical estimation, simplicity of optimization procedures, acceptance by regulators, etc

✍**Example:**

Given a VaR following a Normal law that has been centered and reduced. The conditional loss expectation above 99% (i.e. at the threshold of $\alpha=1\%$) is then given by:

```
=-NORM.S.DIST(NORM.S.INV(99%),FALSE)/(1-99%)=2.67
```

or:

```
=-NORM.S.DIST(2.326,FALSE)/1%=2.67
```

Which is still 15% more than the quantile of 2.326 !!!

This corresponds in comparison to the relative VaR to an equivalent of:

`=1-NORM.S.INV(2.67;1)=99.6%`

So through this example we see that there is no "problem" in working with a centered reduced conditional expected loss since we can always reduce the conditional expectation of a loss to a given relative VaR (that latter being already not accurate...).

After the choice of reserves is purely from the internal policy to the financial institutes.

15.3.10.3.14.11 Modified duration Value At Risk (MdVaR)

We have seen so far how to calculate the relative value of a portfolio whose variation is implicitly assumed to be directly proportional to a change in the rate of return (market rate). There are, however, many types of portfolios or financial instruments whose change in value is not simply proportional to a change in the rate of return, but with a more complex relationship, typically bonds or portfolios (made of bonds) where the yield is at the denominator in the discrete case and in an exponential in the continuous case.

Indeed, remember that for a single bond we have proved (see page 7625) that the present value was given by:

$$P=\sum_{t=1}^{T}\frac{\mathrm{CF}_t}{(1+y)^t} \tag{15.3.1393}$$

We have seen so far how to calculate the relative value of a portfolio whose variation is implicitly assumed to be directly proportional to a change in the rate of return (market rate). There are, however, many types of portfolios or financial instruments whose change in value is not simply proportional to a change in the rate of return, but with a more complex relationship, typically bonds or portfolios (made of bonds) where the yield is at the denominator in the discrete case and in an exponential in the continuous case.

Indeed, remember that for a single bond we have we have proved that the present value was given by (see earlier page 7626):

$$P=\sum_{t=1}^{T}\frac{\mathrm{CF}_t}{(1+y)^t} \tag{15.3.1394}$$

However, in our study of modified duration earlier above (see page 7633), we have proved that in Taylor's first order approximation that we could write traditionally using Modified Duration rather than Macaulay's duration that:

$$\Delta P\cong\frac{\mathrm{d}P}{\mathrm{d}y}\Delta y=(-D^*\cdot P)\Delta y=\left(\sum_{t=1}^{T}t\frac{\mathrm{CF}_t}{(1+y)^{t+1}}\right)\Delta y \tag{15.3.1395}$$

The idea underlying the "modified duration VaR" (which we can also be named "delta VaR") is then to take the y of the day and the historical variance of the variations of the returns assuming they follow a Normal distribution at a given confidence level such that:

$$\boxed{\text{VaR}_{D^*} \cong \left(\frac{1}{P}\sum_{t=1}^{T} t\frac{\text{CF}_t}{(1+y)^{t+1}}\right)\alpha\sigma_{\Delta y} = (-D^* \cdot P)\alpha\sigma_{\Delta y}} \quad (15.3.1396)$$

and we can easily extend the principle by taking the convexity term and hence we have a delta-gamma VaR.

15.3.10.3.14.12 Backtesting Value at Risk

We will see here a naive backtesting model of the VaR (there are many) but when the reader goes further through the predictive models (moving average, exponential smoothing, ARIMA, etc.) we will see that we will compare these models with the same values using error measurements (ME, MAD, MDS, MPE). These comparisons are then considered as a form of backtesting.

So to go back to the VaR, it is relatively obvious that when we have just put in place an annual VaR model and we have little history it is better to bring it back to a daily VaR and do backtesting on the basis of a smaller unit.

Let us recall the example of the beginning where we had a relative daily VaR and annual respectively at the threshold of 1% (thus 99% coverage) of:

$$\begin{aligned}\text{VaR}_d &\cong 14.65.\text{-}\\ \text{VaR}_A &\cong 232.6.\text{-}\end{aligned} \quad (15.3.1397)$$

Suppose we do a backtesting of this model by comparing it to the 600-day data we have in our possession. We observe 9 values above 14.65.-. What can we conclude ???

In fact we must first know that if the N days are independent and we denote by p the probability that one of the days is out of VaR (thus the associated value equal to 1% in our example!), then we are dealing to an experiment of N Bernoulli's tests. It is therefore a Binomial law whose associated cumulative probability is for recall (see section Statistics page 658):

$$\sum_{k=0}^{N} C_k^N p^k(1-p)^{N-k} = \sum_{k=0}^{N}\frac{N!}{k!(N-k)!}p^k(1-p)^{N-k} \quad (15.3.1398)$$

Hence, the expected mean is given by (it's nice to calculate it but in reality it is not very useful):

$$\text{E}(X) = Np = 600 \cdot 1\% = 6 \quad (15.3.1399)$$

However, to know the cumulative probability associated with 9 events, we calculate for example with Microsoft® Excel® 14.0.6129:

```
=BINOM.DIST(9;600;1%;TRUE)=BINOM.DIST(9;600;1%;1)=91.71%
```

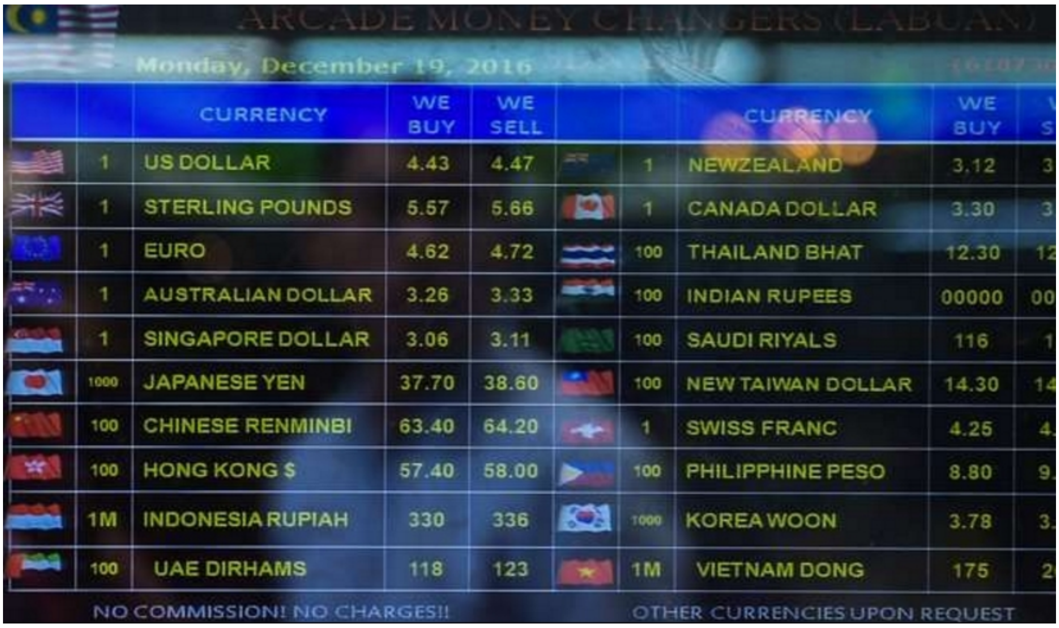
That is, a p-value of 8.29%. So whether it is unilateral or bilateral, this hypothesis test leads us not to reject the VaR model. It should not be forgotten that if N is very large and the probability is small, the binomial law tends towards a Poisson law (see section Statistics page 686) which is easier to manipulate (this is the recommendation of the CreditRisk+ standard).

15.3.11 Exchange rate

In finance, an "exchange rate" (also known as a "foreign-exchange rate", "ForEx rate") between two currencies is the rate at which one currency will be exchanged for another. It is also regarded as the value of one country's currency in relation to another currency. For example, an interbank exchange rate of 119 Japanese yen (JPY, ¥) to the United States dollar (US$) means that ¥119 will be exchanged for each US$1 or that US$1 will be exchanged for each ¥119. In this case it is said that the price of a dollar in relation to yen is ¥119, or equivalently that the price of a yen in relation to dollars is $1/119.

Exchange rates are determined in the foreign exchange market, which is open to a wide range of different types of buyers and sellers, and where currency trading is continuous: 24 hours a day except weekends, i.e. trading from 20:15 GMT on Sunday until 22:00 GMT Friday. The spot exchange rate refers to the current exchange rate. The forward exchange rate refers to an exchange rate that is quoted and traded today but for delivery and payment on a specific future date.

In the retail currency exchange market, different buying and selling rates will be quoted by money dealers. Most trades are to or from the local currency. The buying rate is the rate at which money dealers will buy foreign currency, and the selling rate is the rate at which they will sell that currency. The quoted rates will incorporate an allowance for a dealer's margin (or profit) in trading, or else the margin may be recovered in the form of a commission or in some other way.



ARCADE MONEY CHANGERS (LABUAN)

Monday, December 19, 2016

		CURRENCY	WE BUY	WE SELL			CURRENCY	WE BUY	S
	1	US DOLLAR	4.43	4.47		1	NEWZEALAND	3.12	3
	1	STERLING POUNDS	5.57	5.66		1	CANADA DOLLAR	3.30	3
	1	EURO	4.62	4.72		100	THAILAND BHAT	12.30	12
	1	AUSTRALIAN DOLLAR	3.26	3.33		100	INDIAN RUPEES	00000	00
	1	SINGAPORE DOLLAR	3.06	3.11		100	SAUDI RIYALS	116	1
	1000	JAPANESE YEN	37.70	38.60		100	NEW TAIWAN DOLLAR	14.30	14
	100	CHINESE RENMINBI	63.40	64.20		1	SWISS FRANC	4.25	4.
	100	HONG KONG $	57.40	58.00		100	PHILIPPHINE PESO	8.80	9.
	1M	INDONESIA RUPIAH	330	336		1000	KOREA WOON	3.78	3.
	100	UAE DIRHAMS	118	123		1M	VIETNAM DONG	175	2

NO COMMISSION! NO CHARGES!! OTHER CURRENCIES UPON REQUEST

Different rates may also be quoted for cash (usually notes only), a documentary form (such as traveller's cheques) or electronically (such as a credit card purchase). The higher rate on documentary transactions has been justified as compensating for the additional time and cost of clearing the document. On the other hand, cash is available for resale immediately, but brings security, storage, and transportation costs, and the cost of tying up capital in a stock of banknotes (bills).

Remarks

R1. The "real exchange rate" (RER) is the purchasing power of a currency relative to another at current exchange rates and prices. It is the ratio of the number of units of a given country's currency necessary to buy a market basket of goods in the other country, after acquiring the other country's currency in the foreign exchange market, to the number of units of the given country's currency that would be necessary to buy that market basket directly in the given country. There are various ways to measure RER.

R2. For obvious financial risk reasons that take foreign exchange business (and also because of money usability), when you travel for holidays, it will be the huge majority of times (excepted for very special cases like countries that are on the way to be in bankruptcy or with very weak money) at your advantage to convert your local cash money into a foreign cash money in the country related to the local money (for example, if you have CHF and you want to convert them into USD because you will go in the USA for holidays, then it would be at your advantage to make this conversion in Switzerland, and before coming back to Switzerland to change your USD into CHF in the USA). Obviously the rate won't be the same as they change on a daily basis or even hourly. Also exchanging money at local banks is not only convenient but also much less expensive than exchanging cash at airports or hotels.

R3. When paying by credit card, pay in the local currency! If you don't, not only will you get charged a mediocre rate to convert to your home currency, you will also be charged a percentage for the privilege. Travelex, the currency exchange company that operates kiosks in airports around the world in the beginning of the 121st century (holocene calendar), was offering an exchange rate of 1 EUR for 1.26 USD in June 12018 (holocene calendar). On the same day, Mastercard's exchange rate was 1 EUR for 1.17 USD the same day. Notice that paying with credit card in the local currency is most of the time at your advantage in comparison at when you change cash (especially because the human working at the cash exchange office are more expensive than the computer algorithms doing the transaction electronically).

The world has over 150 different currencies, from the Afghanistan afghani and the Albanian lek all the way through the alphabet to the Zambian kwacha and the Zimbabwean dollar. For international economic transactions, households or firms will wish to exchange one currency for another. Perhaps the need for exchanging currencies will come from a German firm that exports products to Russia, but then wishes to exchange the Russian rubles it has earned for euros, so that the firm can pay its workers and suppliers in Germany. Perhaps it will be a South African firm that wishes to purchase a mining operation in Angola, but to make the purchase it must convert South African rand to Angolankwanza. Perhaps it will be an American tourist visiting China, who wishes to convert U.S. dollars to Chinese yuan to pay the hotel bill.

Exchange rates can sometimes change very swiftly. For example, in the United Kingdom the pound was worth 2 USD in spring 12008 (holocene calendar), but was worth only 1.40 USD six months later. For firms engaged in international buying, selling, lending, and borrowing, these swings in exchange rates can have an enormous effect on profits.

The quantities traded in foreign exchange markets are breathtaking. A survey done in April, 12013 (holocene calendar) by the Bank of International Settlements, an international organization for banks and the financial industry, found that 5.3 USD trillion per day was traded on foreign exchange markets (in comparison in 12007 - according to holocene calendar - the daily average trading volume DATV on derivatives exchanges was about $ 2 trillion), which makes the foreign exchange market the largest market in the world economy. In contrast, 12013 (holocene calendar) U.S.A. real Gross Domestic Product (GDP) was $15.8 trillion per year.

Currency	% Daily share

British pound	11.8%
Australian dollar	8.6%
Swiss franc	5.2%
Canadian dollar	4.6%
Mexican peso	2.5%
Chinese yuan	2, 2%

Table 15.54: Currencies traded most on Foreign Exchange Markets as of April, 12013 (source: `http://www.bis.org/publ/rpfx13fx.pdf`)

Very approximately, about one-tenth of the volume traded is used for hedging. The remaining trades must be for speculative purposes.

Portfolio investment is often linked to expectations about how exchange rates will shift. Look at a U.S. financial investor who is considering purchasing bonds issued in the United Kingdom. For simplicity, ignore any interest paid by the bond (which will be small in the short run anyway) and focus on exchange rates. Say that a British pound is currently worth 1.50 USD. However, the investor believes that in a month, the British pound will be worth 1.60 USD. Thus this investor would change 24, 000 Gross Domestic Product for 16, 000 British pounds. In a month, if the pound is indeed worth 1.60 USD, then the portfolio investor can trade back to U.S. dollars at the new exchange rate, and have 25, 600 USD... a nice profit! A portfolio investor who believes that the foreign exchange rate for the pound will work in the opposite direction can also invest accordingly. Say that an investor expects that the pound, now worth 1.50 USD, will decline to 1.40 USD. Then that investor could start off with 20, 000 in British pound (borrowing the money if necessary), convert it to 30, 000 USD, wait a month, and then convert back to approximately 21, 429 British poind making again making a nice profit! Of course, this kind of investing comes without guarantees, and an investor will suffer losses if the exchange rates do not move as predicted.

Many portfolio investment decisions are not as simple as betting that the value of the currency will change in one direction or the other. Instead, they involve firms trying to protect themselves from movements in exchange rates. Imagine you are running a U.S. firm that is exporting to France. You have signed a contract to deliver certain products and will receive 1 million euros a year from now. But you do not know how much this contract will be worth in USD, because the dollar/euro exchange rate can fluctuate in the next year. Let's say you want to know for sure what the contract will be worth, and not take a risk that the euro will be worth less in USD than it currently is. You can hedge, which means using a financial transaction to protect yourself against a risk from one of your investments (in this case, currency risk from the contract). Specifically, you can sign a financial contract and pay a fee that guarantees you a certain exchange rate one year from now regardless of what the market exchange rate is at that time. Now, it is possible that the euro will be worth more in dollars a year from now, so your hedging contract will be unnecessary, and you will have paid a fee for nothing. But if the value of the euro in dollars declines, then you are protected by the hedge. Financial contracts like hedging, where parties wish to be protected against exchange rate movements, also commonly lead to a series of portfolio investments by the firm that is receiving a fee to provide the hedge.

With the price of a typical good or service, it is clear that higher prices benefit sellers and hurt buyers, while lower prices benefit buyers and hurt sellers. In the case of exchange rates, where the buyers and sellers are not always intuitively obvious, it is useful to trace through how different participants in the market will be affected by a stronger or weaker currency. Consider, for example, the impact of a stronger USD on six different groups of economic actors, as shown in the table below:

Economic actors	**A stronger U.S. dollar**	**A weaker U.S. dollar**
A U.S. exporting firm	☹	☺
A foreign firm exporting to the U.S.	☺	☹
A U.S. tourist abroad	☺	☹
A foreign tourist in the U.S.	☹	☺
A U.S. investor abroad	☹	☺
A foreign investor in the U.S.	☺	☹

However, the foreign exchange value is not always determined by market forces, indeed, we distinguish 4 types of foreign exchange policies:

1. When the ForEx is completely determined by market forces, we speak of "floating exchange rates"
2. When the ForEx is usually determined by market, but central bank sometimes intervenes, we speak then of "soft exchange rate pegs"
3. When the ForEx is fixed at a certain level by in central bank we speak then of "hard exchange rate pegs"
4. When the currency of a country is made identical to the currency of another country we speak then of "merging currencies"

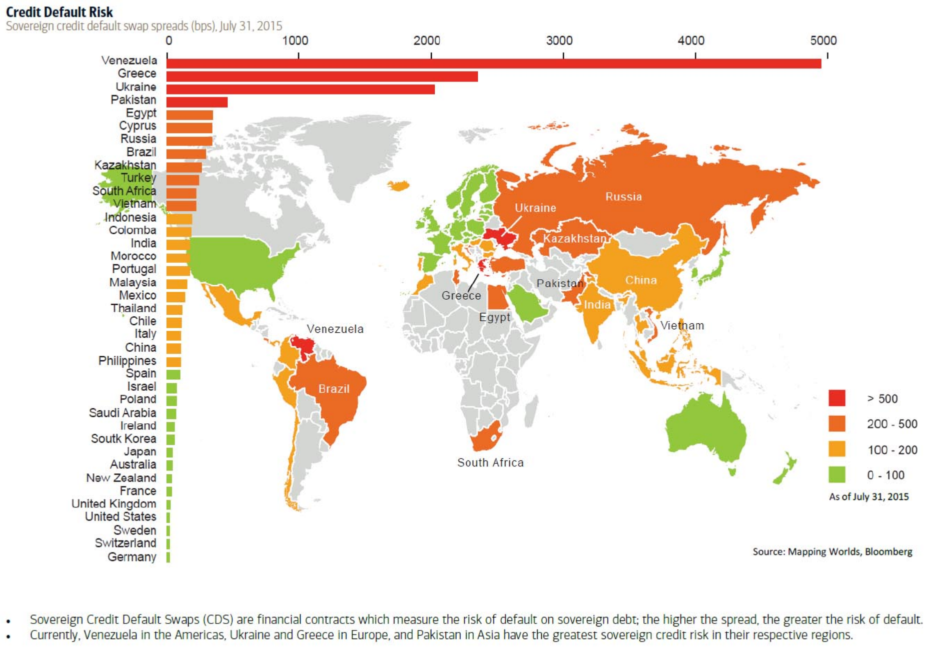
15.3.12 Credit default Risk

Credit risk is the risk involved in all transactions of borrowing and lending. If you lend money, what are the probabilities that the borrower will make the repayment? Credit risk then refers to the risk that the counterparty may fail to meet its obligations in the agreed terms. Quantifying it accurately is of immense importance to all: credit risk managers, regulators, and investors.

In case the borrower is likely to promptly return the money, then you have low credit risk, and in case there is a high probability of default than you have a high credit risk. So each borrowing and lending has its own element of risk involved.

Credit risk can be classified in the following way:

- "Credit default risk": The risk of loss arising from a debtor being unlikely to pay its loan obligations in full or the debtor is more than 90 days past due on any material credit obligation; default risk may impact all credit-sensitive transactions, including loans, securities and derivatives.
- "Concentration risk": The risk associated with any single exposure or group of exposures with the potential to produce large enough losses to threaten a bank's core operations. It may arise in the form of single name concentration or industry concentration.
- "Credit spread risk": The risk occurring due to volatility in the difference between investments' interest rates and the risk free return rate.
- "Country risk": The risk of loss arising from a sovereign state freezing foreign currency payment (transfer/conversion risk) or when it defaults on its obligations (sovereign risk).
- "Country spread risk": The risk occurring due to volatility in the difference between investments' interest rates and the risk free return rate.



Source: Mapping Worlds, Bloomberg

- Sovereign Credit Default Swaps (CDS) are financial contracts which measure the risk of default on sovereign debt; the higher the spread, the greater the risk of default.
- Currently, Venezuela in the Americas, Ukraine and Greece in Europe, and Pakistan in Asia have the greatest sovereign credit risk in their respective regions.

Figure 15.195: **Some countries spread risk**

If we have large enough databases on customer profiles or companies profiles it is possible to set up mathematical models allowing to assign a certain probability of credit default to an economic agent (the most common technique used in the 120th century - according to holocene calendar - being the logistic regression proved in the section of Numerical Methods at page 6449).

15.3.12.1 Credit spread risk

Financial institutions that do not have such databases or the analytical capacity or that just consider that others know how to do better refer most of the times to Standard & Poor's ratings for which a cumulative probability of default over several years i is associated with each rating (the years in the legend are given based on the holocene calendar):

Year/Ranking	AAA	AA	A	BBB	BB	B	CCC/C
1	0.00	0.01	0.04	0.29	1.28	6.24	32.35
2	0.00	0.03	0.13	0.86	3.96	14.33	42.35
3	0.04	0.08	0.26	1.48	7.32	21.57	48.66
4	0.07	0.16	0.43	2.37	10.51	27.47	53.65
5	0.12	0.26	0.66	3.25	13.36	31.81	59.49
6	0.21	0.40	0.90	4.15	16.32	35.47	62.19
7	0.31	0.56	1.16	4.88	18.84	38.71	63.37
8	0.48	0.71	1.41	5.60	21.11	41.69	64.10
9	0.54	0.83	1.71	6.21	23.22	43.92	67.78
10	0.62	0.97	2.01	6.95	24.84	46.27	70.8

Table 15.55: **Standard & Poor rating table between 11981 and 12004**

From the cumulated probability of being in bankrupt at year i, we can determine, as we shall see, the conditional probability of bankrupt at year i, knowing that we survived until year i (that is, the proportion who are insolvent in year i among those who are still "alive" at the beginning of year i).

If c_n is the cumulative probability of going bankrupt between the year 0 and the year n, then we have that $1-c_n$ which is of course the cumulative probability of having survived between year 0 and n. It comes then quite intuitively (we guess by extension that we can apply the biometric function techniques seen in the section of Dynamics of Populations to the study of Credit Risk default):

$$s_n=1-c_n=(1-c_{n-1})(1-d_n)=(1-c_{n-2})(1-d_{n-1})(1-d_n)=\prod_{i=1}^{n}(1-d_i) \qquad (15.3.1400)$$

Thus we immediately see that it is easy to obtain the conditional probability d_n of insolvency in year n among those who are still "alive" at the beginning of year n:

$$d_n=1-\frac{1-c_n}{1-c_{n-1}}=\frac{c_n-c_{n-1}}{1-c_{n-1}} \qquad (15.3.1401)$$

The trap here would be to make use not of conditional probabilities but to calculate the difference:

$$c_n-c_{n-1} \qquad (15.3.1402)$$

which corresponds to the proportion of insolvent firms in year n among all (those that have been insolvent and will be insolvent).

Moreover we can notice that this error is dangerous since from what we obtained above it follows immediately that:

$$d_n \geq c_n - c_{n-1} \tag{15.3.1403}$$

So as I always say: in any case all the risks that one calculates - that the mathematical model is estimated as correct or not - always underestimate the real risks because there exists a quantity of risk that one will not have thought or that one has rightly or wrongly considered it unlikely.

✍**Examples:**

E1. In the second year, for a company (or a country) rated BBB, we then have the conditional probability of default which is:

$$d_n = 1 - \frac{1-c_n}{1-c_{n-1}} = 1 - \frac{1-0.86\%}{1-0.29\%} \cong 0.86\% \tag{15.3.1404}$$

E2. A borrower is rated BBB and we know that in case of default we are to be assured to be able to recover at 37% of the sum invested (it is necessary to know that in practice this rate is also a statistical distribution ...). We can for example for 5 years maturity bonds and a total invested amount of 100 million and by taking in the previous rating table $c_5 = 3.25\%$ calculate that the estimated credit loss is then:

$$100 \cdot 10^6 \cdot 3.25\%(1-37\%) = 2,050,000.\text{-} \tag{15.3.1405}$$

There is a nice thing to notice when using this type of rating: indeed, the cumulative probability of default sometimes used by asset sellers can be estimated indirectly in comparison to risk-free returns and assuming the guaranteed $\%$ income in case of default. Let us see this with a simple case already partially known.

Suppose we want to update a zero coupon bond at the risk-free market rate. We then write as usual:

$$P = \frac{N}{(1+r)^n} \tag{15.3.1406}$$

where N is the nominal (often taken in practice as equal to 100.- as we already know).

For a zero coupon bond that has the cumulative probability c_n of default and denoting by f the guaranteed fraction of the amount in the case of default, a neutral risk market would naturally require that (the expression on the right of the equality is only an expected mean):

$$P = \frac{N}{(1+r)^n} = \frac{N}{(1+r_f)^n}(1-c_n) + \frac{fN}{(1+r_f)^n}c_n \tag{15.3.1407}$$

where r_f is the free risk market rate.

Therefore, by simplifying the nominal disappears:

$$(1+r_f)^n = (1+r)^n\left[(1-c_n)+fc_n\right] = (1+r)^n[1-c_n(1-f)] \tag{15.3.1408}$$

Thus we can play according to what we know to determine different parameters as for example for the most common and interesting cases:

$$\boxed{r=\frac{1+r_f}{\sqrt[n]{1-c_n(1-f)}}-1} \tag{15.3.1409}$$

where we notice for the both extreme cases that in accordance with intuition in the first case where the investment is 100% safe and in the second case where the investment is 100% risky:

$$\begin{gathered}r=\frac{1+r_f}{\sqrt[n]{1-0\%\cdot(1-f)}}-1=r_f\\ r=\frac{1+r_f}{\sqrt[n]{1-100\%\cdot(1-f)}}-1=\frac{1+r_f}{\sqrt[n]{f}}-1\xrightarrow[f\to 0]{}+\infty\end{gathered} \tag{15.3.1410}$$

So it makes sense that the higher our risk, the higher the required return.

We can also deduce the following very interesting equality (since it makes it possible to judge the reliability of a borrower):

$$\boxed{c_n=\frac{1}{1-f}\left[1-\left(\frac{1+r_f}{1+r}\right)^n\right]} \tag{15.3.1411}$$

With the frequent case $f=0$ where this obviously reduces to:

$$c_n=1-\left(\frac{1+r_f}{1+r}\right)^n \tag{15.3.1412}$$

It seems that some practitioner refer to the prior-previous relation as the "estimate reduced model of the implicit credit default".

15.3.12.2 Value At Risk equity coverage rating

The "VaR equity coverage rating" is based on the empirical basis that if an organization wishes to be rated in a certain way by Moody's then according to the Normal loss distribution model (but there are other far more pessimistic models that go so far to a multiple factor from 2 to 4) it can calculate the reserves it must have in order to enter a certain rating class.

Consider, for example, the following Moody's table:

Desired Rating (Moody's)	Probability of default to 1 year (α)	Corresponding Z
Aaa	0.01%	3.72
Aa1	0.02%	3.54
Aa2	0.02%	3.54
Aa3	0.03%	3.43
A1	0.05%	3.29
A2	0.06%	3.24
A3	0.07%	3.19
Baa1	0.13%	3.01
Baa2	0.16%	2.95
Baa3	0.70%	2.46
Ba1	1.25%	2.24
Ba2	1.79%	2.10
Ba3	3.96%	1.76
B1	6.14%	1.54
B2	8.31%	1.38
B3	15.08%	1.03

Table 15.56: Moody's one year risk default

Suppose now that an organization has its profit and loss account that historically has a standard deviation of $70,000$.-. Then the fractional reserves that it should have to be rated Aa2 are:

$$\text{VaR}_{\text{e.c.}} = \alpha\sigma = 3.54 \cdot 70000 = 247,800.\text{-} \tag{15.3.1413}$$

For the people interested here is a grid with the equivalence of different Risk Metrics:

Moody's		S&P		Fitch		
Long-term	**Short-term**	**Long-term**	**Short-term**	**Long-term**	**Short-term**	
Aaa	P-1	AAA	A-1+	AAA	F1+	Prime
Aa1		AA+		AA+		High grade
Aa2		AA		AA		
Aa3		AA-		AA-		
A1		A+	A-1	A+	F1	Upper medium grade
A2		A		A		
A3	P-2	A-	A-2	A-	F2	
Baa1		BBB+		BBB+		Lower medium grade
Baa2	Not prime	BBB	A-3	BBB	F3	
Baa3		BBB-		BBB-		
Ba1		BB+	B	BB+	B	Non-investment grade speculative
Ba2		BB		BB		
Ba3		BB-		BB-		
B1		B+		B+		Highly speculative
B2		B		B		
B3		B-		B-		
Caa1		CCC+	C	CCC	C	Substantial risks
Caa2		CCC				Extremely speculative
Caa3		CCC-				Default imminent with little prospect for recovery
Ca		CC C				
C				DDD		
/		D	/	DD	/	In default
/				D		

Table 15.57: Moody's, S&P and Fitch Riskmetrics

15.3.12.3 Altman Z-score

The "Z-score formula for predicting bankruptcy" was published in 11968 (holocene calendar) by Edward I. Altman, who was, at the time, an Assistant Professor of Finance at New York University. The formula may be used to predict the probability that a firm will go into bankruptcy within two years. Z-scores are used to predict corporate defaults and an easy-to-calculate control measure for the financial distress status of companies in academic studies. The Z-score uses multiple corporate income and balance sheet values to measure the financial health of a company.

The Z-score is a linear combination of four or five common business ratios, weighted by coefficients. The coefficients were estimated by identifying a set of firms which had declared bankruptcy and then collecting a matched sample of firms which had survived, with matching by industry and approximate size (assets).

Altman applied the statistical method of discriminant analysis to a dataset of publicly held manufacturers. The estimation was originally based on data from publicly held manufacturers, but has since been re-estimated based on other datasets for private manufacturing, non-manufacturing and service companies.

The original data sample consisted of 66 firms, half of which had filed for bankruptcy under Chapter 7 of the USA laws. All businesses in the database were manufacturers, and small firms with assets of $< \$1$ million were eliminated.

The original Z-score formula was as follows (there exist also some variation for private firms, non-manufacturers & emerging markets):

$$Z = 1.2X_1 + 1.4X_2 + 3.3X_3 + 0.6X_4 + 1.0X_5 \tag{15.3.1414}$$

with:

- X_1: Working capital / total assets. Measures liquid assets in relation to the size of the company.
- X_2: Retained earnings / total assets. Measures profitability that reflects the company's age and earning power.
- X_3: Earnings before interest and taxes / total assets. Measures operating efficiency apart from tax and leveraging factors. It recognizes operating earnings as being important to long-term viability.
- X_4: Market value of equity / book value of total liabilities. Adds market dimension that can show up security price fluctuation as a possible red flag.
- X_5: Sales / total assets. Standard measure for total asset turnover (varies greatly from industry to industry).

Based on the ranges of Z-scores, we can classify public firms into the following four categories:

Z-score range	Definition
> 3.0	Safe
2.7 to 2.99	On alert
1.8 to 2.7	Good chances of going bankrupt within two years
< 1.80	Probability of financial distress is very high

Table 15.58: **Altman's Z-score criteria ranges**

Eidelman (11975 according to holocene calendar) found that the Z-score correctly predicted 72% of bankruptcies two years prior to the event.

15.3.12.4 Merton's Distance to Default and KMV Expected Default Frequency

One measure to assess the credit risk of a firm is Distance to Default (DtD), which is measured as the difference between the asset value of the firm and the face value of its debt, scaled by the standard deviation of firm's asset value. It captures how many standard deviations away a firm is from the default. Higher values of DtD imply lesser likelihood of the firm to default on its credit obligations. The measure is derived using the structural default model of Merton (11974 according to holocene calendar), also referred to as the "Merton's model", which exploits the interpretation of equity as a Call option on the firm's underlying assets.

The KMV model for Kealhofer, McQuown and Vasicek, who found a company focusing on measuring default risks is an important example of industry model derive from Merton's one. It was first introduced in the late 11980's (according to holocene calendar) by and is one of the most important methods to estimate the probability of default for a given company by using its balance-sheet information and the equity-market information[32] (`http://www.moodyskmv.com`). Form a purely theoretical point of view, as we will prove it, the difference between KMV and Merton's models are not dramatic. The KMV model, however relies on an extensive empirical testing and it is implemented using a very large proprietary database.

The objective here will be to estimate the market value of total assets $\mathcal{A}$, and it corresponding volatility $\sigma_{\mathcal{A}}$. The basic idea is to treat the equity of a firm as a Call option and the debt (liabilities) $\mathcal{L}$ as its strike price.

Indeed, suppose $\mathcal{A}$ is the value of the company and $\mathcal{L}$ is the face value of the liabilities. If a firm has a debt (or liability[33]) of 80.- and an equity of 20.-, then the total assets will be $\mathcal{E}=\mathcal{A}-\mathcal{L}=100$.- Assume that the assets jump to 110.-. The debt remains the same while the equity increases to 30.-. On the other hand, if the assets drop to 90.-, the equity $\mathcal{E}$ will be only 10.-. Since the equity holders are the residual claimer, their value position in one year is then:

$$\boxed{\mathcal{E}=\max(\mathcal{A}-\mathcal{L},0)} \qquad (15.3.1415)$$

This is the payoff from a Call option on $\mathcal{A}$ with strike price $\mathcal{L}$. Obviously, the idea it that the default occurs when the value of the firm $\mathcal{A}$, goes below the outstanding debt $\mathcal{L}$ (credit risk is driven by the firm value process).

---

[32] Still in the beginning of the 121st century (holocene calendar), a large number of world financial institutions are subscriber of the model.

[33] The debt refers to borrowed money; the liabilities to an obligation of any kind. All debts are liabilities, but not all liabilities are debts.

Remark

Let us recall that for a Call option, we have the following payoff function:

$$\text{Payoff (Call)} = \max(S_T - K, 0) \quad (15.3.1416)$$

and more generally:

Rule	**Payoff** **(lower limit of the purchase / respectively sale price)**
Call Buyer	$\max(S_T - K, 0)$
Call Seller	$-\max(S_T - K, 0)$
Put Buyer	$\max(K - S_T, 0)$
Put Seller	$-\max(K - S_T, 0)$

The debt (liabilities) holder get:

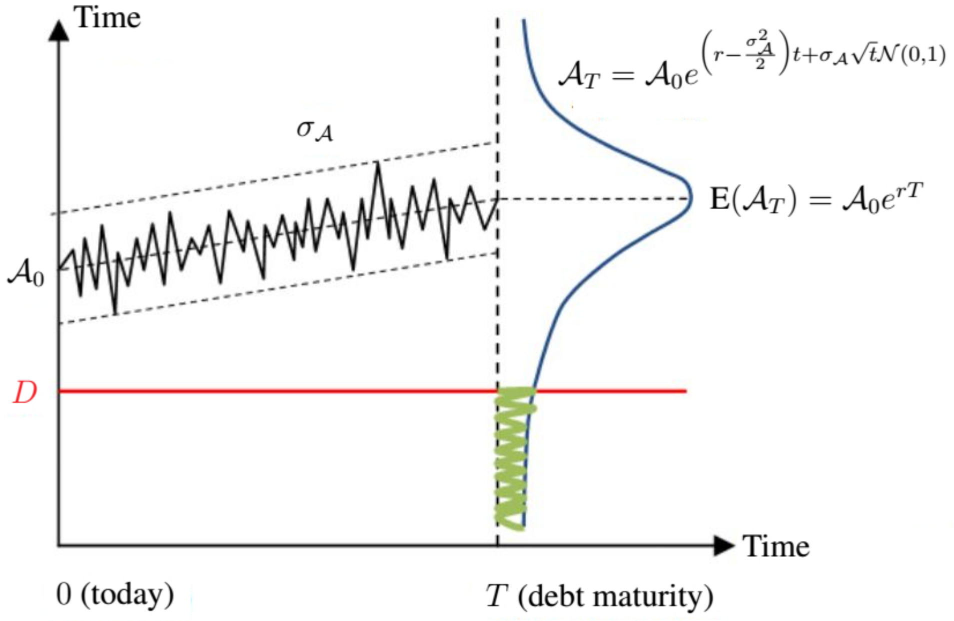
$$\min(\mathcal{A}, \mathcal{L}) = \mathcal{L} - \max(\mathcal{L} - \mathcal{A}, 0) \quad (15.3.1417)$$

Is equivalent to a risk debt $\mathcal{L}$ plus a short guarantee on the assets of the borrower.

Following Merton's model for the valuation of corporate securities we usually consider a simplified case of a firm with risky assets valued today by the market at $\mathcal{A}_0$ level. The value at time t in the future $\mathcal{A}_t$ is uncertain, due to many external and internal factors (economic risk, business risk, foreign exchange risk, industry risk, etc.). Typically we assume, that the returns on the firm's as-sets are distributed normally and their behaviour can be described with Brownian motion formulation (diffusion expression):

$$\frac{\mathrm{d}\mathcal{A}_t}{\mathcal{A}_t} = \mu_\mathcal{A}\mathrm{d}t + \sigma_\mathcal{A}\mathrm{d}W \Leftrightarrow \mathrm{d}\mathcal{A}_t = \mu_\mathcal{A}\mathcal{A}_t\mathrm{d}t + \sigma_\mathcal{A}\mathcal{A}_t\mathrm{d}W \quad (15.3.1418)$$

The symbol $\sigma_\mathcal{A}$ stands for constant assets volatility and $\mu_\mathcal{A}$ for constant drift. Value $\mathrm{d}W$ denotes for random value taken from standardized Normal distribution:



Time
$\sigma_\mathcal{A}$
$\mathcal{A}_T = \mathcal{A}_0 e^{\left(r-\frac{\sigma_\mathcal{A}^2}{2}\right)t+\sigma_\mathcal{A}\sqrt{t}\mathcal{N}(0,1)}$
$\mathrm{E}(\mathcal{A}_T) = \mathcal{A}_0 e^{rT}$
$\mathcal{A}_0$
D
Time
0 (today)
T (debt maturity)

Consequently, the firm's assets value assumed to obey a log-normal diffusion process with a constant volatility is given by:

$$\mathcal{A}_T=\mathcal{A}_0 e^{\left(r-\frac{\sigma_{\mathcal{A}}^2}{2}\right)t+\sigma_{\mathcal{A}}\sqrt{t}\mathcal{N}(0,1)} \tag{15.3.1419}$$

The expected value of the assets at the time t can be given by:

$$\mathrm{E}(\mathcal{A}_t)=\mathcal{A}_0 e^{rt} \tag{15.3.1420}$$

That means that we can treat equity E as a Call option with debt as exercise price. With appropriate notations, we will have the following relations for a firm's equity. KMV model is then defined as below (under the same important assumptions as the Black-Scholes model!!!):

$$\mathcal{E}=C^{\text{BS}}\left(\mathcal{A}_T,\mathcal{L},T,\sigma_{\mathcal{A}},r\right)=\mathcal{A}\Phi\left(d_1\right)-\mathcal{L}e^{-rT}\Phi\left(d_2\right) \tag{15.3.1421}$$

With for recall:

$$d_1=\frac{\ln\left(\dfrac{\mathcal{A}}{\mathcal{L}}\right)+\left(r+\dfrac{1}{2}\sigma_{\mathcal{A}}^2\right)T}{\sigma_{\mathcal{A}}\sqrt{T}} \tag{15.3.1422}$$

$$d_2=d_1-\sigma_{\mathcal{A}}\sqrt{T} \tag{15.3.1423}$$

Let us recall now the diffusion expression:

$$\mathrm{d}\mathcal{E}=\mu_{\mathcal{E}}\mathcal{E}\mathrm{d}t+\sigma_{\mathcal{E}}\mathcal{E}\mathrm{d}W \tag{15.3.1424}$$

and let us write Itō's lemma:

$$\begin{aligned}\mathrm{d}\mathcal{E}&=\frac{\partial\mathcal{E}}{\partial\mathcal{A}}\mathrm{d}\mathcal{A}+\frac{\partial\mathcal{E}}{\partial t}\mathrm{d}t+\frac{1}{2}\sigma_{\mathcal{E}}^2\mathcal{A}^2\frac{\partial^2\mathcal{E}}{\partial\mathcal{A}^2}(\mathrm{d}\mathcal{A})^2\ldots\\&\cong\left(\frac{1}{2}\sigma_{\mathcal{A}}^2\mathcal{E}^2\frac{\partial^2\mathcal{E}}{\partial\mathcal{A}^2}+\mu_{\mathcal{A}}\mathcal{A}\frac{\partial\mathcal{E}}{\partial\mathcal{A}}+\frac{\partial\mathcal{E}}{\partial t}\right)\mathrm{d}t+\sigma_{\mathcal{A}}\mathcal{A}\frac{\partial\mathcal{E}}{\partial\mathcal{A}}\mathrm{d}W\end{aligned} \tag{15.3.1425}$$

When we compare diffusion expressions shown in the two previous relations, then we can regain the relationship that:

$$\sigma_{\mathcal{E}}\mathcal{E}=\sigma_{\mathcal{A}}\mathcal{A}\frac{\partial\mathcal{E}}{\partial\mathcal{A}} \tag{15.3.1426}$$

Therefore:

$$\sigma_{\mathcal{E}}=\sigma_{\mathcal{A}}\frac{\mathcal{A}}{\mathcal{E}}\frac{\partial\mathcal{E}}{\partial\mathcal{A}} \tag{15.3.1427}$$

But we know recognize here the delta Δ and we know it's worth $\Phi(d_1)$, hence:

$$\sigma_{\mathcal{E}}=\sigma_{\mathcal{A}}\frac{\mathcal{A}}{\mathcal{E}}\Delta=\sigma_{\mathcal{A}}\frac{\mathcal{A}}{\mathcal{E}}\Phi(d_1) \tag{15.3.1428}$$

In practice, $\mathcal{E}$, $\sigma_{\mathcal{E}}$, $\mathcal{A}$, T, r are known. To compute $\mathcal{A}$ and $\sigma_{\mathcal{A}}$, we have to solve the system of two non-linear equations:

$$\begin{cases}\mathcal{E}=\mathcal{A}\Phi\left(d_1\right)-\mathcal{L}e^{-rT}\Phi\left(d_2\right)\\ \sigma_{\mathcal{E}}=\sigma_{\mathcal{A}}\dfrac{\mathcal{A}}{\mathcal{E}}\dfrac{\partial\mathcal{E}}{\partial\mathcal{A}}\end{cases} \tag{15.3.1429}$$

to minimize the sum of square error:

$$\boxed{\begin{aligned}&\underset{\mathcal{A},\sigma_{\mathcal{A}}}{\text{minimize}}\ \text{TSSE}=\text{SSE}_1+\text{SSE}_2\\&\qquad\qquad=\left(\mathcal{E}-\mathcal{A}\Phi\left(d_1\right)-\mathcal{L}e^{-rT}\Phi\left(d_2\right)\right)^2+\left(\sigma_{\mathcal{E}}-\sigma_{\mathcal{A}}\frac{\mathcal{A}}{\mathcal{E}}\frac{\partial\mathcal{E}}{\partial\mathcal{A}}\right)^2\\&\text{subject to }\mathcal{A}\geq 0\quad\sigma_{\mathcal{A}}>0\end{aligned}}\tag{15.3.1430}$$

Remark

We can test the result obtained of $\mathcal{A}$ and $\sigma_{\mathcal{A}}$ by plugging back these values into the Black-Scholes options pricing relation. We then compare the obtained value of the option price with the market value of the equity firm. In principal, the two should be the same.

Once the value of $\mathcal{A}$ and $\sigma_{\mathcal{A}}$ are obtained, the "Distance to Default" (DtD) is computed, as already mentioned earlier, in its naive version by:

$$\boxed{\text{DtD}=\frac{\mathcal{A}-\mathcal{L}}{\mathcal{A}\sigma_{\mathcal{A}}}}\tag{15.3.1431}$$

That means the number of standard deviations between the expected asset value at maturity T and the liability threshold $\mathcal{A}$ (that can obviously be chosen rather than calculated if necessary).

We can calculate the probability of DtD by remembering first that:

$$\frac{\mathrm{d}\mathcal{A}}{\mathcal{A}}=r\mathrm{d}t+\sigma_{\mathcal{A}}\sqrt{t}\mathrm{d}Z_t\tag{15.3.1432}$$

Hence (DPT means "Default Point Threshold"):

$$\begin{aligned}P\left(\mathcal{A}\leq\text{DPT}_T\right)&=P\left(\mathcal{A}_0e^{(r-\frac{\sigma_{\mathcal{A}}}{2})T+\sigma_{\mathcal{A}}\sqrt{T}Z_T)}\leq\text{DPT}_T\right)\\&=P\left(\ln(\mathcal{A}_0)+\left(r-\frac{\sigma_{\mathcal{A}}^2}{2}\right)T+\sigma_{\mathcal{A}}\sqrt{T}Z_T\leq\ln(\text{DPT}_T)\right)\\&=P\left(Z_T\leq-\frac{\ln\left(\dfrac{\mathcal{A}_0}{\text{DPT}_T}\right)+\left(r-\dfrac{\sigma^2}{2}\right)T}{\sigma_{\mathcal{A}}\sqrt{T}}\right)=\Phi\left(-d_2^*\right)\end{aligned}\tag{15.3.1433}$$

with:

$$d_2^*=\frac{\ln\left(\dfrac{\mathcal{A}_0}{\text{DPT}_T}\right)+\left(r-\dfrac{\sigma_{\mathcal{A}}^2}{2}\right)T}{\sigma_{\mathcal{A}}\sqrt{T}}\tag{15.3.1434}$$

And it's not uncommon to find the definition of the DtD as the following quantity in the literature:

$$\text{DtD}=-\frac{\ln\left(\dfrac{\mathcal{A}_0}{\text{DPT}_T}\right)+\left(r-\dfrac{1}{2}\sigma_{\mathcal{A}}^2\right)T}{\sigma_{\mathcal{A}}\sqrt{T}}\tag{15.3.1435}$$

Therefore the relationship between DtD and DP (default probability) is given by "Merton's DP":

$$\boxed{\mathrm{DP}=\Phi(\mathrm{DtD})=\Phi\left(-\frac{\ln\left(\dfrac{\mathcal{A}_0}{\mathrm{DPT}_T}\right)+\left(r-\dfrac{1}{2}\sigma_{\mathcal{A}}^2\right)T}{\sigma_{\mathcal{A}}\sqrt{T}}\right)} \tag{15.3.1436}$$

From the symmetry of the Normal distribution, we know that:

$$\Phi(x)=1-\Phi(-x):=\bar{\Phi}(-x) \tag{15.3.1437}$$

Hence we can write:

$$\mathrm{DP}=\bar{\Phi}(-\mathrm{DtD})=\bar{\Phi}\left(\frac{\ln\left(\dfrac{\mathcal{A}_0}{\mathrm{DPT}_T}\right)+\left(r-\dfrac{1}{2}\sigma_{\mathcal{A}}^2\right)T}{\sigma_{\mathcal{A}}\sqrt{T}}\right) \tag{15.3.1438}$$

If we put $T=1$ we just get:

$$\mathrm{DP}=\bar{\Phi}(-\mathrm{DtD})=\bar{\Phi}\left(\frac{\ln\left(\dfrac{\mathcal{A}_0}{\mathrm{DPT}}\right)+\left(r-\dfrac{1}{2}\sigma_{\mathcal{A}}^2\right)}{\sigma_{\mathcal{A}}}\right) \tag{15.3.1439}$$

That is nothing but the probability that a given firm will default within 1 year according to the KMV methodology. So the 1 year DP is named the "Expected Default Frequency" and abbreviated EDF$^{\text{TM}}$.

Remark

You don't dream... EDF$^{\text{TM}}$ is indeed a registered trademark! But in reality, the real KMV model is supposed to have the $\bar{\Phi}$ that is replaced with some empirical unknown function (as for most industry models, some specific parameters and implementations of the model are not completely known, and we can simply rely on what the company allows us to discover).

Now let us see a very suspicious development that is supposed to justify the definition of the DtD that you can find in some textbooks or presentations... Focus on:

$$\frac{\ln\left(\dfrac{\mathcal{A}_0}{\mathrm{DPT}_T}\right)+\left(r-\dfrac{1}{2}\sigma_{\mathcal{A}}^2\right)T}{\sigma_{\mathcal{A}}\sqrt{T}} \tag{15.3.1440}$$

Some empirical research seems to have shown that the quantity $r-\frac{1}{2}\sigma_{\mathcal{A}}^2$ is usually very close to zero. Given this, we have:

$$\frac{\ln\left(\dfrac{\mathcal{A}_0}{\mathrm{DPT}_T}\right)+\left(r-\dfrac{1}{2}\sigma_{\mathcal{A}}^2\right)T}{\sigma_{\mathcal{A}}\sqrt{T}}\cong\frac{\ln\left(\dfrac{\mathcal{A}_0}{\mathrm{DPT}_T}\right)}{\sigma_{\mathcal{A}}\sqrt{T}} \tag{15.3.1441}$$

If we take $T=1$, this reduces to:

$$\frac{\ln\left(\dfrac{\mathcal{A}_0}{\text{DPT}}\right)}{\sigma_{\mathcal{A}}} \tag{15.3.1442}$$

So far... everything seems acceptable. But now comes the crazy part... Indeed, let us assume that $\mathcal{A}_0 \cong \text{DPT}$ (hummmm....), using the first order Taylor series of $\ln(x)$ at $x\cong 1$ we then have (very rough approximation!!!!):

$$\frac{\ln\left(\dfrac{\mathcal{A}_0}{\text{DPT}}\right)}{\sigma_{\mathcal{A}}} \cong \frac{\dfrac{\mathcal{A}_0}{\text{DPT}}-1}{\sigma_{\mathcal{A}}} = \frac{\mathcal{A}_0-\text{DPT}}{\text{DPT}\sigma_{\mathcal{A}}} \tag{15.3.1443}$$

And now comes the even more crazy stuff... (only some very rare documents on the KMV do that...), as $\mathcal{A}_0 \cong \text{DPT}$, why not just write:

$$\frac{\mathcal{A}_0-\text{DPT}}{\text{DPT}\sigma_{\mathcal{A}}} \cong \frac{\mathcal{A}_0-\text{DPT}}{\mathcal{A}_0\sigma_{\mathcal{A}}} \tag{15.3.1444}$$

And after all this successive rough approximation and suspicious substitution of variables, we recognize here the DtD...

15.3.13 Time Series Analysis

The main goal of "time series analysis" (TSA) is not to link variables together, but to focus on the dynamics of a unique variable in time to discover some regularities in order to extrapolate or to forecast under the assumption that we can connect an observation with those that preceded it[34].

Therefore the difference between times series and econometric models differs from the fact that times series models do not start with a conceptual framework that defines the relationship between the economic variable and economic theory. Time series models use a variable's own history values to estimate the future values of the same variable as a hypothetical description process.

With a fine analysis, it is even possible to make "robust" forecasting vis-à-vis sudden breaks and non-anticipated changes.

Remark

This study domain is often named "Business Intelligence" in companies (this is a sub-family in fact limited to descriptive elementary statistics that should be named "Business Facts" instead... as we have described during our study of Data Mining at page 6768). A variable analysed using TSA tools will be named a "Key Performance Indicator" (KPI) and a set of KPI a "dashboard".

Figure 15.196: **Bloomberg$^{\text{TM}}$ terminal KPI's dashboard**

---

[34] For anyone wishing to deepen and having a more rigorous presentation of time series analysis than the present book we strongly recommend the lecture of the 800 pages master piece *Time Series Analysis* of J.D. Hamilton ([428])!

But there are some other typical tasks in Time Series Analysis apart from forecasting (some of the techniques below were already treated in details in some other chapters of this textbook):

- Cross-correlation/Clustering of time series
- Auto-correlation
- Similarity (pattern matching)
- Anomaly detection/removal
- Gap filling
- Detrending
- Smoothing/Denoising
- Decomposition
- Normalization
- Spectrum Analysis
- ...

Definition (#15.3.700): A "discrete time series" or "discrete chronological series" is a series of observations Y_t of a variable y at different dates t. Usually the basis space t is countable, so that $t = 1 \ldots T$. The whole being denoted:

$$\{Y_T\}_{t=1}^{T} \tag{15.3.1445}$$

and sometimes the capital Y is denoted by X (anyway it doesn't really matter...).

Remark

We differentiate significantly models that predict real values (values in $\mathbb{R}$) of those who can only predict purely integer values (count data belonging to $\mathbb{N}$). To this date, the content of this textbook deals only with models especially suitable for continuous TSA variables.

A time series is thus every sequence of observations corresponding to the same variable: it can comes to macroeconomic data (GDP of a country, inflation, exports), microeconomics (sales of a given company, number of employees, the income of an individual, the production quantity...), financial (the CAC 40, S&P 500, the price of a Call option or Put option, the course of stock), weather (rainfall, number of sunny days per year,...), political (the number of voters, of votes received by a candidate ...), demographic (the average size of population, age, the propagation of an epidemy...).

In practice, all that is quantifiable and vary over time can be analysed relatively efficiently by TSA since the person handling the model should knows what she does (which is quite rare in reality...). But the reader must keep in mind that Economics and Finance ask many questions to which the answers are more difficult and complex than those often pondered in mathematics and physics. For example, economic agents can react to economic forecasts, which makes predicting the stock market even harder than predicting the weather. Imagine how much more difficult it would be for meteorologists to forecast if the weather could read its own forecast and then change its behaviour because it reads the weather forecast!

Therefore in finance we use these models to forecast returns, volatility (standard deviation), resupply stocks, demand, VaR and so on. In short, there really are no limits to the application of TSA.

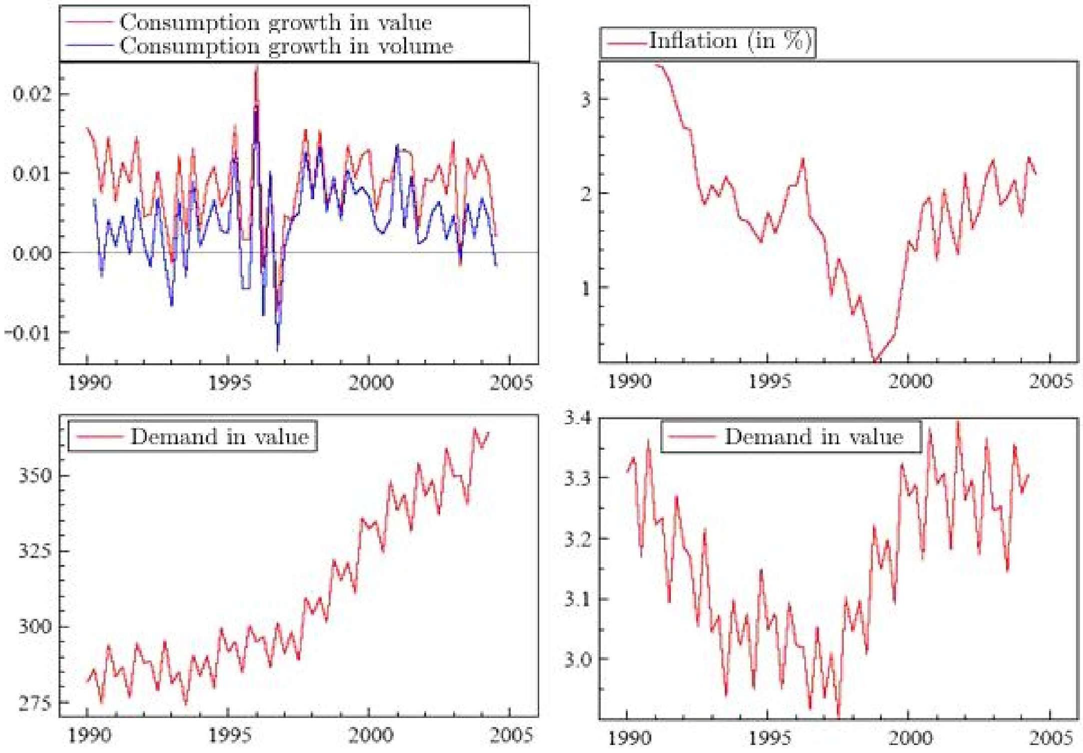

Figure 15.197: Some time series without forecasting

The time dimension is important here because it is the analysis of a historical chronicle: the variations of the same variable over time in the purpose to understand its dynamics. We generally represent 2D time series on value charts (ordinate) versus time (abscissa). Such observation is an essential tool that allows the modeller with little experience to immediately realize the main dynamic properties to see what statistical test practice (at least in the univariate and bivariate case...). The previous figure shows different time series as examples.

A time series is divided mainly into four basic components:

- The "secular long-term trend" or simply "trend". It corresponds to a non-seasonal cyclical movement that reflects the long-term evolution of the measured variable (can be linear or not).
- The "seasonal variations" that are periodic fluctuations that occur regularly (periodically: days, months, quarters, years or more...).
- The "hazards" or "residual/incidental variations" or "irregularities" are random type fluctuations, generally of low amplitude.

Definitions (#15.3.701):

D1. The series which oscillate around their average are named "stationary series" (we'll see a rigorous definition of this further below).

D2. The series that seem to grow (bullish) or fall (bearish) on all of the observed sample are named "trend series" or "short history" and their averages are not constant.

D3. The series that are neither stationary nor bullish or bearish on the long term trend are named "non-stationary series" or "random series" or "stochastic series". Any process whose time evolution can be analysed in terms of probability is named as we know "stochastic process".

D4. The series which have a regular frequency fluctuation are named "seasonal series" Regularly, stationary series are trend series with a periodic component.

D5. The series that seem to be seasonal or appear to have a seasonal component but whose frequency is variable, are named "cyclic series".

D6. A times series that has a significant jump (variation) at one moment in time is say to have a "level shift".

D7. A times series that has a significant jump (variation) at various moment in time and fall back to zero after every jump is "intermittent series".

Given y_t a value of the time series, t_t its trend component, s_t its seasonal component and ε_t its random part, we define:

Definitions (#15.3.702):

D1. An "additive model by an expression like:

$$\boxed{Y_t = t_t + s_t + \varepsilon_t} \tag{15.3.1446}$$

where $\{s_t\}$ is periodic with period T that is $s_{t-T} = s_t \forall t$.

D2. A "simple multiplicative model" by an expression like:

$$\boxed{Y_t = t_t(1 + s_t) + \varepsilon_t} \tag{15.3.1447}$$

where we have the seasonal component that is then related to the trend component (as opposed to the additive model where the seasonal component is the same from multiple periods to another).

D3. A "complete multiplicative model" by an expression like:

$$\boxed{Y_t = t_t(1 + s_t)(1 + \varepsilon_t)} \tag{15.3.1448}$$

D4. A "mixed model" by an expression like:

$$\boxed{Y_t = t_t(1 + s_{1,t}) + s_{2,t} + \varepsilon_t} \tag{15.3.1449}$$

The characteristics of these graphs are all modelled and analysed in the context of time series analysis. For this there exists are more or less complex tools, some of which can not be doubted and others of which are heuristics and need to be handle and use with caution.

In the text that follows, we will look to the elementary models available without a heavy mathematical artillery.

Humility in the forecaster's job is however set to accept the mistake repeatedly, while seeking to improve the quality of its forecasts (sales, market volatility, correlation of assets, etc.) and identification of non-random components phenomena. It is important to remember the following four criteria:

1. The forecasts are generally not accurate. We need a robust ecosystem to react quickly to the unexpected events (that we can't predict! that doesn't mean that we can not take advantage of the unpredictable) and this especially true when we know that some multinationals and governments (which I will not give the name ...) request projections over twenty months or sometimes fifteen years...!!!).
2. A good forecast is more than a numerical value!!Because forecasts are generally not accurate, a good forecast should ALWAYS include a measurement (or plot) of expected error for prediction (confidence interval). It is obvious that most of time the confidence interval (prediction errors) increases as we move further into the future!!!!
3. Aggregate forecasts are in general more accurate (yes we know this from the properties of the variance of an average). In general, we notice that the error made to the sales forecast of a line of products is generally less than the error made in the sales forecast of a single element.
4. Long-term forecasts are less accurate. There is not much to say because it's intuitive...
5. Forecasts can be sensitive to initial conditions (think of the chaotic patterns in meteorology or population dynamics...).

Remark

Examples of where large multinational executives or governments have, for lack of statistical knowledge or misguided by non-statisticians managers / non-economists made projections of earnings or sales over ten to twenty years (this is an aberration!!), without confidence interval are legion! Obviously the values communicated and the associated development strategies led some of these multinationals and governments to go bankrupt.

Let us notice that quantitative forecasting techniques also use mainly the following tools (it is of course possible to combine them) for which we have already given examples in the respective mentioned chapters in parenthesis:

- Simple random walk (see section Thermodynamics page 3582)
- Simple linear regression (see section Numerical Methods page 6322)
- Multiple linear regression (see section Numerical Methods page 6379)
- General linear models (see section Numerical Methods page 6530)
- Logistic regression (see section Numerical Methods page 6449)
- Polynomial interpolation (see section Numerical Methods page 6594)

- Logarithmic and exponential linearisation (see section Numerical Methods page 6323)
- Modelling by Brownian motion (see section Mechanics page 7765)
- Moving Average (see section Statistics page 7919)
- Correlation Analysis (see section Statistics page 613)
- Control Charts (see section Industrial Engineering page 8934)
- Jackknife or Bootstrapping regression (see section Numerical Methods page 6747 page 6740)
- Neural Networks[35] (see section Numerical Methods page 6951)
- Fourier Transform (see section Sequences and Series page 1758)

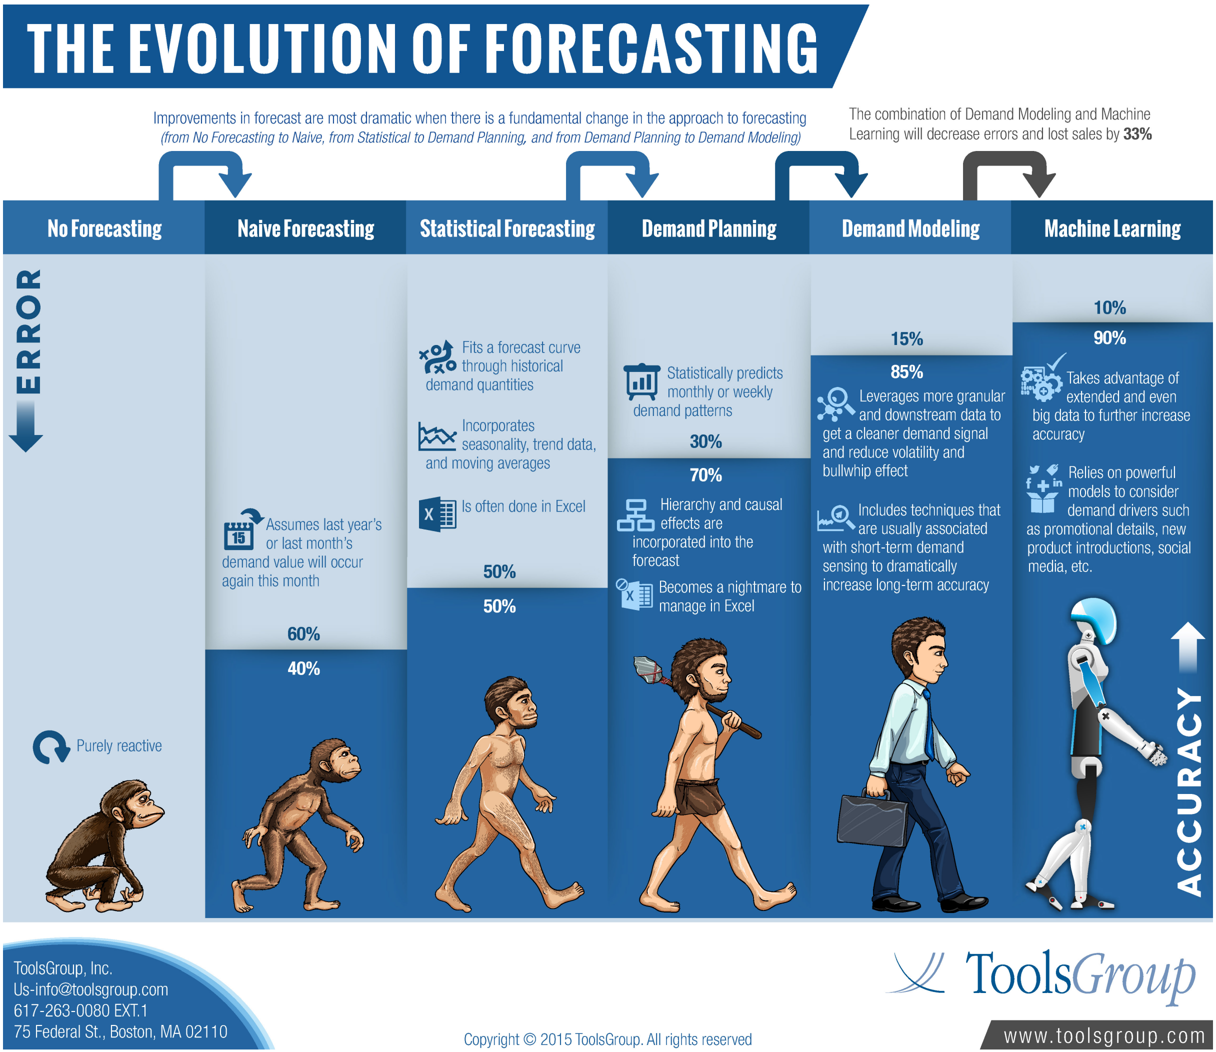
and they can be grouped into five main families (not mutually exclusive!):

1. Causes & effects models based on several variables
2. Time-series models whose only explanatory variable is time
3. Permutations simulations
4. Machines Learning modelization
5. Spectral Analysis

and it is always difficult for forecasters to choose which is the best suited model to his working framework and the level of understanding of his superiors and colleagues. The interesting part of the job is that once the model(s) selected (quite hard to choose from the hundreds of published empirical models...), we can compare them with past statistical data of the company and see if predictions are in agreement with what had really happened (i.e. run some back-testing).

---

[35] Especially recurrent neural networks (RNN) - that their are vanilla RNN (i.e. short term) or long short-term memory (LSTM) - or autoregressive neural networks (ANN).



THE EVOLUTION OF FORECASTING
Improvements in forecast are most dramatic when there is a fundamental change in the approach to forecasting
(from No Forecasting to Naive, from Statistical to Demand Planning, and from Demand Planning to Demand Modeling)
The combination of Demand Modeling and Machine Learning will decrease errors and lost sales by 33%
No Forecasting
Naive Forecasting
Statistical Forecasting
Demand Planning
Demand Modeling
Machine Learning
ERROR
Purely reactive
Assumes last year's or last month's demand value will occur again this month
15
60%
40%
Fits a forecast curve through historical demand quantities
Incorporates seasonality, trend data, and moving averages
Is often done in Excel
50%
50%
Statistically predicts monthly or weekly demand patterns
30%
70%
Hierarchy and causal effects are incorporated into the forecast
Becomes a nightmare to manage in Excel
15%
85%
Leverages more granular and downstream data to get a cleaner demand signal and reduce volatility and bullwhip effect
Includes techniques that are usually associated with short-term demand sensing to dramatically increase long-term accuracy
10%
90%
Takes advantage of extended and even big data to further increase accuracy
Relies on powerful models to consider demand drivers such as promotional details, new product introductions, social media, etc.

Remark

It is preferable to use statistical based models based rather than deterministic models that are of poor quality (as the simple moving average or double exponential smoothing).

15.3.13.1 Type of Errors

Before building predictive models we must be able to estimate the quality thereof (for comparison purposes between models) and it is customary to use several empirical indicators.

Measuring forecast accuracy (or error) is not an easy task as there at the time we write these line no one-size-fits-all indicator. Only experimentation will show us what Key Performance Indicator (KPI) is best for us. As we will see, each indicator will avoid some pitfalls but will be prone to others.

- The "forecast error":

  $$e_t = Y_t - \hat{Y}_t \qquad (15.3.1450)$$

  which is the difference between the relation value Y_t and the value given by the model $\hat{Y}_t$.

- The "mean error" or "forecasting bias":

  $$\text{ME} = \frac{1}{n}\sum_{t=1}^{n} e_t \qquad (15.3.1451)$$

  that will only tell us if there is a positive or negative bias between the forecast and the real values (because if the value ME is not null then the model is biased). As a positive error on one item can offset a negative error on another item, a forecast model can achieve very low bias and not be precise at the same time. Obviously, the bias alone won't be enough to evaluate your forecast precision. But a highly biased forecast is already an indication that something is wrong in the model.

  As the mean error is often very small (negative values balancing the positive in some models) we prefer the next following measurement below.

- The "Average Absolute Deviation" (named also "Mean Absolute Deviation" or "Mean Absolute Error" or "Mean Forecast Error"):

  $$\text{MAD} = \text{MAE} = \text{MFE} = \frac{1}{n}\sum_{t=1}^{n} |e_t| \qquad (15.3.1452)$$

  which is the mean of the absolute errors made by the forecasting model on the duration of it, notwithstanding the fact that the error is overestimate or underestimate.

- The "Average Squared Residuals" (also named "Mean Square Deviation" or "Mean Square Errors"):

  $$\text{MSD} = \text{MSE} = \frac{1}{n}\sum_{t=1}^{n} e_t^2 \qquad (15.3.1453)$$

  allowing to penalize the large errors more than the small errors since each is multiplied by itself, giving a greater weight to large errors than to small errors.

  The problem with the previous indicators is that the magnitude of the error depends on the amplitudes of the analysed values. To avoid this, it is more interesting to work with a percentage (relative value). Thus, we define the "relative error" or "percentage error" indicated in percent by:

$$\text{PE}_t = \frac{Y_t - \hat{Y}_t}{Y_t} = \frac{e_t}{Y_t} \qquad (15.3.1454)$$

which is the difference in percent between the real values and modelling one. It follows then the "Mean Relative Error", also named "Relative Bias of Prediction" or "Mean Percentage Error", always indicated in percents:

$$\text{MPE} = \frac{1}{n}\sum_{t=1}^{n} \text{PE}_t \qquad (15.3.1455)$$

For the same reasons that for the ME we prefer the following indicator error:

- The "Relative Absolute Average Deviation" also named "Mean Absolute Percentage Error" always indicated in percents:

$$\text{MAPE} = \frac{1}{n}\sum_{t=1}^{n} |\text{PE}_t| \qquad (15.3.1456)$$

The only problem with the relative indicators is when the analysed time series contains zeros...

Here is a guide for decision making relatively to this indicator:

MAPE	Forecasting power
$<10\%$	Highly accurate forecasting
$10\% \sim 20\%$	Good forecasting
$20\% \sim 50\%$	Reasonable forecasting
$>50\%$	Weak and inaccurate forecasting

Table 15.59: **Various MAPE value decision guide (source: Lewis 11982)**

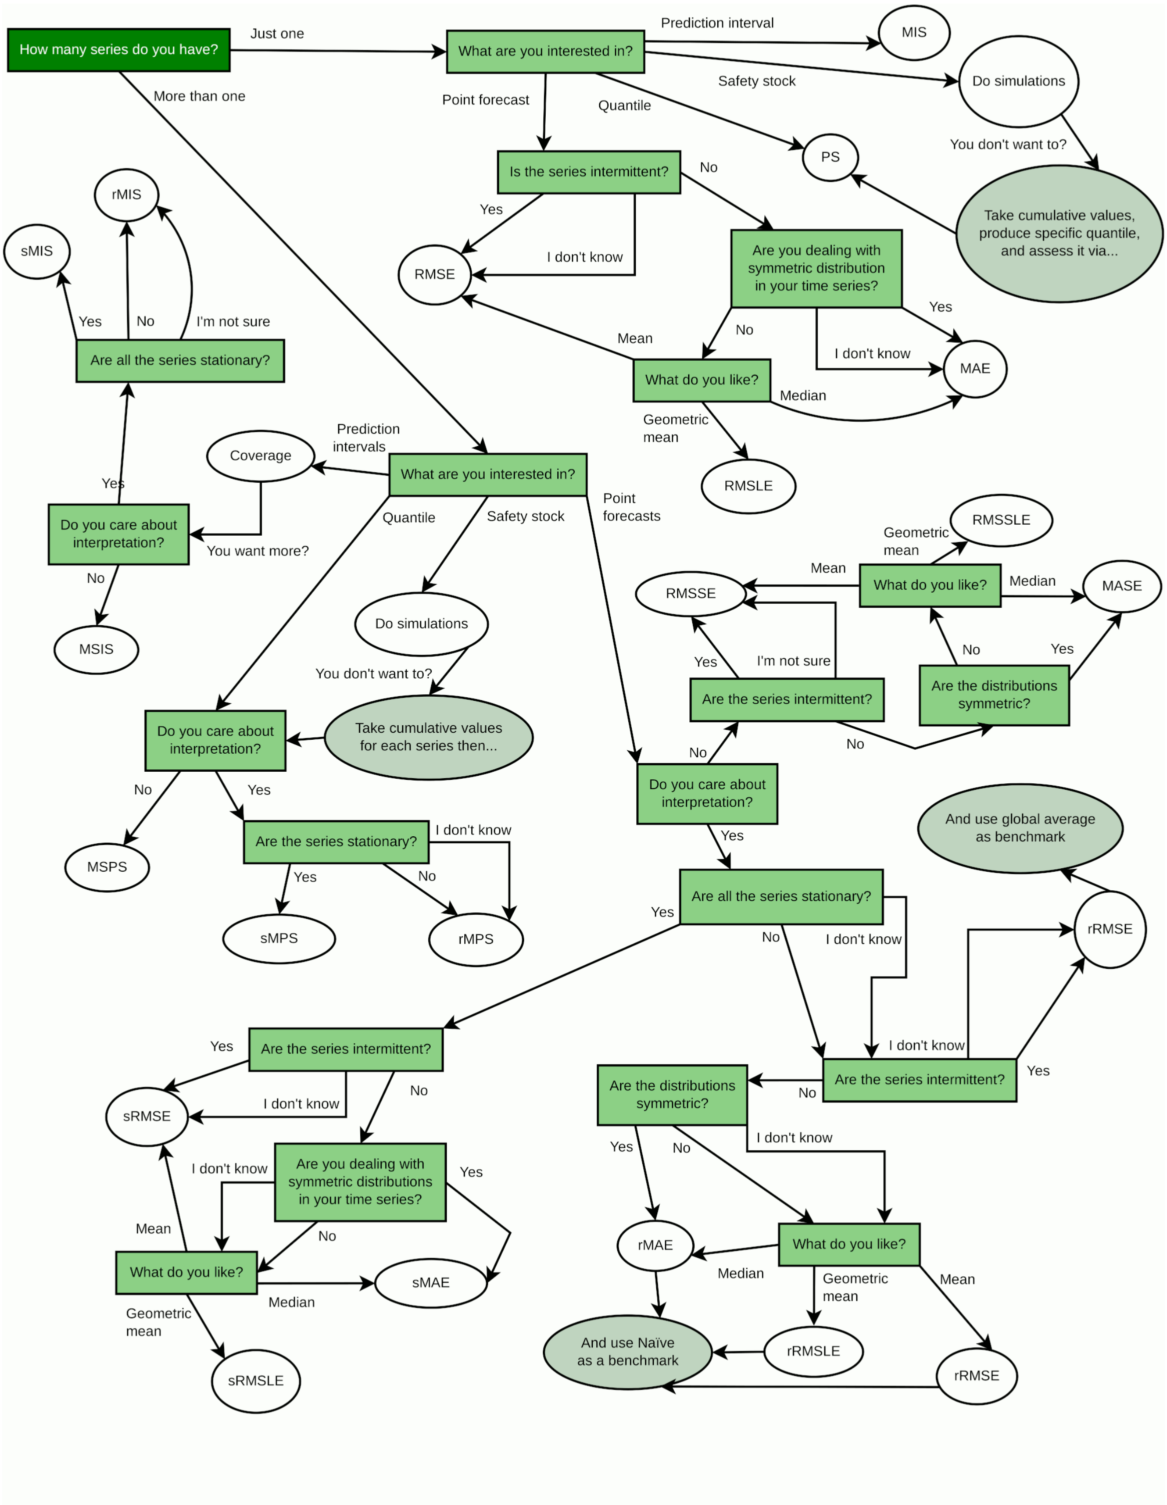
- The "time momentum" are the basic position and dispersion parameters that we know in statistics that are the mean and standard deviation but just taken over a time period (widely used in finance!). Thus, the average and standard deviation of a measured variable of a time-window $[t-p,t]$ is obviously given by:

$$\begin{aligned}\mu(t,p) &= \frac{1}{p+1}\sum_{\theta=0}^{p} x_{t-\theta}\\ \sigma(t,p) &= \sqrt{\frac{1}{p+1}\sum_{\theta=0}^{p}(x_{t-\theta}-\mu(t,p))^2}\end{aligned} \qquad (15.3.1457)$$

- The "hit score" (widely used in finance markets), the idea is very simple: it is simply the ratio of the number of good periodicals forecasts (the concept of "good" being quite empirical because there are dozens of choices) on the total number of past periods.

Finally, to end this section on error indicators, notice that in the field of forecasting we must also checked on the long term if a theoretical model is viable or not to replace it with another one. The basic techniques for this are to make use for example of an Autocorrelated controls chart (see section Industrial Engineering page 9007) where the measurement are simply the deviations (without taking their absolute value!) between the projected values and what really happened.

Caution! There are some commonly used accuracy measures whose scale depends on the scale of the data (like MAE, MSE, WAPE, MAE%). These are useful when comparing different methods applied to the same set of data, but should not be used, for example, when comparing across data sets that have different scales.



How many series do you have?
Just one
What are you interested in?

Figure 15.199: **Forecasting error measures decision flow chart (author: Ivan Svetunkow)**

Remark

Let us notice also the usage in practice (especially banks) of the "drawdown" that is the measure of the decline from a historical peak in some variable (typically the cumulative profit or total open equity of a financial trading strategy).

Somewhat more formally, if $X=(X(t),t\geq 0)$ is a random process with $X(0)=0$, the drawdown at time T, denoted $D(T)$, is defined as:

$$\mathrm{D}(T)=\max\left\{0,\max_{t\in(0,T)}(X(t)-X(T))\right\} \tag{15.3.1458}$$

The "maximum drawdown" (MDD) up to time T is the maximum of the Drawdown over the history of the variable. More formally:

$$\mathrm{MDD}(T)=\max_{\tau\in(0,T)}\left[\max_{t\in(0,\tau)}X(t)-X(\tau)\right] \tag{15.3.1459}$$

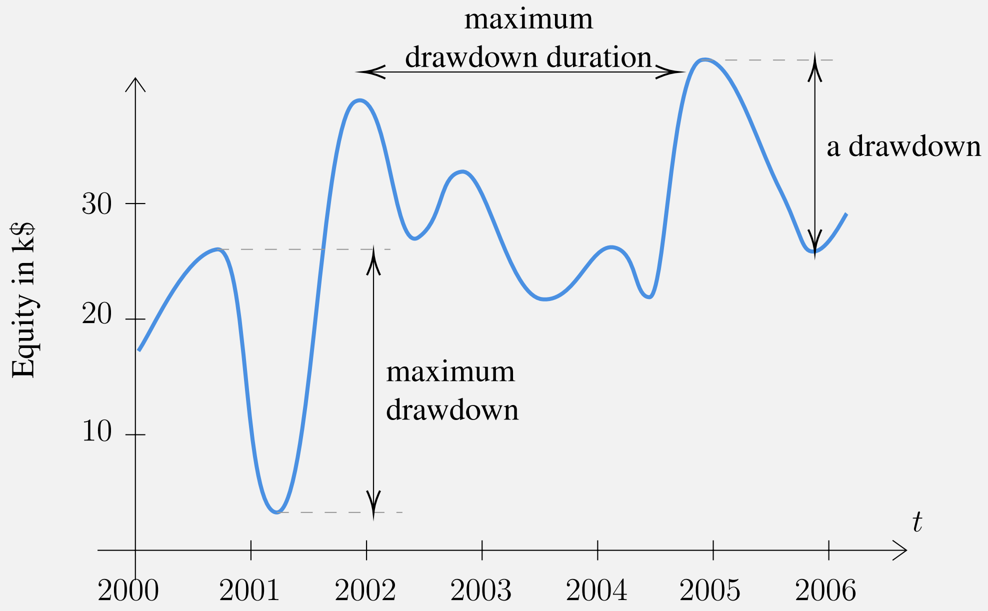

Figure 15.200: **Maximum Drawdown**

15.3.13.2 Decompositions

Some models using time series are adequate forecasting tools provided that the variations have shown some a stable pattern over time and that the conditions in which the pattern appeared always apply and that the past measurements don't have a to big intrinsic error.

Sometimes a pattern is not apparent in the analysis of raw data; these can however be decomposed so as to reveal patterns that facilitate the projection data in the future (we will see the spectral decomposition by Fourier transform further below). The 4 generally recognized components (already mentioned above) for time series out spectral analysis are: trend t_t (linear, exponential, sigmoid, etc.), seasonality s_t, cyclicity c_t, random (irregular) i_t.

Hence a time series using an additive model can be thought of as:

$$\boxed{Y_t = t_t + c_t + s_t + i_t} \tag{15.3.1460}$$

While a multiplicative model would be:

$$\boxed{Y_t = t_t \cdot c_t \cdot s_t \cdot i_t} \tag{15.3.1461}$$

An additive model would be used when the variations around the trend does not vary with the level of the time series where as a multiplicative model would be appropriate if the trend is proportional to the level of the time series.

Let us see this with a small companion practical example using (for simplicity) the Microsoft® Excel® 14.0.6123.

Let us create a random component based on the absolute value of a Normal distribution of mean of 10 and standard deviation of 20 and over a period of 32 months with the following formula in column `B` (`B1` to `B32`):

```
=ABS(NORM.INV(RAND(),10,20))
```

where column `A` will contain the numbering of the periods ranging from 1 to 32 (`A1` to `A32`).

Which will give a simulation of a random graph for which we will fix the values. For example:

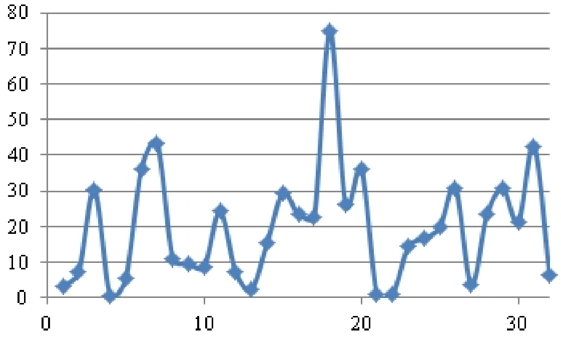

Figure 15.201: **Plot of an example of the random function with Microsoft® Excel® 14.0.6123**

Then we add a linear trend component (drift) linear of slope 4 and of ordinate at the origin 20 to the random component so as to have this time in column `B` the following formula:

```
=ABS(NORM.INV(RAND(),10,20))+(4*A1+20)
```

The sum gives graphically:

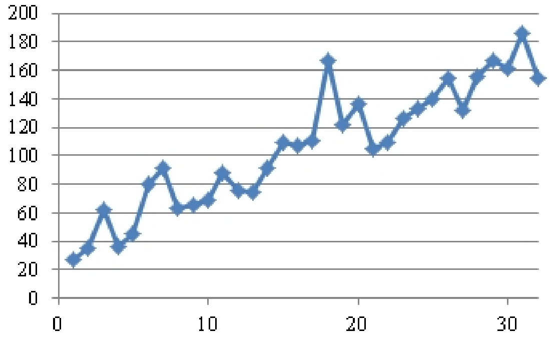

Figure 15.202: Plot of the sum of the random function and the trend with Microsoft® Excel® 14.0.6123

Now let add a seasonal component of the sinusoidal type with a range of 50 and 12 months and without phase:

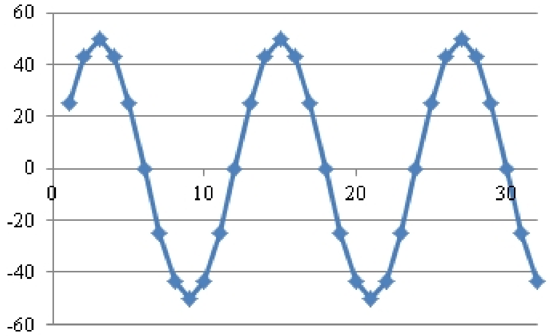

Figure 15.203: Plot of the seasonal part only with Microsoft® Excel® 14.0.6123

The sum of the three components will give in column `B`:

```
=ABS(NORM.INV(RAND(),10,20))+(4*A1+20)+50*SIN(A1*2*PI()*1/12)
```

and graphically it gives:

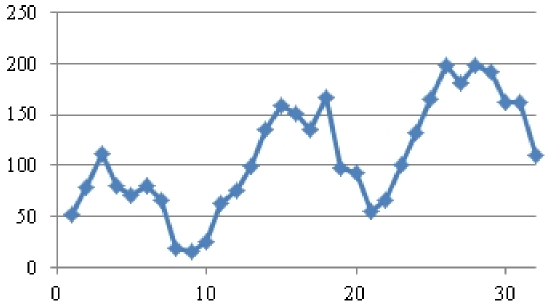

Figure 15.204: Plot of the sum of the random function, the trend and seasonality with Microsoft® Excel® 14.0.6123

and finally let us add a cyclical component which will again be for example a sinusoidal function of amplitude 20 and period 64:

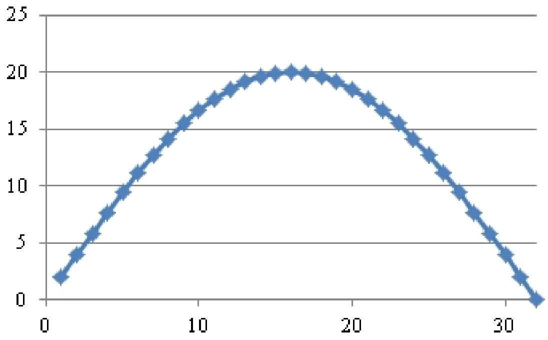

Figure 15.205: **Plot of the cyclic component with Microsoft® Excel® 14.0.6123**

The sum of the four components gives in column `B`:

```
=ABS(NORM.INV(RAND(),10,20))+(4*A1+20)+50*sin(A1*2*PI()*1/12)+20*SIN(A1*2*PI(
                                   )*1/64)
```

and graphically it gives:

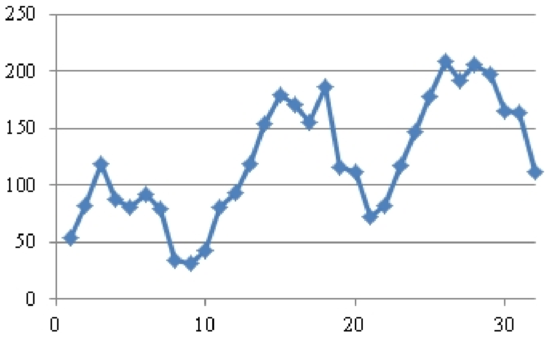

Figure 15.206: **Sum of all components with Microsoft® Excel® 14.0.6123**

Now, as we have introduced in detail in the section of Sequences and Series, let us make a fast Fourier transform (spectral analysis) - abbreviated FFT - with the integrated Data Analysis Tools in Microsoft® Excel® 14.0.6123. This gives us then:

	A	B	C	D
1	**Month**	**Somme Aléa+Lin+Sais+Cycl**	***C*n**	**|*C*n|**

Figure 15.207: **Table of the FFT with the Data Analysis Toolpack of Microsoft® Excel® 14.0.6123**

But unlike the section of Sequences and Series we will this time plot the frequency spectrum. For this, we first create a column with numbers from 0 to 31 and just next we put the formula visible in the screenshot below:

	E	F
1	*n*	**Frequencies**
2	0	0
3	1	=E3*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
4	2	=E4*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
5	3	=E5*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
6	4	=E6*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
7	5	=E7*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
8	6	=E8*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
9	7	=E9*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
10	8	=E10*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
11	9	=E11*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
12	10	=E12*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
13	11	=E13*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
14	12	=E14*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
15	13	=E15*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
16	14	=E16*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
17	15	=E17*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
18	16	=E18*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
19	17	=E19*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
20	18	=E20*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
21	19	=E21*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
22	20	=E22*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
23	21	=E23*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
24	22	=E24*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
25	23	=E25*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
26	24	=E26*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
27	25	=E27*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
28	26	=E28*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
29	27	=E29*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
30	28	=E30*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
31	29	=E31*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
32	30	=E32*(COUNT($B$2:$B$33)/($A$33-$A$2))/32
33	31	=E33*(COUNT($B$2:$B$33)/($A$33-$A$2))/32

Figure 15.208: **Formulas to get the frequencies in Microsoft® Excel® 14.0.6123**

which gives:

	D	E	F	G
1	$\|Cn\|$	n	Frequencies	Periods
2	3906	0	-	-
3	726	1	0.03	31.00

5	610	3	0.10	10.33
6	58.6	4	0.13	7.75
7	157	5	0.16	6.20
8	87.7	6	0.19	5.17
9	59.2	7	0.23	4.43
10	166	8	0.26	3.88
11	115	9	0.29	3.44
12	81.7	10	0.32	3.10
13	110	11	0.35	2.82
14	88.7	12	0.39	2.58
15	50.4	13	0.42	2.38
16	59.1	14	0.45	2.21
17	91.5	15	0.48	2.07
18	42.7	16	0.52	1.94
19	91.5	17	0.55	1.82
20	59.1	18	0.58	1.72
21	50.4	19	0.61	1.63
22	88.7	20	0.65	1.55
23	110	21	0.68	1.48
24	81.7	22	0.71	1.41
25	115	23	0.74	1.35
26	166	24	0.77	1.29
27	59.2	25	0.81	1.24
28	87.7	26	0.84	1.19
29	157	27	0.87	1.15
30	58.6	28	0.90	1.11
31	610	29	0.94	1.07
32	590	30	0.97	1.03
33	726	31	1.00	1.00

Figure 15.209: **Values of the frequencies and periods of the FFT in Microsoft® Excel® 14.0.6123**

Or graphically for the first 16 points (the other being identical by symmetry):

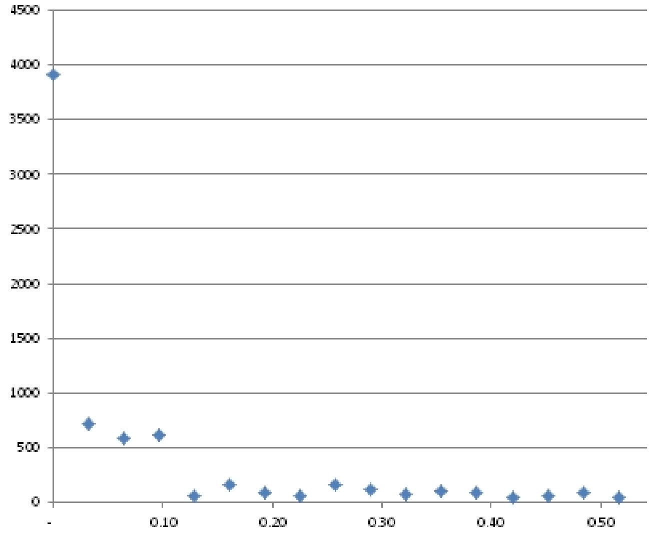

Figure 15.210: **Plot of the frequency peaks of the FFT with Microsoft® Excel® 14.0.6123**

So we see that the transformation highlights a constant component (zero frequency), which is very important. We can abusively assimilate it with the linear component.

We then see then that three points stand out with the respective periods (inverse of frequency): 31 months, 15.50, 10.33. But we will only consider the first two values to associate them to the cyclicity (having the greatest period by definition) and seasonality.

Thus, the Fourier transform leads us to consider a consistent trend, a cyclical phenomenon with a period of 31 months (while we simulated a cycle with a period of 64 months ...) and a seasonal phenomenon having a period 15 months (while we had a simulation with a period of 12 months).

So we see that this type of analysis has limitations but it can be useful as a tool for decision support.

15.3.13.3 Types of Forecasting Models

Definition (#15.3.703): "Forecasting" is the set of mathematical methods and techniques that helps organizations (corporations, governments) to anticipate future events by analysing past data to identify systematic relationships, patterns, and trends with a given probabilistic confidence. It plays many times vital role in decision-making.

Remark

A "forecast" must not be confused with the concept of "prophecy". For scientists the definition of prophecy is the following: *A "prophecy" is a claim that, without using the scientific method or any mathematical calculations, anticipates the details of occurrence of a given event (exact magnitude, exact number of people involved, exact names of things involved, etc.) with a high accurate time (at the second) and space precision (at the meter) without providing any probability confidence interval. A "prophet" is someone who can succeed multiple prophecies that beats the hazard at a high level enough statistical power.*

Time series analysis has two main approaches for forecasting:

1. The deterministic approach that doesn't use at all statistical tools
2. The statistical approach that allows to infer on forecasts[36]

It goes without saying that the first method is easier than the second, but the second includes the first and is scientifically more acceptable since it will be possible to define confidence intervals (it fact it should be the only acceptable one!).

These general concepts being presented we'll move on to the presentation of some regression mathematical models of time series. You should know about it that:

1. There are (to my knowledge) almost 60 different mathematical well known models
2. Some models are deterministic, other stochastic (the latter being the best in the scientific point of view), some causal (like regression obviously) or non-causal (depending only on previous values)

---

[36] Also named "predictive analytics"

3. They are (to my knowledge) all empirical and no one is perfect
4. A spreadsheet software like Microsoft® Excel® is enough to model the majority of them in school classes

> ❞ *The way to cope with the future is to create it!* ❞
>
> Ilya Prigogine

quote
15.3:7915.#88

Obviously there are a lot of forecasting models used by some (mainly) multinational companies. Most of them are presented further below in details but as requested by a reader here is a list of the most known one in increasing order of ascending complexity[37]:

1. Extrapolation (linear regression prediction)
2. Simple moving average
3. Linear model with seasonal coefficient (LMSC)
4. Simple exponential smoothing (EWMA)
5. Double exponential smoothing with one parameter (Brown Method)
6. Holt's double exponential smoothing with 2 parameters
7. Holt's and Winter triple exponential smoothing with 3 parameters[38]
8. Logistic model
9. Croston's method (and adjusted Croston's methods)
10. Kalman filtering
11. Autoregressive processes (AR) or Vector Autoregressive processes[39] (VAR)
12. Moving average autoregressive processes (MA)
13. Discrete autoregressive moving average (DARMA)
14. Autoregressive moving average (ARMA)
15. Integrated-value moving average (INARMA)
16. Autoregressive integrated moving average (ARIMA)
17. Autoregressive distributed lag (ARDL)
18. Autoregressive integrated moving average with explanatory variable (ARIMAX)
19. Fractional ARIMA (FARIMA)
20. Seasonal ARIMA (SARIMA) and seasonal fractional ARIMA (SARFIMA)
21. Generalized linear model (GLM)
22. Generalized autoregressive conditional heteroskedasticity (GARCH or

---

[37] As far as we know, the only software that implement them all is the R Software.

[38] Form information, all models based on exponential smoothing belongs to the family of "ETS models]" (acronym of "Error Trend Seasonality))

[39] There is a type of VAR where when at least two of the series are cointegrated (the residuals estimated on the long term are not stationary) that we name Vector Error Correction Model (VECM).

sGARCH), Rich univariate GARCH (RUGARCH), integrated GARCH (iGARCH), multivariate GARCH (MGARCH), Copula-GARCH

23. Non-linear ARCH (NARCH)
24. Threshold ARCH (TARCH)
25. Neural networks (FFNN, RNN, LSTM, GRU etc.)
26. Facebook Prophet's model
27. TBATS (**T**rigonometric seasonality, **B**ox-Cox transformation, **ARMA** errors, **T**rend and **S**easonal components)
28. Theta models
29. ...

We will see below the proof of those that require a mathematical approach and not already studied in previous chapters (like the Generalized Linear Models). The others being only toolboxes, they don't have their place in such a book.

Typical time series patterns can be seen in the figure below:

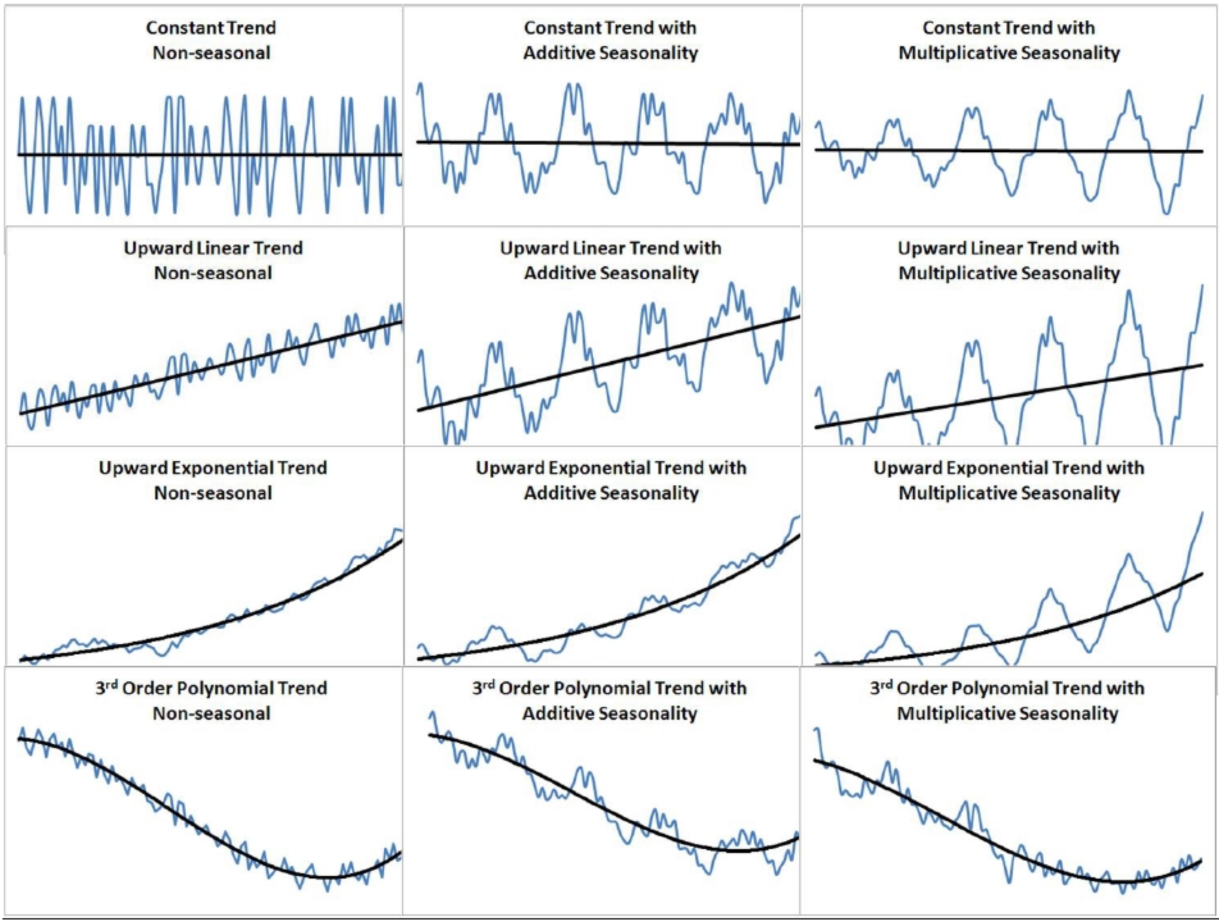

Figure 15.211: **Exhibit of easily recognizable time series patterns**

and a common classification of existing models can visually be given by:

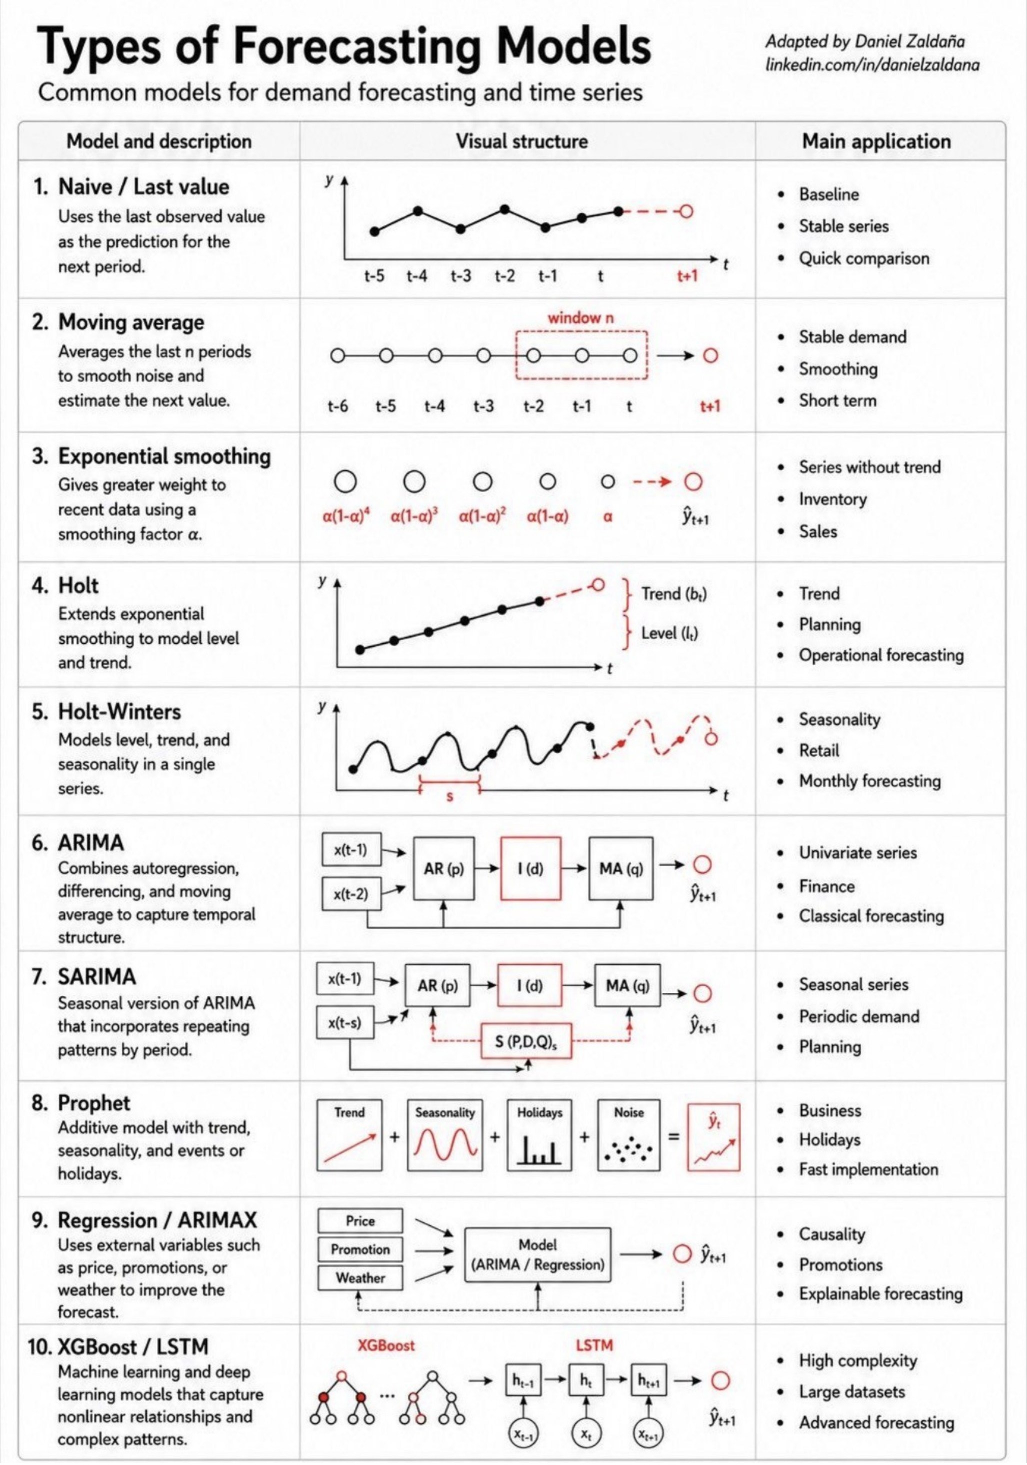
Figure 15.212: Non-exhaustive orgchart of forecasting techniques

Or another nice summary of the most famous one only:



Types of Forecasting Models

Common models for demand forecasting and time series

Adapted by Daniel Zaldaña
linkedin.com/in/danielzaldana

Model and description	Visual structure	Main application
1. Naive / Last value Uses the last observed value as the prediction for the next period.	y t-5 t-4 t-3 t-2 t-1 t t+1 t	- Baseline - Stable series - Quick comparison
2. Moving average Averages the last n periods to smooth noise and estimate the next value.	window n t-6 t-5 t-4 t-3 t-2 t-1 t t+1	- Stable demand - Smoothing - Short term
3. Exponential smoothing Gives greater weight to recent data using a smoothing factor α.	$\alpha(1-\alpha)^4$ $\alpha(1-\alpha)^3$ $\alpha(1-\alpha)^2$ $\alpha(1-\alpha)$ α $\hat{y}_{t+1}$	- Series without trend - Inventory - Sales
4. Holt Extends exponential smoothing to model level and trend.	y Trend (b_t) Level (l_t) t	- Trend - Planning - Operational forecasting
5. Holt-Winters Models level, trend, and seasonality in a single series.	y s t	- Seasonality - Retail - Monthly forecasting
6. ARIMA Combines autoregression, differencing, and moving average to capture temporal structure.	x(t-1) x(t-2) AR (p) → I (d) → MA (q) → $\hat{y}_{t+1}$	- Univariate series - Finance - Classical forecasting
7. SARIMA Seasonal version of ARIMA that incorporates repeating patterns by period.	x(t-1) x(t-s) AR (p) → I (d) → MA (q) → $\hat{y}_{t+1}$ $S(P,D,Q)_s$	- Seasonal series - Periodic demand - Planning
8. Prophet Additive model with trend, seasonality, and events or holidays.	Trend + Seasonality + Holidays + Noise = $\hat{y}_t$	- Business - Holidays - Fast implementation
9. Regression / ARIMAX Uses external variables such as price, promotions, or weather to improve the forecast.	Price Promotion Weather Model (ARIMA / Regression) → $\hat{y}_{t+1}$	- Causality - Promotions - Explainable forecasting
10. XGBoost / LSTM Machine learning and deep learning models that capture nonlinear relationships and complex patterns.	XGBoost ... → LSTM h_{t-1} → h_t → h_{t+1} → $\hat{y}_{t+1}$ x_{t-1} x_t x_{t+1}	- High complexity - Large datasets - Advanced forecasting

We will in what follows obviously focus first on classic undergraduate family of models.

Remark

Using a single variable to analyse a complex situation is a good way to reach bad conclusions (never forget this when you make time forecasting based only with time t as explanatory variable...!).

15.3.13.3.1 Simple Moving Average (moving average smoothing)

The simple moving average (MA) forecast technique of order k is certainly the simplest and also the worst empirical technique in terms of predictive power. Based on the definition of the moving average (see section Statistics page 567) it is defined by:

$$\boxed{\mathrm{MA}(k)=F_{t+1}=\frac{\displaystyle\sum_{i=t-k+1}^{t} Y_i}{k}} \tag{15.3.1462}$$

and is therefore a deterministic forecast on only a single subsequent period.

Let us see an example with Microsoft® Excel® 11.8346 with a forecast on the horizon of a month with moving average smoothing models in columns `D` and `E`:

	A	B	C	D	E
1	**Month**	**Period**	Y_i	**MA(3)**	**MA(5)**
2	Jan	1	200		
3	Feb	2	135		
4	Mar	3	195		
5	Apr	4	197	176.7	
6	May	5	310	175.7	
7	Jun	6	175	234.0	207.4

11	Oct	10	277	=AVERAGE(C8:C10)	=AVERAGE(C6:C10)
12	Nov	11	235	=AVERAGE(C9:C11)	=AVERAGE(C7:C11)
13	Dec	12		**=AVERAGE(C10:C12)**	**=AVERAGE(C8:C12)**

Figure 15.214: Base list for the MA example with explicit formulas in Microsoft® Excel® 11.8346

and the corresponding chart:

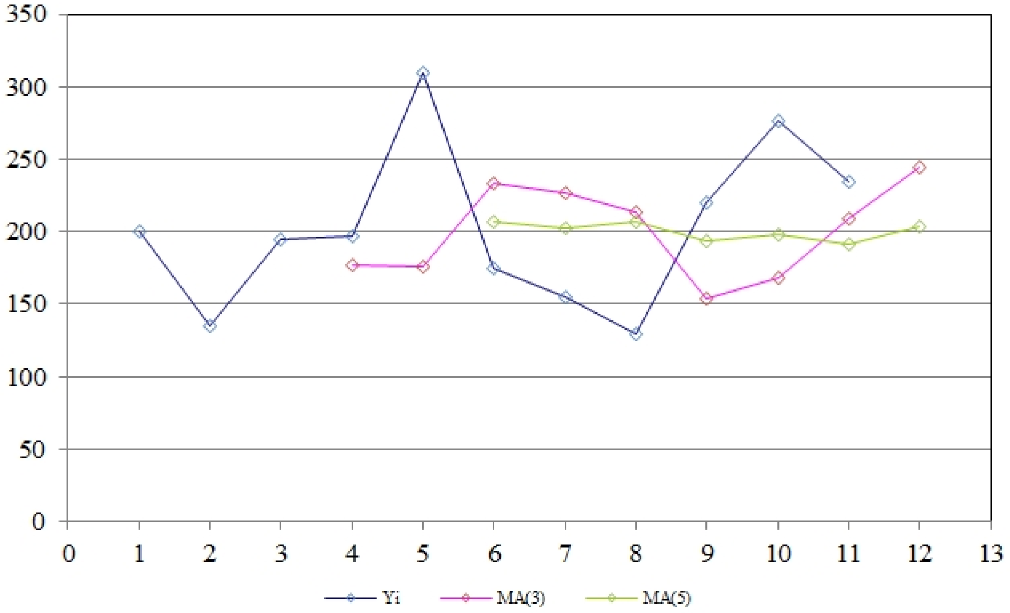

Figure 15.215: MA(3) and MA(5) plot with Microsoft® Excel® 11.8346

And elementary calculations give (we can provide the details with Microsoft® Excel® on readers request):

$$\text{MAPE} = 100\frac{1}{n}\sum_{t=1}^{n}\frac{|e_t|}{Y_t} = 34.84\% \qquad \text{MAD} = \frac{1}{n}\sum_{t=1}^{n}|e_t| = 71.\bar{3} \qquad \text{MSD} = \frac{1}{n}\sum_{t=1}^{n}e_t^2 = 6380.\bar{6} \tag{15.3.1463}$$

We have not used the Analysis Toolpack of Microsoft® Excel® 11.8346 (the latter incorporating a tool automatically making the calculations of the moving average) only because we wanted show the reader the explicit application of the mathematical relationship given above.

Figure 15.216: **Microsoft® Excel® Moving Average choice in the Analysis Toolpack**

The choice of the number of periods k to be used in calculating the simple moving average depends very much on expected variations in the data. This can be illustrated by two characteristics of the forecast:

- "Stability": By averaging several periods, we attenuate the random fluctuations and therefore the prediction is more stable. Stability is the property of the forecast to not fluctuate randomly. Win in stability is an advantage if there is a lot of random fluctuations in the data. A moving average will win in stability if a larger number of periods is used in the calculation of the average. A win in stability is desirable only to the point where random fluctuations are mitigated. If the number of periods used in the calculation of the average is too large, the average will be so stable that it will respond too slowly to non-random changes.
- "Reactivity": Reactivity is the property that the forecast quickly adjust to a change in the actual average level. The use of a reactive forecast is appropriate in the case where random fluctuations are small. The smaller the number of periods used in the calculation of the moving average is, the more the forecast model will be reactive.

Remark

Let us notice that some forecasting techniques do moving averages of moving averages ... In the literature, this is named "double moving average" ... There are also models that apply empirical weight to past periods, this is named "weighted moving average" and this is in my opinion out of interest.

15.3.13.3.2 Linear Model With Seasonal Coefficients (LMSC)

The linear predictive technique with seasonal factors is simple to implement and to understand for most people. It combines a simple linear regression (see section Numerical Methods page 6322) and seasonal factors calculated on the basis of past values relatively to the linear model. This technique allows to identify trends by smoothing the time series and showing significant variations in time.

Let us see a companion example with Microsoft® Excel® 11.8346:

	A	B	C
1	**Period**	**Month**	**Sales**
2	1	Janvier 1987	890.00
3	2	Février 1987	1,115.00
4	3	Mars 1987	1,280.00
5	4	Avril 1987	1,328.00
6	5	Mai 1987	1,253.00
7	6	Juin 1987	1,124.00
8	7	Juillet 1987	1,192.00
9	8	Août 1987	876.00
10	9	Septembre 1987	1,401.00
11	10	Octobre 1987	1,501.00
12	11	Novembre 1987	1,065.00
13	12	Décembre 1987	976.00
14	13	Janvier 1988	895.00
15	14	Février 1988	1,179.00
16	15	Mars 1988	1,315.00
17	16	Avril 1988	1,452.00
18	17	Mai 1988	1,325.00
19	18	Juin 1988	1,202.00
20	19	Juillet 1988	1,175.00
21	20	Août 1988	933.00
22	21	Septembre 1988	1,412.00
23	22	Octobre 1988	1,528.00
24	23	Novembre 1988	1,171.00
25	24	Décembre 1988	1,012.00

Figure 15.217: **Companion LMSC example starting values in Microsoft® Excel® 11.8346**

Which looks like:

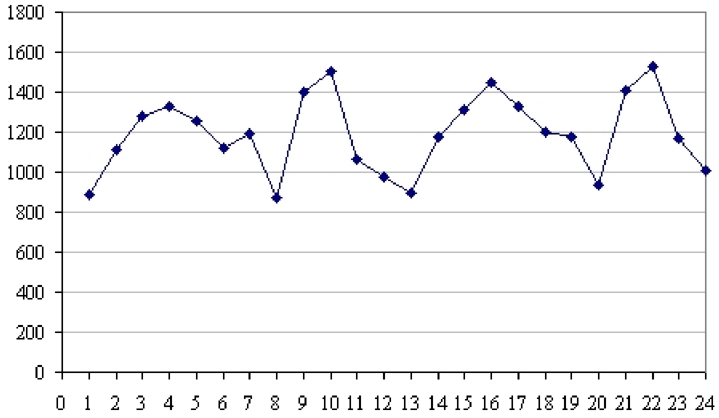

Figure 15.218: Corresponding Sales plot in Microsoft® Excel® 11.8346

The first thing to do is to determine the equation of the regression line (which allows verbatim also to make inference!). That's simple to solve with the least squares method proved in the section of Numerical Methods and extremely simple to obtain with automatic tools like the one integrated in Microsoft® Excel® 11.8346 (Analysis Toolpack again... or the functions already seen in the section of Numerical Methods):

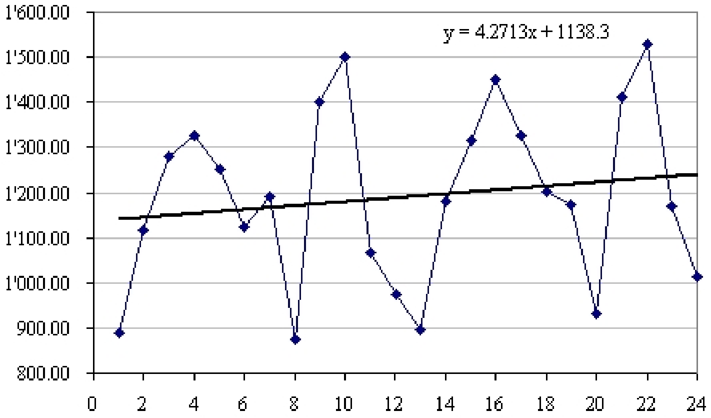

Figure 15.219: Linear regression equation for Sales in Microsoft® Excel® 11.8346

This allows us to have three new columns in our Microsoft® Excel® list. One with the values of the linear model and another with the ratio between the actual and the linear model (which corresponds to the seasonal coefficients!):

	A	B	C	D	E	F
1	Period	Month	Sales	Linear Model	Coeff.	LMSC
2	1	Janvier 1987	890.00	1,142.57	0.78	873.29
3	2	Février 1987	1,115.00	1,146.84	0.97	1,121.78
4	3	Mars 1987	1,280.00	1,151.11	1.11	1,269.47
5	4	Avril 1987	1,328.00	1,155.39	1.15	1,359.16
6	5	Mai 1987	1,253.00	1,159.66	1.08	1,260.96
7	6	Juin 1987	1,124.00	1,163.93	0.97	1,137.65
8	7	Juillet 1987	1,192.00	1,168.20	1.02	1,158.81
9	8	Août 1987	876.00	1,172.47	0.75	884.96
10	9	Septembre 1987	1,401.00	1,176.74	1.19	1,377.03
11	10	Octobre 1987	1,501.00	1,181.01	1.27	1,482.72
12	11	Novembre 1987	1,065.00	1,185.28	0.90	1,093.73
13	12	Décembre 1987	976.00	1,189.56	0.82	973.10
14	13	Janvier 1988	895.00	1,193.83	0.75	912.46
15	14	Février 1988	1,179.00	1,198.10	0.98	1,171.92
16	15	Mars 1988	1,315.00	1,202.37	1.09	1,326.00
17	16	Avril 1988	1,452.00	1,206.64	1.20	1,419.46
18	17	Mai 1988	1,325.00	1,210.91	1.09	1,316.69
19	18	Juin 1988	1,202.00	1,215.18	0.99	1,187.75
20	19	Juillet 1988	1,175.00	1,219.45	0.96	1,209.65
21	20	Août 1988	933.00	1,223.73	0.76	923.65
22	21	Septembre 1988	1,412.00	1,228.00	1.15	1,437.01
23	22	Octobre 1988	1,528.00	1,232.27	1.24	1,547.07
24	23	Novembre 1988	1,171.00	1,236.54	0.95	1,141.03

Figure 15.220: LMSC full analysis starting values in Microsoft® Excel® 11.8346

That is to say visually:

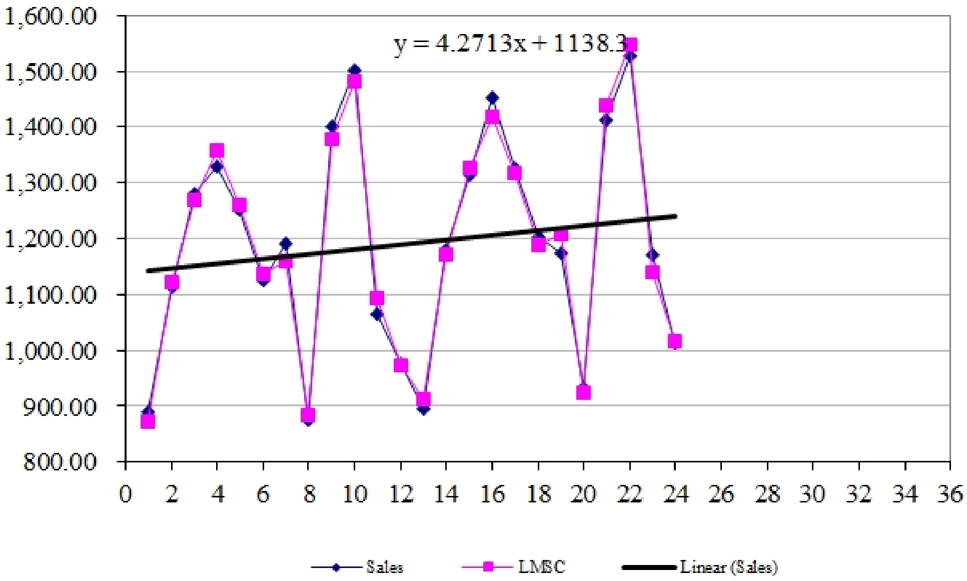

Figure 15.221: LMSC full plot in Microsoft® Excel® 11.8346

We can then make a prediction based on the linear regression multiplied by the average of the seasonal coefficients of each month. What we write in this case:

$$\boxed{F_t=(at_i+b)\bar{c}_{i \mod 12}} \tag{15.3.1464}$$

So this is a deterministic method to make forecasts on as many future periods as desired with the ability to make statistical inference if necessary as there is an underlying linear Gaussian model (this is the only deterministic model on which the inference is directly applicable as far as we know).

So for example:

	A	B	C	D	E	F	G	H	I	J
1	**Period**	**Month**	**Sales**	**Linear Model**	**Coeff.**	**LMSC**		**Coeff:**	**Calculated**	**Solveur**

Figure 15.223: **LMSC projection with formulas in Microsoft® Excel® 11.8346**

That is to say visually:

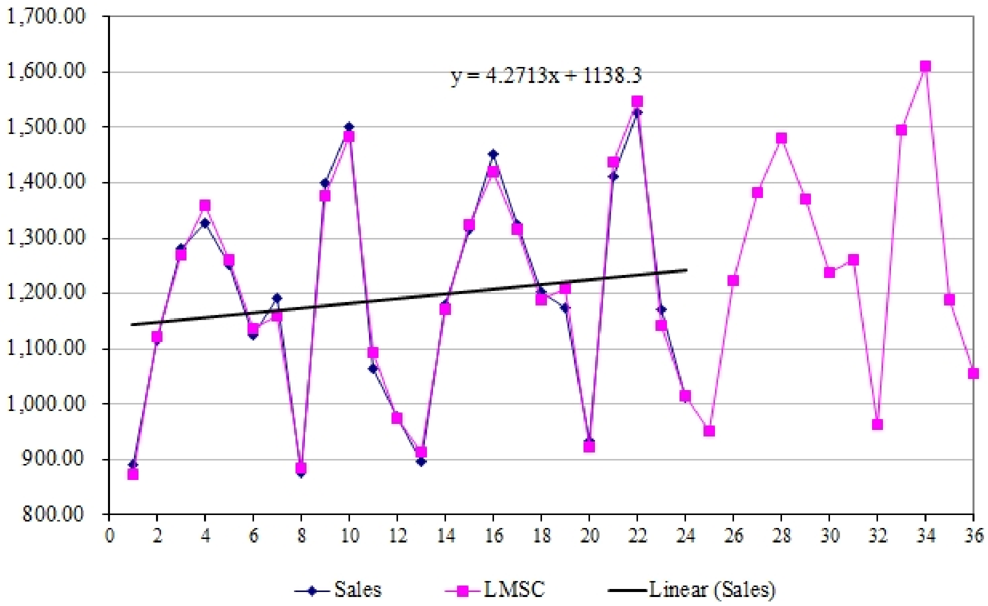

Figure 15.224: **LMSC plot with projection in Microsoft® Excel® 11.8346**

And elementary calculations give (we can provide the details with Microsoft® Excel® on readers request):

$$\text{MSD} = \frac{1}{n}\sum_{t=1}^{n} e_t^2 \cong 398.898 \qquad (15.3.1465)$$

15.3.13.3.3 Exponential Smoothing models

Exponential smoothing is a very common time series forecasting procedure capable of including both trend and seasonality. The exponential smoothing procedure is a combination of three other much simpler components, all of which are smoothing methods:

- **Simple Exponential Smoothing (SES)**: Simple exponential smoothing, also named single exponential smoothing, assumes that the time series has no change in level. Thus, it can not be used with series that contain trend, seasonality, or both.
- **Holt's Exponential Smoothing (HES)**: Holt's exponential smoothing is one step above simple exponential smoothing, as it allows the time series data to have a trend component. Holt's exponential smoothing is still incapable of cope with seasonal data.
- **Winter's Exponential Smoothing (WES)**: Winter's exponential smoothing is an extension to Holt's exponential smoothing that finally allows for the inclusion of seasonality. Winter's exponential smoothing is what is referred to as the Holt-Winters method.

15.3.13.3.3.1 Simple Exponential Smoothing (EWMA)

The prediction F_t provided by the exponential smoothing method (also named "Exponential Weighted Moving Average (EWMA)" or "Single Exponential Smoothing (SES)"), also named "exponential weighted moving average", with "smoothing constant" $\beta \in]0,1[$ is given as we will prove it later by:

$$F_{t+1}=(1-\beta)\sum_{i=0}^{t-1}\beta^i Y_{t-i} \tag{15.3.1466}$$

This definition is based on a simple idea (yet totally empirical!): we assume that the observations influence less the forecast as they are far from the time t for which we forecast and that this influence decreases exponentially (this model remains even in the early 121st century (holocene calendar) is still very used to model the variance of financial instruments). We then see easily at first glance that:

- Note the closest the smoothing constant β is to 1, the more the influence of past observations goes back further in time and the forecast is rigid, that is to say not very sensitive to early economic fluctuations.
- On the contrary, more the smoothing constant is close to zero, more the forecast is influenced by recent observations (flexible forecasting).

Let us prove first that the previous definition can be written in another form less technique and that is most common in statistical books:

$$F_{t+1}=(1-\beta)\sum_{i=0}^{t-1}\beta^i Y_{t-i}=(1-\beta)\sum_{i=1}^{t-1}\beta^i Y_{t-i}+(1-\beta)Y_t \tag{15.3.1467}$$

and we also have verbatim:

$$F_t=(1-\beta)\sum_{i=0}^{t-2}\beta^i Y_{t-1-i} \tag{15.3.1468}$$

Therefore if we reindex the sum we find a well-known writing in the finance world (volatility measurement of the RiskMetrics model):

$$\begin{aligned}F_{t+1}&=(1-\beta)\sum_{i=1}^{t-1}\beta^i Y_{t-1}+(1-b\beta)Y_t=(1-\beta)\sum_{i=0}^{t-1-1}\beta^{i+1}Y_{t-1-i}+(1-\beta)Y_t\\&=(1-\beta)\sum_{i=0}^{t-2}\beta^{i+1}Y_{t-1-i}+(1-\beta)Y_t=\beta(1-\beta)\sum_{i=0}^{t-2}\beta^i Y_{t-1-i}+(1-\beta)Y_t\\&=\beta F_t+(1-\beta)Y_t\end{aligned} \tag{15.3.1469}$$

The forecast F_{t+1} appears as the weighted average between the forecast made at time t and the last observation Y_t, the weight given to the latter observation is even stronger than the smoothing constant is small.

We will now demonstrate why softwares forecast the EWMA models with a mean equal to the last measurement:

$$\begin{aligned}\mathrm{E}(F_{t+1})&=\mathrm{E}(\beta F_t+(1-\beta)Y_t)=\beta\mathrm{E}(F_t)+(1-\beta)\mathrm{E}(Y_t)\\&=\beta\mathrm{E}(Y_t)+(1-\beta)\mathrm{E}(Y_t)=\mathrm{E}(Y_t)\end{aligned}\qquad(15.3.1470)$$

In practice, the choice of the smoothing constant is often based on subjective criteria of rigidity or flexibility of the prediction. But there is a more objective method of determining the constant using operational research tools (see section Numerical Methods page 6645) where the constant minimizes the sum of squared forecast errors.

However in the majority of contemporary statistics books, the smoothing constant is defined as:

$$\lambda=1-\beta\qquad(15.3.1471)$$

It comes then:

$$F_{t+1}=\lambda\sum_{i=0}^{t-1}(1-\lambda)^iY_{t-i}=(1-\lambda)F_t+\lambda Y_t=F_t+\lambda(Y_t-F_t)\qquad(15.3.1472)$$

writing that leads us to consider the single exponential smoothing as a simple weighted moving average.

Remark

The above relation is denoted in the framework of ARIMA as:

$$X_{t+1}=X_t+\alpha\varepsilon\qquad(15.3.1473)$$

and we recognise here an ARIMA$(0,1,1)$.

Now, let us start again from the above relation to write it in another form using recursion:

$$\begin{aligned}F_{t+1}&=\lambda Y_t+(1-\lambda)F_t=\lambda Y_t+(1-\lambda)(\lambda Y_{t-1}+(1-\lambda)F_{t-1})\\&=\left(\sum_{i=0}^{t-1}\lambda(1-\lambda)^iY_{t-i}\right)+(1-\lambda)^tF_1\end{aligned}\qquad(15.3.1474)$$

Let us now prove that the sum of weights is equal to the unit to see that it is indeed a weighted system. So we have:

$$\left(\sum_{i=0}^{t-1}\lambda(1-\lambda)^i\right)+(1-\lambda)^i=\lambda\left(\sum_{i=0}^{t-1}(1-\lambda)^i\right)+(1-\lambda)^t=\lambda\left(\sum_{i=0}^{t-1}x^i\right)+(1-\lambda)^t\qquad(15.3.1475)$$

We have proved in the section of Sequences and Series (see page 1679) that:

$$S_n=u_0\frac{1-q^{n+1}}{1-q}\qquad(15.3.1476)$$

Then it comes into our example:

$$S_{t-1}=u_0\frac{1-q^t}{1-q}=\frac{1-x^t}{1-x}=\frac{1-(1-\lambda)^t}{(1-(1-\lambda)}\qquad(15.3.1477)$$

Therefore:

$$\begin{aligned}\lambda\left(\sum_{i=0}^{t-1}x^i\right)+(1-\lambda)^t&=\lambda\frac{1-(1-\lambda)^t}{1-(1-\lambda)}+(1-\lambda)^t\\&=\lambda\frac{1-(1-\lambda)^t}{\lambda}+(1-\lambda)^t=1-(1-\lambda)^t+(1-\lambda)^t=1\end{aligned}\tag{15.3.1478}$$

Finally, let us talk about the origin of the name of this technique. So we have:

$$\begin{aligned}F_{t+1}&=(1-\lambda)F_t+\lambda Y_t=(1-\lambda)[(1-\lambda)F_{t-1}+\lambda Y_{t-1}]+\lambda Y_t\\&=(1-\lambda)^2F_{t-1}+\lambda(1-\lambda)Y_{t-1}+\lambda Y_t\\&=(1-\lambda)^2[(1-\lambda)F_{t-2}+\lambda Y_{t-2}]+\lambda(1-\lambda)Y_{t-1}+\lambda Y_t\\&=(1-\lambda)^3F_{t-2}+\lambda(1-\lambda)^2Y_{t-2}+\lambda(1-\lambda)Y_{t-1}+\lambda Y_t=\ldots\end{aligned}\tag{15.3.1479}$$

So we see in there the coefficients (weights) are exponentially decreasing with every previous unrolled estimate:

$$\ldots,\lambda(1-\lambda)^2,\lambda(1-\lambda),\lambda\tag{15.3.1480}$$

and as $1-\lambda$ is strictly less than unity, the factors $(1-\lambda)^2$ decreases exponentially (just plot the function to see it) as:

$$f(n)=(1-\lambda)^n\tag{15.3.1481}$$

with obviously $n\in\mathbb{N}$.

This being done, let us talk now about the problem of the initial values. So we have:

$$F_2=\lambda Y_1+(1-\lambda)F_1=\lambda Y_1+F_1-\lambda F_1\tag{15.3.1482}$$

It is then agreement to take:

$$F_1=Y_1\tag{15.3.1483}$$

Which gives us:

$$F_2=F_1\tag{15.3.1484}$$

This is why a program like Microsoft® Excel® 11.8346 returns for F_1 the error `#N/A`.

For the rest it is necessary that we study the origin of the expression of the single exponential smoothing. The idea at the base of mathematicians was to reduce the error between the real value Y_{t-j} and the prediction considered as constant a:

$$E=\sum_{j=0}^{t-1}(Y_{t-j}-a)\tag{15.3.1485}$$

but the goal was also to weaken the errors smaller than the unit and amplify those that were larger by squaring deviations such as:

$$E=\sum_{j=0}^{t-1}(Y_{t-j}-a)^2\tag{15.3.1486}$$

and finally to weight those that were remote in time from the prediction by a factor such that we have minimize finally:

$$E=\sum_{j=0}^{t-1}\beta^j(Y_{t-j}-a)^2 \tag{15.3.1487}$$

Taking the derivative of E with respect to a, and by cancelling it comes:

$$\frac{\partial E}{\partial a}=-2\sum_{j=0}^{t-1}\beta^j(Y_{t-j}-a)=0 \tag{15.3.1488}$$

We then get for $\beta\neq 1$: We then get for $\beta\neq 1$:

$$\sum_{j=0}^{t-1}\beta^jY_{t-j}=a\sum_{j=0}^{t-1}\beta^j=a\frac{1-\beta^t}{1-\beta} \tag{15.3.1489}$$

and thus finally:

$$a=\frac{1-\beta}{1-\beta^t}\sum_{j=0}^{t-1}\beta^jY_{t-j} \tag{15.3.1490}$$

and for large t we get:

$$a\cong(1-\beta)\sum_{j=0}^{t-1}\beta^jY_{t-j} \tag{15.3.1491}$$

We thus fall back on the relation defined at the beginning of the study of this model, which was:

$$\boxed{F_{t+1}=(1-\beta)\sum_{i=0}^{t-1}\beta^iY_{t-i}=(1-\beta)\sum_{i=1}^{t}\beta^{i-1}Y_{t+1-i}=(1-\beta)Y_t+\beta F_t} \tag{15.3.1492}$$

Notice that it is not obvious that the desired constant that minimizes the error can be used as prediction function. However it is the usage that is made by many practitioners... Some experts prefer to write the latter result as (do not try to compare this notation with that of the previous relation):

$$S_t=(1-\beta)Y_t+\beta S_{t-1}=\lambda Y_t+(1-\lambda)S_{t-1} \tag{15.3.1493}$$

where S refers to the "S" there is in the word "eStimated" or in the following form:

$$L_t=\alpha y_t+(1-\alpha)L_{t-1} \tag{15.3.1494}$$

This equation is known as the "level update equation" (as single exponential smoothing method does not take into account any trend or seasonality but rahter assumes that the time series data only has a level L).

There are even statistical softwares offering to our astonishment to do forecasts at time $t+n$ based on this method ... which seems to us quite crazy...

Remark

The simple exponential smoothing seems that it was first suggested by Charles C. Holt in 11957 (holocene calendar), but the formulation (the form of the predictive relation) is attributed to Brown. This is a technique that can be found implemented in almost all statistical software.

✍**Example:**

So we want to apply:

$$F_{t+1}=(1-\beta)Y_t+\beta F_t=\lambda Y_t+(1-\lambda)F_t \tag{15.3.1495}$$

Let us consider the following table (the column `C` already contains the mathematical model which we will detail the formulas just after):

	A	B	C	E	F
3	Period	Y_t	SES	Absolute Relative Deviation	Relative Deviation
4	1	143	143		
5	2	152	143.00	0.06	9.00
6	3	161	143.00	0.11	18.00
7	4	139	143.00	0.03	4.00
8	5	137	143.00	0.04	6.00
9	6	174	143.00	0.18	31.00
10	7	142	143.00	0.01	1.00
11	8	141	143.00	0.01	2.00
12	9	162	143.00	0.12	19.00
13	10	180	143.00	0.21	37.00
14	11	164	143.00	0.13	21.00
15	12	171	143.00	0.16	28.00
16	13	206	143.00	0.31	63.00
17	14	193	143.00	0.26	50.00
18	15	207	143.00	0.31	64.00

23	20	227	143.00	0.37	84.00
24	21	223	143.00	0.36	80.00
25	22	242	143.00	0.41	99.00
26	23	239	143.00	0.40	96.00
27	24	266	143.00	0.46	123.00
28			143.00		

Figure 15.225: **List of data of Exponential Smoothing in Microsoft® Excel® 14.0.6123**

We will not use the Analysis Toolpack of Microsoft® Excel® (the latter incorporating a tool doing automatically the calculations of the simple exponential smoothing) in the purpose to show the reader the explicit application of the previous proven mathematical relation. Furthermore, the Analysis Toolpack of Microsoft® Excel® 14.0.6123 (and previous releases) suffers from a major flaw: it requires a manual input of the value of the smoothing constant rather than calculating it from an optimisation research.

There are only three columns that have formulas, the remainder being static entries. We have:

	A	B	C	D	E	F
3	**Period**	**Y_t**	**SES**	**Analysis Toolpack**	**Absolute Relative Deviation**	**Relative Deviation**
4	1	143	=B4	#N/A		
5	2	152	=$H$3*B4+(1-$H$3)*C4	=B4	=ABS(C5-B5)/B5	=ABS(B5-C5)
6	3	161	=$H$3*B5+(1-$H$3)*C5	=0.65*B5+0.35*D5	=ABS(C6-B6)/B6	=ABS(B6-C6)
7	4	139	=$H$3*B6+(1-$H$3)*C6	=0.65*B6+0.35*D6	=ABS(C7-B7)/B7	=ABS(B7-C7)
8	5	137	=$H$3*B7+(1-$H$3)*C7	=0.65*B7+0.35*D7	=ABS(C8-B8)/B8	=ABS(B8-C8)
9	6	174	=$H$3*B8+(1-$H$3)*C8	=0.65*B8+0.35*D8	=ABS(C9-B9)/B9	=ABS(B9-C9)
10	7	142	=$H$3*B9+(1-$H$3)*C9	=0.65*B9+0.35*D9	=ABS(C10-B10)/B10	=ABS(B10-C10)

27	24	266	=$H$3*B26+(1-$H$3)*C26	=0.65*B26+0.35*D26	=ABS(C27-B27)/B27	=ABS(B27-C27)
28			=$H$3*B27+(1-$H$3)*C27	=0.65*B27+0.35*D27		

Figure 15.226: **Explicit list of data of SES in Microsoft® Excel® 14.0.6123**

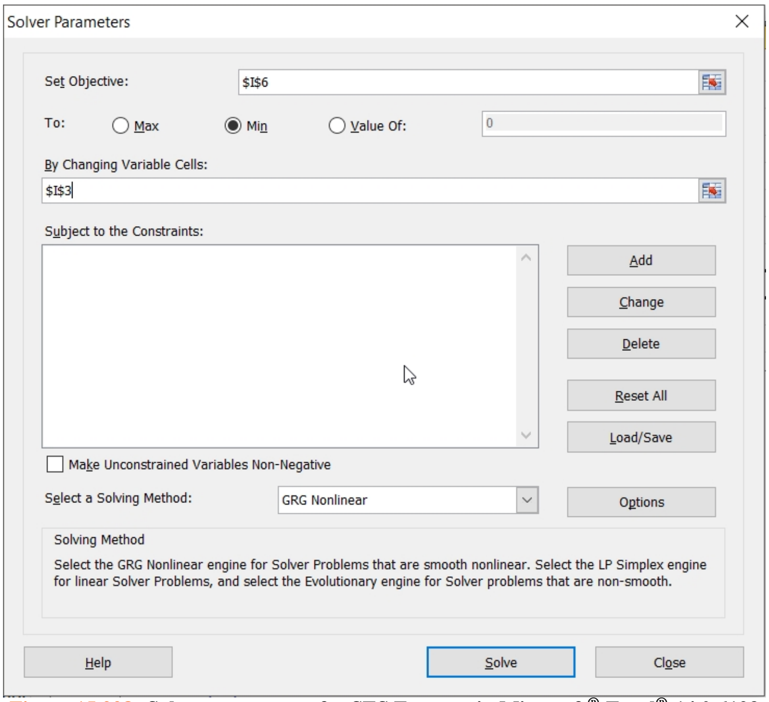
where the attentive reader will have noticed the forecast at the line 28 over a period of one month.

Little bit more far in the worksheet we have put values essential to the optimization of the model thanks to the solver that we will immediately see:

	H	I
3	**λ:**	
4	**Smoothing parameter:**	=1-I3
5		
6	**MAPE:**	=AVERAGE(E5:E27)
7		
8	**MAD:**	=AVERAGE(F5:F27)
9		
10	**MSD:**	=SUM((F5:F27)*(F5:F27))/COUNT(F5:F27)

Figure 15.227: **Parameters cells and SES Forecast errors in Microsoft® Excel® 14.0.6123**

Now we will use the solver to minimize either MAPE, MAD or MSD. We then get for example by minimizing the MAPE error:



Solver Parameters

Set Objective: $I$6

To: ○ Max ● Min ○ Value Of: 0

By Changing Variable Cells: $I$3

Subject to the Constraints:

☐ Make Unconstrained Variables Non-Negative

Select a Solving Method: GRG Nonlinear

Solving Method

Select the GRG Nonlinear engine for Solver Problems that are smooth nonlinear. Select the LP Simplex engine for linear Solver Problems, and select the Evolutionary engine for Solver problems that are non-smooth.

Figure 15.228: **Solver parameters for SES Forecast in Microsoft® Excel® 14.0.6123**

This gives the following result:

	H	I
3	**λ:**	0.64447
4	**Smoothing parameter:**	0.35553
5		
6	**MAPE:**	7.89%
7		
8	**MAD:**	14.71
9		
10	**MSD:**	311.75

Figure 15.229: **Solver results for SES Forecast in Microsoft® Excel® 14.0.6123**

and graphically:

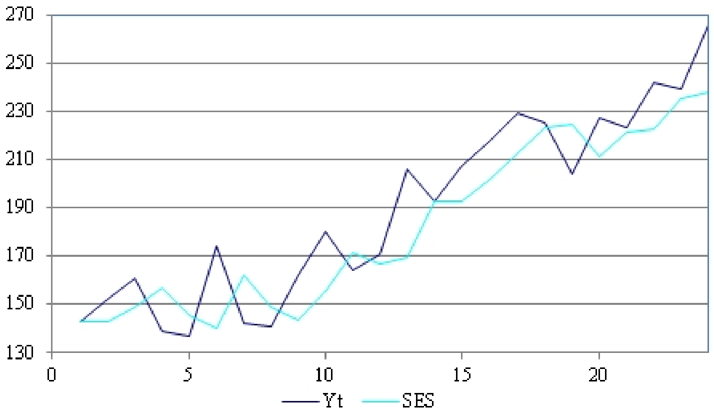


Figure 15.230: **SES Forecast plot in Microsoft® Excel® 14.0.6123**

and therefore the table of values becomes:

	A	B	C	E	F

27	24	266	237.59	0.11	28.41

Figure 15.231: SES Forecast final values in Microsoft® Excel® 14.0.6123

so we see that the forecast on line 28 of the table is:

$$F_{24+1}=255.90 \qquad (15.3.1496)$$

With for recall:

$$\text{MAPE}=100\frac{1}{n}\sum_{t=1}^{n}\frac{|e_t|}{Y_t}=7.89\% \quad \text{MAD}=\frac{1}{n}\sum_{t=1}^{n}|e_t|=14.71 \quad \text{MSD}=\frac{1}{n}\sum_{t=1}^{n}e_t^2=311.75 \qquad (15.3.1497)$$

To conclude, let us indicate that if we make the strong assumption that for any time t:

$$Y_{t+1}=a_t+\varepsilon_t=c^{te}+\mathcal{N}\left(0,\sigma_{Y-\bar{Y}}\right) \qquad (15.3.1498)$$

Then in the case of an infinite series (or supposed as such ...) with independent values:

$$\begin{aligned}\mathrm{V}(F_{t+1})&=\mathrm{V}\left((1-\beta)\sum_{i=0}^{t-1}\beta^i Y_{t-1}\right)=(1-\beta)^2\mathrm{V}\left(\sum_{i=0}^{t-1}\beta^i\left(c^{te}+\mathcal{N}\left(0,\sigma_{Y-\bar{Y}}\right)\right)\right)\\&=(1-\beta)^2\mathrm{V}\left(\sum_{i=0}^{t-1}\beta^i c^{te}\right)+(1-\beta)^2\mathrm{V}\left(\sum_{i=0}^{t-1}\beta^i\mathcal{N}\left(0,\sigma_{Y-\bar{Y}}\right)\right)\\&=(1-\beta)^2\sum_{i=0}^{t-1}\mathrm{V}\left(\beta^i c^{te}\right)+(1-\beta)^2\sum_{i=0}^{t-1}\mathrm{V}\left(\beta^i\mathcal{N}\left(0,\sigma_{Y-\bar{Y}}\right)\right)\\&=(1-\beta)^2\sum_{i=0}^{t-1}\beta^{2i}\mathrm{V}\left(c^{te}\right)+(1-\beta)^2\sum_{i=0}^{t-1}\beta^{2i}\mathrm{V}\left(\mathcal{N}\left(0,\sigma_{Y-\bar{Y}}\right)\right)\\&=(1-\beta)^2\sum_{i=0}^{t-1}\beta^{2i}\cdot 0+(1-\beta)^2\sum_{i=0}^{t-1}\beta^{2i}\mathrm{V}\left(\mathcal{N}\left(0,\sigma_{Y-\bar{Y}}\right)\right)\\&=(1-\beta)^2\sum_{i=0}^{t-1}\beta^{2i}\mathrm{V}\left(\mathcal{N}\left(0,\sigma_{Y-\bar{Y}}\right)\right)=(1-\beta)^2\sum_{i=0}^{t-1}\beta^{2i}\sigma_{Y-\bar{Y}}^2\\&=\sigma_{Y-\bar{Y}}^2(1-\beta)^2\sum_{i=0}^{t-1}\beta^{2i}=\sigma_{Y-\bar{Y}}^2(1-\beta)^2\frac{1-\beta^{2(t-1)+2}}{1-\beta^2}\\&=\sigma_{Y-\bar{Y}}^2(1-\beta)^2\frac{1-\beta^{2t}}{1-\beta^2}=\sigma_{Y-\bar{Y}}^2\frac{(1-\beta)(1-\beta^{2t})}{1+\beta}\end{aligned}\tag{15.3.1499}$$

However, as $\beta\in]0,1[$ and if t is large enough, we get:

$$\mathrm{V}(F_{t+1})=\sigma_{Y-\bar{Y}}^2\frac{(1-\beta)(1-\beta^{2t})}{1+\beta}\cong\sigma_{Y-\bar{Y}}^2\frac{1-\beta}{1+\beta}=\sigma_{Y-\bar{Y}}^2\frac{\lambda}{2-\lambda}\tag{15.3.1500}$$

and let us consider the error:

$$e(t)=Y_t-F_t\tag{15.3.1501}$$

We have under the assumption that the two subtracted terms are independent ...:

$$\begin{aligned}\mathrm{V}(e(t))&=\mathrm{V}(Y_t-F_t)=\mathrm{V}(Y_t)+\mathrm{V}(F_{t+1})\cong\mathrm{V}(Y-\bar{Y})+\mathrm{V}(F_{t+1})\\&=\sigma_{Y-\bar{Y}}^2+\sigma_{Y-\bar{Y}}^2\frac{\lambda}{2-\lambda}=\sigma_{Y-\bar{Y}}^2\left(1+\frac{\lambda}{2-\lambda}\right)=\frac{2\sigma_{Y-\bar{Y}}^2}{2-\lambda}\end{aligned}\tag{15.3.1502}$$

It follows under the assumption of Normality (which is the case since the beginning of this development) and that F_t is the mean of Y_t:

$$\frac{Y_t-F_t}{\sigma_{Y-\bar{Y}}\sqrt{\dfrac{2}{2-\lambda}}}\tag{15.3.1503}$$

and under the assumption that the variance is well known, we get:

$$Y_t=F_t\pm Z_{\alpha/2}\sigma_{Y-\bar{Y}}\sqrt{\frac{2}{2-\lambda}}\tag{15.3.1504}$$

But if the standard deviation is only estimated, it is obviously necessary to use the Student law (see section Statistics page 783):

$$Y_t = F_t \pm T_{\alpha/2}\hat{\sigma}_{Y-\bar{Y}}\sqrt{\frac{2}{2-\lambda}} \tag{15.3.1505}$$

And that will be all so far regarding to the simple exponential smoothing model.

15.3.13.3.3.2 Double Exponential Smoothing with One Parameter (Brown Method)

The idea of the "double exponential Brown smoothing" or also sometimes named "Holt's linear method" is again to reduce the total error but this time using not a constant but a straight linear the neighbourhood of t such that:

$$E = \sum_{j=0}^{t-1} \beta^j (Y_{t-j} - (a_t j + b_t))^2 \tag{15.3.1506}$$

what is written traditionally (the $-$ sign is absorbed into the parameter a and the fact that the parameters of the straight line are recalculated at each t is omitted in the way to not make any confusion with the index of summation...):

$$E = \sum_{j=0}^{t-1} \beta^j (Y_{t-j} - b + aj)^2 \tag{15.3.1507}$$

To minimize we differentiate the error E:

$$\begin{aligned}\frac{\partial E}{\partial b} &= -2\sum_{j=0}^{t-1} \beta^j (Y_{t-j} - b + aj) = 0\\ \frac{\partial E}{\partial a} &= 2\sum_{j=0}^{t-1} j\beta^j (Y_{t-j} - b + aj) = 0\end{aligned} \tag{15.3.1508}$$

Therefore:

$$\begin{aligned}&\sum_{j=0}^{t-1} \beta^j Y_{t-j} - b\sum_{j=0}^{t-1}\beta^j + a\sum_{j=0}^{t-1} j\beta^j = 0\\ &\sum_{j=0}^{t-1} j\beta^j Y_{t-j} - b\sum_{j=0}^{t-1} j\beta^j + a\sum_{j=0}^{t-1} j^2\beta^j = 0\end{aligned} \tag{15.3.1509}$$

Let us simplify all this by first replacing when t is large:

$$\sum_{j=0}^{t-1} b^j = \frac{1-\beta^t}{1-\beta} \cong \frac{1}{1-\beta} \tag{15.3.1510}$$

For the others, under certain conditions that are met in our case, we can derivate one term to one term a convergent series to get derivative thereof. Thus, given that:

$$\frac{\mathrm{d}}{\mathrm{d}\beta} = \sum_{j=0}^{t-1} \beta^j = \sum_{j=0}^{t-1} j\beta^{j-1} \tag{15.3.1511}$$

and as in the above conditions:

$$\sum_{j=0}^{t-1} b^j \cong \frac{1}{1-\beta} \tag{15.3.1512}$$

we then have immediately:

$$\sum_{j=0}^{t-1} j\beta^{j-1} \cong \frac{\mathrm{d}}{\mathrm{d}\beta}\left(\frac{1}{1-\beta}\right) = \frac{1}{(1-\beta)^2} \tag{15.3.1513}$$

Multiplying by β on the left and right we get to finally:

$$\sum_{j=0}^{t-1} j\beta^{j} \cong \frac{\beta}{(1-\beta)^2} \tag{15.3.1514}$$

which is the second desired simplification we were looking form.

For the third one we simply derivate once again the previous equality. We then get:

$$\sum_{j=0}^{t-1} j^2\beta^{j-1} \cong \frac{1}{(1-\beta)^2} + \frac{2\beta}{(1-\beta)^3} = \frac{(1-\beta)+2\beta}{(1-\beta)^3} = \frac{1+\beta}{(1-\beta)^3} \tag{15.3.1515}$$

And we end by multiplying left and right by β:

$$\sum_{j=0}^{t-1} j^2\beta^{j-1} \cong \frac{\beta(1+\beta)}{(1-\beta)^3} \tag{15.3.1516}$$

We then get:

$$\begin{gathered}
\sum_{j=0}^{t-1} \beta^j Y_{t-j} - b\sum_{j=0}^{t-1} \beta^j + a\sum_{j=0}^{t-1} j\beta^j \cong \sum_{j=0}^{t-1} \beta^j Y_{t-j} - \frac{b}{t-j} + \frac{a\beta}{(1-\beta)^2} = 0\\
\sum_{j=0}^{t-1} j\beta^j Y_{t-j} - b\sum_{j=0}^{t-1} j\beta^j + a\sum_{j=0}^{t-1} j^2\beta^j \cong \sum_{j=0}^{t-1} j\beta^j Y_{t-j} - \frac{b\beta}{(1-\beta)^2} + \frac{a\beta(1+\beta)}{(1-\beta)^3} = 0
\end{gathered} \tag{15.3.1517}$$

What we can write under the form:

$$\begin{gathered}
(1-\beta)\sum_{j=0}^{t-1} \beta^j Y_{t-j} - b + \frac{\beta}{1-\beta} = 0\\
(1-\beta)^2\sum_{j=0}^{t-1} j\beta^j Y_{t-j} - b\beta + a\frac{\beta(1+\beta)}{1-\beta} = 0
\end{gathered} \tag{15.3.1518}$$

Let us define now the smoothed series (the reader will notice that this is in fact the simple exponential smoothing):

$$S_1(t) = (1-\beta)\sum_{j=0}^{t-1} \beta^j Y_{t-j} = F_{t+1} \tag{15.3.1519}$$

and the double smooths series (hence the technical name of the method we are studying now):

$$\begin{aligned}S_2(t)&=(1-\beta)\sum_{j=0}^{t-1}\beta^j S_1(t-j)=(1-\beta)^2\sum_{j=0}^{t-1}\beta^j\sum_{i=0}^{t-j-1}\beta^i X_{t-j-i}\\&=(1-\beta)^2\sum_{j=0}^{t-1}\sum_{i=0}^{t-j-1}\beta^{i+j}X_{t-j-i}={F'}_{t+1}\end{aligned}\tag{15.3.1520}$$

In practice will just use:

$$\boxed{\begin{aligned}&S_1(t)=(1-\beta)\sum_{j=0}^{t-1}\beta^j Y_{t-j}\\&S_2(t)=(1-\beta)\sum_{j=0}^{t-1}\beta^j S_1(t-j)\end{aligned}}\tag{15.3.1521}$$

After the change of variable $i+j=k\Leftrightarrow -i-j=-k$ we get:

$$S_2(t)=(1-\beta)^2\sum_{j=0}^{t-1}\sum_{k=j}^{t-1}\beta^k X_{t-k}\tag{15.3.1522}$$

The index of the second sum is explained by the fact that k is the new indexation variable (so it must necessarily be in the index!). And when i is zero we have:

$$i+j=k\underset{i=0}{\Rightarrow}0+j=k\Leftrightarrow k=j\tag{15.3.1523}$$

For the suffix of the sum it is explained by the fact that for the maximum value we have $i=t-j-1$ and therefore as $i+j=k$ it comes if we substitute in it i:

$$(t-j-1)+j=k\Leftrightarrow t-1=k\tag{15.3.1524}$$

Then, the reader can check by itself... on paper... that we can rearrange the terms as follows:

$$S_2(t)=(1-\beta)^2\sum_{j=0}^{t-1}\sum_{k=j}^{t-1}\beta^k X_{t-k}=(1-\beta)^2\sum_{k=0}^{t-1}\sum_{j=0}^{k}\beta^k X_{t-k}\tag{15.3.1525}$$

Then we have:

$$\begin{aligned}S_2(t)&=(1-\beta)^2\sum_{k=0}^{t-1}\sum_{j=0}^{k}\beta^k X_{t-k}=(1-\beta)^2\sum_{k=0}^{t-1}(k+1)\beta^k X_{t-k}\\&=(1-\beta)^2\sum_{k=0}^{t-1}k\beta^k X_{t-k}+(1-\beta)^2\sum_{k=0}^{t-1}\beta^k X_{t-k}=(1-\beta)^2\sum_{k=0}^{t-1}k\beta^k X_{t-k}+(1-\beta)S_1(t)\end{aligned}\tag{15.3.1526}$$

Substituting these results in:

$$\begin{aligned}&(1-\beta)\sum_{j=0}^{t-1}\beta^j Y_{t-j}-b+\frac{\beta}{1-\beta}=0\\&(1-\beta)^2\sum_{j=0}^{t-1}j\beta^j Y_{t-j}-b\beta+a\frac{\beta(1+\beta)}{1-\beta}=0\end{aligned}\tag{15.3.1527}$$

we get:

$$\begin{aligned}
&S_1(t)-b+1\frac{\beta}{1-\beta}=0\\
&S_2(t)-(1-\beta)S_1(t)-b\beta+a\frac{\beta(1+\beta)}{1-\beta}=0
\end{aligned}\tag{15.3.1528}$$

Then it comes after successive simplifications:

$$\begin{aligned}
&S_1(t)-b-\frac{\beta}{1-\beta}\left[\frac{1-\beta}{\beta(1+\beta)}\left(S_2(t)-(1-\beta)S_1(t)-b\beta\right)\right]=0\\
&S_1(t)-b-\frac{1}{1+\beta}\left(S_2(t)-(1-\beta)S_1(t)-b\beta\right)=0\\
&b-\frac{1}{1+\beta}b\beta=S_1(t)-\frac{1}{1+\beta}\left(S_2(t)-(1-\beta)S_1(t)\right)\\
&(1+\beta)b-b\beta=(1+\beta)S_1(t)-\left(S_2(t)-(1-\beta)S_1(t)\right)\\
&b\left[(1+\beta)-\beta\right]=(1+\beta)S_1(t)-S_2(t)+(1-\beta)S_1(t)\\
&b=2S_1(t)-S_2(t)
\end{aligned}\tag{15.3.1529}$$

and therefore also after successive simplifications:

$$\begin{aligned}
&S_1(t)-b+a\frac{\beta}{1-\beta}=0\\
&S_1(t)-\left(2S_1(t)-S_2(t)\right)+a\frac{\beta}{1-\beta}=0\\
&-S_1(t)+S_2(t)+a\frac{\beta}{1-\beta}=0\\
&a=\frac{1-\beta}{\beta}\left(S_1(t)-S_2(t)\right)
\end{aligned}\tag{15.3.1530}$$

Results that it is customary to write:

$$\boxed{\begin{aligned}
&a=\frac{\lambda}{1-\lambda}\left(S_1(t)-S_2(t)\right)=\gamma\left(S_1(t)-S_2(t)\right)\\
&b=2S_1(t)-S_2(t)
\end{aligned}}\tag{15.3.1531}$$

Therefore:

$$\boxed{S_t=a_tj+b_t}\tag{15.3.1532}$$

is the straight line constituted by a double exponential smoothing that approximates at best (the estimator) at a time t the real values that minimizes the total error. Unlike the simple exponential smoothing, we can by now against making predictions (however it remains an abusive use of this mathematical result) thanks to the presence of the variable j.

Explicitly, this straight line will be written by changing a little bit the notations (do not forget that at the beginning we had implicitly injected a negative sign in the term a):

$$\boxed{a_tj+b_t=\frac{\lambda}{1-\lambda}\left({F'}_{t+1}-F_{t+1}\right)j+\left(2F_{t+1}-{F'}_{t+1}\right)}\tag{15.3.1533}$$

It comes then that our forecast will be written:

$$F''_{t-j}=\frac{\lambda}{1-\lambda}\left(F'_{t+1}-F_{t+1}\right)j+\left(2F_{t+1}-F'_{t+1}\right) \tag{15.3.1534}$$

And obviously, if we want F''_{t+1}, we will have to choose $j=-1$. Therefore:

$$\boxed{F''_{t+1}=\frac{\lambda}{1-\lambda}\left(F_{t+1}-F'_{t+1}\right)+\left(2F_{t+1}-F'_{t+1}\right)} \tag{15.3.1535}$$

To start the forecast with this model, we need an estimate of $S_1(0)$ and $S_2(0)$. The first forecasts will be greatly affected by these estimates. The practitioner should also always check what his softwares use as method for the determination for these first parameters in the purpose to specify it in his reports!

Remark

Brown's exponential smoothing is rarely integrated in statistical softwares. We prefer to it the Holt's model that we will introduce immediately below and that contains the Brown model implicitly.

✍**Example:**

Let us consider the following list in Microsoft® Excel® 14.0.6123 that contains the observed data in column `B`, and the model in columns `C` through `F` for which we will detail the explicit formulas just after:

	A	B	C	D	E	F	G	H	I
3	**Period**	**Y_t**	**SES1**	**SES2**	***a***	***b***	**Forecast**	**Relative absolute Error**	**Absolute Error**

Figure 15.233: **Explicit formulas for the Brown's double exponential smoothing model with Microsoft® Excel® 14.0.6123**

With a little bit more far in the worksheet the values essential to the optimization model (and standard forecast errors) with the solver that we will immediately see:

	K	L
3	**λ:**	
4	**j(≤0):**	**-1**
5		
6	MAPE=	=AVERAGE(H5:H27)
7		
8	MAD=	=AVERAGE(I5:I27)
9		
10	MSD=	=SUM((I5:I27)*(I5:I27))/COUNT(I5:I27)

Figure 15.234: **Initial double SES parameters in Microsoft® Excel® 14.0.6123**

After optimization with the solver by minimizing MAPE we get:

	K	L
3	**λ:**	**0.264153**
4	**j(≤0):**	**-1**
5		
6	MAPE=	7.45%
7		
8	MAD=	13.43
9		
10	MSD=	278.37

Figure 15.235: **Final double SES parameters in Microsoft® Excel® 14.0.6123**

So finally the whole table gives:

	A	B	C	D	E	F	G	H	I
3	**Period**	Y_t	**SES1**	**SES2**	***a***	***b***	**Forecast**	**Relative absolute Error**	**Absolute Error**

Figure 15.236: **Final double SES values in Microsoft® Excel® 14.0.6123**

The result gives graphically (and also in comparison with the simple exponential smoothing) still for $j=-1$:

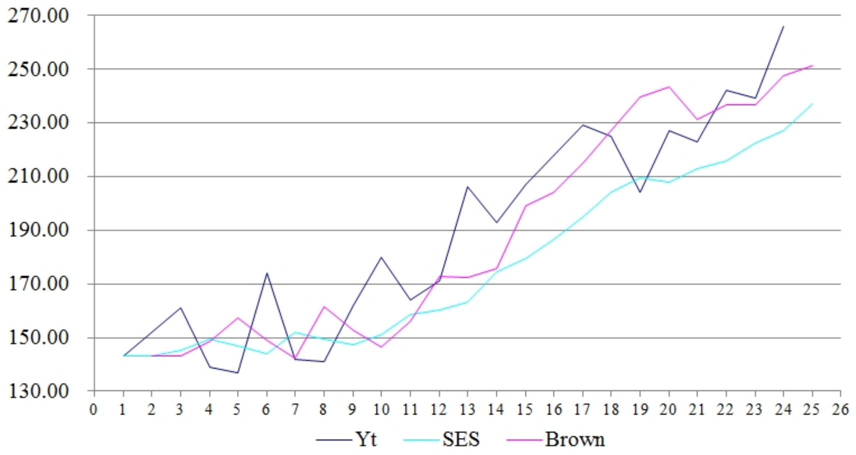

Figure 15.237: **Final double SES values in Microsoft® Excel® 14.0.6123**

What is interesting and special with the double exponential smoothing is to play with the value of j. Thus, by putting $j=-1$, we will have that for each value in column `G` its projection in the corresponding period plus $|j|$ period.

Let us make a little visual example. By putting $j=-6$ (thus a projection to 6 months ...) then we have:

	A	B	G
3	**Period**	**Y_t**	**Forecast**
4	1	143.00	143.00
5	2	152.00	143.00
6	3	161.00	152.88
7	4	139.00	168.04
8	5	137.00	151.62
9	6	174.00	139.65
10	7	142.00	173.58
11	8	141.00	156.87
12	9	162.00	145.69
13	10	180.00	162.35
14	11	164.00	191.10
15	12	171.00	188.33
16	13	206.00	192.82
17	14	193.00	232.13
18	15	207.00	237.33
19	16	218.00	252.41
20	17	229.00	269.48
21	18	225.00	287.20
22	19	204.00	288.34
23	20	227.00	261.50
24	21	223.00	268.19
25	22	242.00	264.55
26	23	239.00	280.53
27	24	266.00	283.20
28	25		311.19

Figure 15.238: **Projection $j=-6$ with the DSES in Microsoft® Excel® 14.0.6123**

Then, what is interesting is to remember is that if we put $j=-6$, the 20th period then projects for the 26th period, the 21th on the 27th, etc. We get therefore graphically:

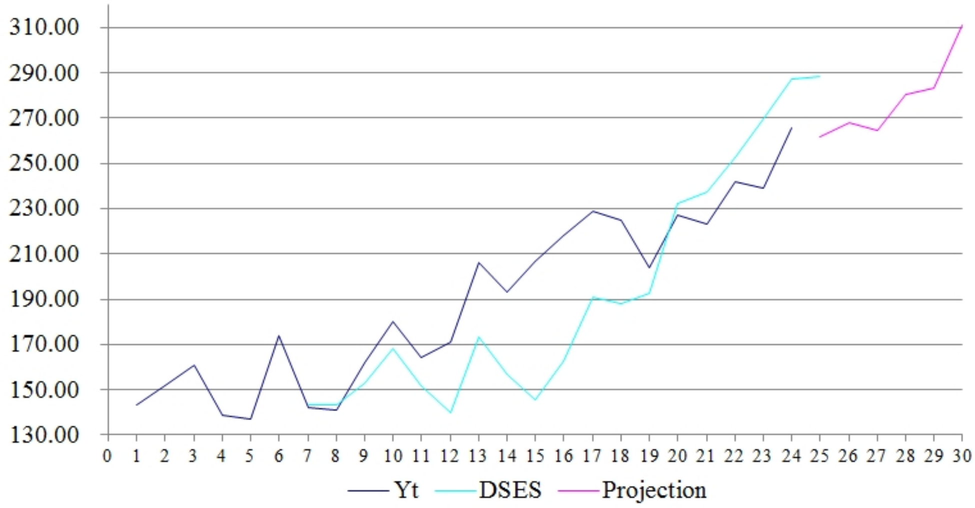

Figure 15.239: **Projection over a period of one semester using DEBS with Microsoft® Excel® 14.0.6123**

Obviously, like any model, the practitioner must be very careful with projections to 6 months (or less or more) because the model does not take into account the factors of the stock market, natural disasters, pandemics, wars, etc. So long as there is no statistical inference, it is not possible to give a confidence interval for the forecasting what is scientifically speaking not acceptable.

15.3.13.3.3.3 Holt's Double Exponential Smoothing with 2 Parameters (Additive Method)

We will discuss now a technique named "Holt's Double Exponential Smoothing with 2 Parameters (Additive Method)", whose construction is empirical and that is due to Charles C. Holt (11957 according to holocene calendar). Even if in the original article of C. Holt there is no rigorous proof of the construction of this model... so it is more mathematical engineering that pure mathematics itself.

The idea is as with the previous model, to have a model of the form (Holt's method extends simple exponential smoothing by assuming that the time series has both a level and a trend):

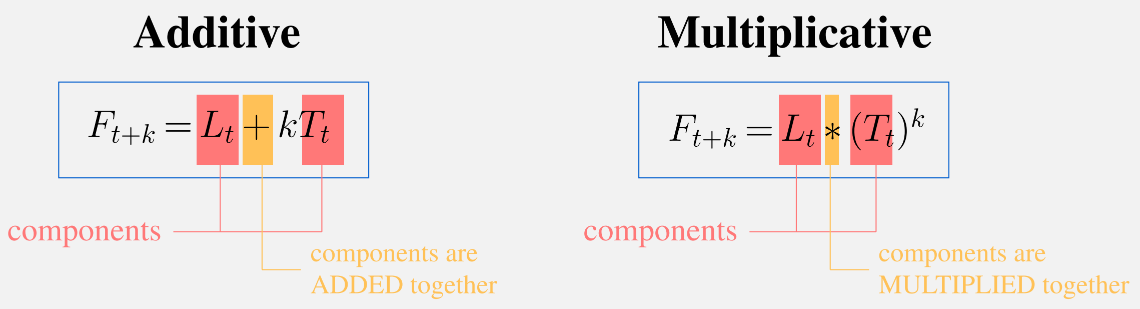
$$F_{t+j}=a_t j+b_t \tag{15.3.1536}$$

(also often denoted $F_{t+k}=L_t+kT_t$) but with an empirical approach that requires:

- The slope a_t of the straight line of model which origin of the frame is in t will be obtained by a simple exponential smoothing of all the slopes of the previous straight lines.
- The intercept b_t of the straight line on t will be obtained by a simple exponential smoothing all intercepts also of all the previous straight lines.

Remark

However, it is important to note that there are two types of time series (and hence of Holt's exponential smoohting), each with their own slightly different forecasting equation:



Let us first recall that we have obtain for the simple exponential smoothing:

$$S_t=(1-\beta)Y_t+\beta S_{t-1}=\lambda Y_t+(1-\lambda)S_{t-1} \tag{15.3.1537}$$
